Pediatric Cardiac Surgery

Pediatric Cardiac Surgery

FOURTH EDITION

Editor

Constantine Mavroudis MD
Director, Congenital Heart Institute, Florida Hospital for Children
Site Director, Johns Hopkins Children's Heart Surgery, Florida Hospital for Children
Orlando, FL, USA

Associate Editor

Carl L. Backer MD
Division Head, Cardiovascular-Thoracic Surgery
Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital
Professor of Surgery
Department of Surgery
Northwestern University Feinberg School of Medicine
Chicago, IL, USA

With illustrations by Rachid F. Idriss

WILEY-BLACKWELL
A John Wiley & Sons, Ltd., Publication

This edition first published 2013, © 2013 by Blackwell Publishing Ltd

Blackwell Publishing was acquired by John Wiley & Sons in February 2007. Blackwell's publishing program has been merged with Wiley's global Scientific, Technical and Medical business to form Wiley-Blackwell.

Registered office: John Wiley & Sons Ltd, The Atrium, Southern Gate, Chichester, West Sussex, PO19 8SQ, UK

Editorial offices: 9600 Garsington Road, Oxford, OX4 2DQ, UK
The Atrium, Southern Gate, Chichester, West Sussex, PO19 8SQ, UK
111 River Street, Hoboken, NJ 07030-5774, USA

Contents

List of Contributors, vii

Preface, xiii

Chapter 1 Development of the Heart and Great Vessels, 1
Peter J. Gruber, Andy Wessels, and Steven W. Kubalak

Chapter 2 Nomenclature and Classification of Pediatric and Congenital Heart Disease, 27
Jeffrey P. Jacobs

Chapter 3 Physiology of the Fetal and Neonatal Circulations and Fetal Cardiac Surgery, 52
Ashok Muralidaran, Vadiyala Mohan Reddy, and Frank L. Hanley

Chapter 4 Preoperative Diagnostic Evaluation, 60
Lourdes R. Prieto, Marcy L. Schwartz, Richard Sterba, Janine Arruda, and Tamar J. Preminger

Chapter 5 Hybrid Procedures for Congenital Heart Disease, 84
Mark Galantowicz, John P. Cheatham, Alistair Phillips, Ralf J. Holzer, Sharon L. Hill, and Vincent F. Olshove

Chapter 6 Anesthesia for the Patient with Congenital Heart Disease, 103
H. Jay Przybylo

Chapter 7 Perioperative Care, 113
Carl L. Backer, John M. Costello, Jason M. Kane, and Constantine Mavroudis

Chapter 8 The Nurse Practitioner's Role in Patient Management, 143
Nancy Benson, Denise Davis, Fejeania Hunter, Kim Teknipp, and Jamie Thomas

Chapter 9 Palliative Operations, 155
Carl L. Backer and Constantine Mavroudis

Chapter 10 Management of Pediatric Cardiopulmonary Bypass, 169
Darryl H. Berkowitz and J. William Gaynor

Chapter 11 Intraoperative Myocardial Protection, 214
Paul J. Chai

Chapter 12 Patent Ductus Arteriosus, 225
Muhammad Ali Mumtaz, Athar Qureshi, Constantine Mavroudis, and Carl L. Backer

Chapter 13 Vascular Rings and Pulmonary Artery Sling, 234
Carl L. Backer and Constantine Mavroudis

Chapter 14 Coarctation of the Aorta, 256
Carl L. Backer, Sunjay Kaushal, and Constantine Mavroudis

Chapter 15 Interrupted Aortic Arch, 283
Richard A. Jonas

Chapter 16 Atrial Septal Defect, Partial Anomalous Pulmonary Venous Connection, and Scimitar Syndrome, 295
Carl L. Backer and Constantine Mavroudis

Chapter 17 Ventricular Septal Defect, 311
Constantine Mavroudis, Carl L. Backer, Jeffrey P. Jacobs, and Robert H. Anderson

Chapter 18 Atrioventricular Canal Defects, 342
Carl L. Backer and Constantine Mavroudis

Chapter 19 Truncus Arteriosus, 361
Constantine Mavroudis and Carl L. Backer

Chapter 20 Aortopulmonary Window and Aortic Origin of a Pulmonary Artery, 376
Stephanie Fuller and J. William Gaynor

Chapter 21 Isolated Right Ventricular Outflow Tract Obstruction, 385
John M. Karamichalis, Jeffrey R. Darst, Max B. Mitchell, and David R. Clarke

Chapter 22 Tetralogy of Fallot, 410
Robert D. Stewart, Constantine Mavroudis, and Carl L. Backer

Chapter 23 Surgical Treatment of Pulmonary Atresia with Ventricular Septal Defect, 428
Vadiyala Mohan Reddy and Frank L. Hanley

Chapter 24 Ventricular to Pulmonary Artery Conduits, 443
John W. Brown, Osama M. Eltayeb, Mark Ruzmetov, Mark D. Rodefeld, and Mark W. Turrentine

Chapter 25 Double-Outlet Ventricles, 457
Henry L. Walters III and Constantine Mavroudis

Chapter 26 Transposition of the Great Arteries, 492
Constantine Mavroudis and Carl L. Backer

Chapter 27 Congenitally Corrected Transposition of the Great Arteries, 530
Eric J. Devaney and Edward L. Bove

Chapter 28 The Functionally Univentricular Heart and Fontan's Operation, 542
Marshall L. Jacobs

Chapter 29 Ebstein Anomaly, 571
Morgan L. Brown and Joseph A. Dearani

Chapter 30 Left Ventricular Outflow Tract Obstruction, 588
Christo I. Tchervenkov, Pierre-Luc Bernier, Danny Del Duca, Samantha Hill, Noritaka Ota, and Constantine Mavroudis

Chapter 31 Hypoplastic Left Heart Syndrome, 619
Jennifer C. Hirsch, Eric J. Devaney, Richard G. Ohye, and Edward L. Bove

Chapter 32 Aortico-Left Ventricular Tunnel, 636
Stephanie Fuller and Thomas L. Spray

Chapter 33 Congenital Anomalies of the Mitral Valve, 640
Richard D. Mainwaring and John J. Lamberti

Chapter 34 Total Anomalous Pulmonary Venous Connection, 659
Nicola Viola and Christopher A. Caldarone

Chapter 35 Cor Triatriatum Sinister, Pulmonary Vein Stenosis, Atresia of the Common Pulmonary Vein, and Cor Triatriatum Dexter, 674
Ralph E. Delius and Henry L. Walters III

Chapter 36 Anomalous Systemic Venous Connections, 685
Henry L. Walters III and Ralph E. Delius

Chapter 37 Sinus of Valsalva Aneurysm, 704
W. Steves Ring

Chapter 38 Coronary Artery Anomalies, 715
Constantine Mavroudis, Ali Dodge-Khatami, Carl L. Backer, and Richard Lorber

Chapter 39 Cardiac Tumors, 744
Rüdiger Lange and Thomas Günther

Chapter 40 Diseases of the Pericardium, 758
Victor O. Morell and Ergin Kocyildirim

Chapter 41 Surgical Therapy of Cardiac Arrhythmias, 769
Constantine Mavroudis, Barbara J. Deal, and Carl L. Backer

Chapter 42 Heart Transplantation, 813
Joseph W. Rossano, David L.S. Morales, and Charles D. Fraser Jr

Chapter 43 Pediatric Lung and Heart-Lung Transplantation, 827
Dewei Ren, George B. Mallory Jr, David L.S. Morales, and Jeffrey S. Heinle

Chapter 44 Infective Endocarditis, 845
Muhammad Ali Mumtaz, Lara Danziger-Isakov, Constantine Mavroudis, and Carl L. Backer

Chapter 45 Pediatric Mechanical Circulatory Support, 856
Brian W. Duncan

Chapter 46 Adult Congenital Heart Disease, 867
Stamatia Prapa, Konstantinos Dimopoulos, Darryl F. Shore, Mario Petrou, and Michael A. Gatzoulis

Index, 910

List of Contributors

Robert H. Anderson BSc, MD, FRCPath
Emeritus Professor
University College
London, UK
Visiting Professor
University of Newcastle
Newcastle, UK
Visiting Professor of Pediatrics
Medical University of South Carolina
Charleston, SC, USA

Janine Arruda, MD
Staff, Pediatric Cardiology
Center for Pediatric and Congenital Heart Disease
Cleveland Clinic Children's Hospital
Cleveland, OH, USA

Carl L. Backer, MD
Division Head, Cardiovascular-Thoracic Surgery
Ann & Robert H. Lurie Children's Hospital of Chicago, formerly
Children's Memorial Hospital
Professor of Surgery
Department of Surgery
Northwestern University Feinberg School of Medicine
Chicago, IL, USA

Nancy Benson, MSN
Center for Congenital Heart Surgery
Cleveland Clinic Children's Hospital
Cleveland, OH, USA

Darryl H. Berkowitz, MD
Attending Physician
Society Hill Anesthesia Consultants
Pennsylvania Hospital
Philadelphia, PA, USA

Pierre-Luc Bernier, MD, FRCSC
Attending Surgeon
Division of Cardiovascular Surgery
The Montreal Children's Hospital
McGill University
Montreal, QC, Canada

Edward L. Bove, MD
Helen and Marvin Kirsh Professor of Surgery
Chair, Department of Cardiac Surgery
C.S. Mott Children's Hospital at the University of Michigan
Ann Arbor, MI, USA

John W. Brown, MD
Harris B. Shumacker Professor Emeritus of Surgery
Indiana University School of Medicine
Indianapolis, IN, USA

Morgan L. Brown, MD
Research Fellow
Cardiovascular Surgery
Mayo Clinic
Rochester, MN, USA

Christopher A. Caldarone, MD
Professor and Chair, Division of Cardiac Surgery
University of Toronto
Staff Cardiovascular Surgeon
Labatt Family Heart Center
The Hospital for Sick Children
Toronto, ON, Canada

Paul J. Chai, MD
Associate Medical Director
All Children's Hospital Heart Center
Thoracic and Cardiovascular Surgeon
Johns Hopkins Children's Heart Surgery, All Children's Hospital
Saint Petersburg, FL, USA

John P. Cheatham, MD, FAAP, FACC, FSCAI
George H. Dunlap Endowed Chair in Interventional Cardiology
Director, Cardiac Catheterization & Interventional Therapy
Co-Director, The Heart Center
Nationwide Children's Hospital
Professor, Pediatrics & Internal Medicine, Cardiology Division
The Ohio State University
Columbus, OH, USA

David R. Clarke, MD
Clinical Professor of Cardiothoracic Surgery
School of Medicine
University of Colorado Denver
Aurora, CO, USA

John M. Costello, MD, MPH
Medical Director, Regenstein Cardiac Care Unit
Ann & Robert H. Lurie Children's Hospital of Chicago, formerly
Children's Memorial Hospital
Associate Professor of Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, IL, USA

Lara Danziger-Isakov, MD, MPH
Staff, Center for Pediatric Infectious Diseases
Director for Pediatric Clinical Research
Cleveland Clinic Children's Hospital
Assistant Professor of Pediatrics
Cleveland Clinic Lerner College of Medicine of Case Western
Reserve University
Cleveland, OH, USA

Jeffrey R. Darst, MD
Assistant Professor, Pediatrics
Section of Cardiology
Children's Hospital Colorado
Aurora, CO, USA

Denise Davis, RN, MSN, CPNP-AC/PC
Center for Congenital Heart Surgery
Cleveland Clinic Children's Hospital
Cleveland, OH, USA

Barbara J. Deal, MD
Division Head, Cardiology
Getz Professor of Cardiology
Ann & Robert H. Lurie Children's Hospital of Chicago, formerly
Children's Memorial Hospital
Professor of Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, IL, USA

Joseph A. Dearani, MD
Professor of Surgery
Cardiovascular Surgery
Mayo Clinic
Rochester, MN, USA

Danny Del Duca, MD
Resident, Cardiac Surgery
McGill University
Montreal, QC, Canada

Ralph E. Delius, MD
Vice Chief, Department of Cardiovascular Surgery
Children's Hospital of Michigan
Associate Professor of Surgery
Wayne State University School of Medicine
Detroit, MI, USA

Eric J. Devaney, MD
Associate Professor of Surgery
University of California, San Diego
Rady Children's Hospital at the University of California
San Diego, CA, USA

Konstantinos Dimopoulos, MD, MSc, PhD, FESC
Consultant Cardiologist
Adult Congenital Heart Centre and Centre for Pulmonary
Hypertension
Royal Brompton Hospital
National Heart & Lung Institute
Imperial College London
London, UK

Ali Dodge-Khatami, MD, PhD
Chief of Pediatric Cardiac Surgery
Program Head for Congenital Heart Disease
University Heart Center
Professor of Cardiac Surgery
University of Hamburg-Eppendorf School of Medicine
Hamburg, Germany

Brian W. Duncan, MD, MBA
BioEnterprise
Arboretum Ventures
Cleveland, OH, USA

Osama Eltayeb, MD
Fellow in Pediatric Cardiothoracic Surgery
Indiana University School of Medicine
Indianapolis, IN, USA

Charles D. Fraser Jr, MD
Chief of Congenital Heart Surgery and Cardiac Surgeon In-Charge
Texas Children's Hospital
Baylor College of Medicine
Houston, TX, USA

Stephanie Fuller, MD
Assistant Professor
Division of Cardiothoracic Surgery
The Children's Hospital of Philadelphia
University of Pennsylvania School of Medicine
Philadelphia, PA, USA

Mark Galantowicz, MD
Chief, Department of Cardiothoracic Surgery
Murray D. Lincoln Chair of Cardiothoracic Surgery
Co-Director, The Heart Center
Nationwide Children's Hospital
Professor of Surgery
The Ohio State University
Columbus, OH, USA

Preface

This is the *4th Edition* of *Pediatric Cardiac Surgery*. The first edition was published by Arciniegas in 1985, was followed by the *2nd Edition* in 1994, and the *3rd Edition* in 2003 by the present editors. Timely updates are important for any textbook as scientific intellectual curiosity, sentinel discoveries, and technological improvements have progressed at lightning speed. Even cardiac embryology, a field thought to be constant and thoroughly studied, has emerged with new findings of a second heart field, detailed results of syndromic genomes, and the promise of new paradigms and ontologies. Our readership from around the world has included numerous colleagues comprised of surgeons, cardiologists, intensivists, anesthesiologists, residents, students, perfusionists, and nurses. They have found the book to be well organized, easy to read, and to the point. We have preserved this format for the *4th Edition* and added several chapters that have mirrored the directions and practice of pediatric and congenital heart surgery in the twenty-first century.

Several new chapters by new authors have highlighted the advances of congenital heart surgery. While this textbook emphasizes the pediatric nature of the specialty, it is clear that there are more adults with congenital heart disease living today than there are children with congenital heart disease. This is a testimony to the years of scientific and clinical research that have combined to improve the lot of these patients who now present with medical and surgical problems of their own. The new chapter on adult congenital heart disease reviews these very important issues and serves as an important contribution to the textbook. Several new and updated chapters, written by experts in their field, review advances that have been made in congenital heart surgery such as right ventricular to pulmonary artery conduits, arrhythmia surgery, double-outlet ventricles, and cardiac transplantation, among many others. In some cases, the same authors have updated their previous chapters. In others, new authors have been selected because of their demonstrated expertise.

The *4th Edition* maintains its comprehensive coverage of the breadth of congenital heart surgery and related fields. Each chapter reviews the embryology, physical findings, diagnostic criteria, and therapeutic choices associated with each disease entity. State-of-the art technology and the latest in surgical techniques are discussed.

As in previous editions of *Pediatric Cardiac Surgery*, the figures have predominantly been illustrated by Rachid Idriss. His drawing techniques are legendary not only because of his artistic talents, but more so for his ability to see an operation in his mind's eye and demonstrate with a few lines the important parts of the relative anatomy and reparative operation. Sutures are clear, pledgets are well placed, and structures are anatomically correct. Hidden intracardiac anatomy is displayed by ghost techniques that transform the image into a three-dimensional living characterization of reality. His contribution to this *4th Edition* cannot be overstated.

This textbook is reflective of the cooperation, expertise, and altruism that the contributing authors have so generously shared with the readership. Simply stated, these chapters are a delight to read. We are sure that the reader will have the same experience. All royalties from the sale of this book will be contributed to the Thoracic Surgery Foundation for Research and Education for the purpose of supporting congenital heart surgery initiatives. We are greatly indebted to the editorial staff at Wiley-Blackwell for their support, in particular, Kate Newell. Important editorial contributions were made by Patricia Heraty and, in particular, Melanie Gevitz who was so instrumental in organizing the successful efforts associated with the *2nd* and *3rd Editions*. In the Orlando Office, we found a jewel, Allison Siegel, who took on this project with an impressive zeal, expertise, and commitment that are rarely found anywhere.

The concluding paragraph in this Preface is quoted from the Preface of the *3rd Edition* because it stands as a timeless dedication to our loved ones and family members who have shown their devotion, calmed the children, and explained our absences on countless occasions without rancor, excuses, or disappointment. It reads, "Finally, as with all surgeons and physicians, our accomplishments are

facilitated by the sacrifices made by our families. Every author who wrote a chapter for this textbook, no doubt, has loved ones who have contributed in one way or another to their creativity, stability, and industry. We thank each and every one of these wives, husbands, children, parents, and friends, including our own, which have had the patience, perseverance, and equanimity to stand by."

Constantine Mavroudis, MD
Carl L. Backer, MD

CHAPTER 1

Development of the Heart and Great Vessels

Peter J. Gruber,[1] Andy Wessels,[2] and Steven W. Kubalak[2]

[1]Primary Children's Medical Center, Salt Lake City, UT, USA
[2]Medical University of South Carolina, Charleston, SC, USA

Introduction

Modern cardiac embryology combines molecular and cellular biologic techniques with traditional embryologic morphologic approaches during development. The limited descriptions of human cardiac development are necessarily supplemented by nonhuman models of cardiac development. Avian embryos have traditionally been favored experimental models because of the ease with which they can be observed and manipulated. More recently, the developing mouse has become the preferred model for studying cardiac development because of the strength of genetic and molecular investigative tools available in this species. Where possible, this chapter discusses how results in experimental animal models relate to human cardiac development. Table 1.1 provides a simplified comparison of two widely utilized developmental schemes for developmental staging in chick and mouse embryos [1–7]. The comparison of multiple species provides an important platform for understanding the development of the human heart and the pathogenesis of human disease.

Formation of Cardiac Precursors

All of the cells that will become part of the heart derive from populations of undifferentiated precursors that will be influenced by external signals into their final developmental pathways. In addition to the intellectual challenge of understanding how these acts of differentiation occur, intense activity in this field is also driven by the possibility of controlling cardiac tissue differentiation to replace diseased myocardium in the postnatal heart.

Repeated cell divisions of the fertilized egg form a cell mass that evolves into two distinct layers of cells. The epiblast layer is separated from a second layer of cells, called the hypoblast in the chick or the primitive endoderm in the mouse and human. The next critical stage of development is gastrulation where widespread cell migration into and reorganization within the blastocoele cavity result in the formation of three germ layers (ectoderm, mesoderm, and endoderm) and the determination of the future body plan of the embryo (Figure 1.1) [7,8].

Gastrulation of precardiac cells is an early event in all species. In the human, gastrulation takes place at the beginning of the third week of development and angioblasts in the cardiogenic region are present shortly thereafter. At the time that precardiac cells gastrulate in chick embryos (Hamburger–Hamilton stage 3), the primitive streak is less than 1 mm in length; the portion of the streak through which the precardiac cells ingress extends as a relatively broad swath 0.125–0.75 mm from the anterior limit of the streak [9]. The most anteriorly gastrulating cells contribute to the most anterior portion of the primitive heart tube.

After cells have undergone gastrulation they enter the undifferentiated mesenchyme. Uncommitted precardiac cells enter the primitive streak only to become specified to their cell type or migratory pathways in the mesoderm after leaving the streak [9]. Subsequently, the precardiac cells will move laterally to join the lateral plate mesoderm at the level of Hensen's node. The lateral plate mesoderm then splits into two layers, a splanchnic layer directly above the endoderm and a somatic layer directly below the ectoderm. The anterior endoderm provides signals to splanchnic mesodermal cells to enter the precardiac lineage. Fibroblast growth factors (FGFs)-1, -2, and -4 and bone morphogenetic protein 2 (BMP-2) are proteins that appear to be critical to this process [10]. However, to date no single gene has been identified whose ablation leads to a specific failure of all myocardial differentiation from precardiac mesoderm. This observation may argue the presence of either a considerable genetic redundancy in precardiac myocyte differentiation or an unsuspected diversity of

precardiac myocyte lineages following independent genetic pathways.

Precardiac cells are found in an epithelial sheet at the cranial end of the splanchnic mesoderm and can be identified at this point by a variety of molecular markers such as the transcription factors NKX2-5, MEF2, HAND1, HAND2, GATA4, TBX5, and ISL1 [11–17]. The region of splanchnic mesoderm expressing precardiac markers is also known as the "heart-forming field" and is larger than the region that will actually contribute cells to the heart tube [18]. In rodent embryos, but not chick embryos, precardiac mesodermal cells exhibit spontaneous contractile activity, indicating a relatively advanced state of differentiation towards the cardiac myocyte lineage [19,20].

The precardiac mesodermal cell mass migrates as a single unit rather than as a collection of independent cells. The precardiac mesodermal sheets on each side of the embryo migrate together towards the midline cranial to the anterior intestinal portal. When the most cranial portions of the bilateral precardiac mesoderm masses meet in the midline, the total premyocardial cell population forms a horseshoe-shaped crescent called the first (primary) heart field. The cues that enable and promote movement of these cells are provided by a noncardiac tissue, the endoderm, as demonstrated by experimental removal of the endoderm and/or ectoderm. The extracellular matrix molecule fibronectin may be one of the important components of the endodermal surface to which the precardiac cells are responding [21].

Precursors of the endocardium follow similar migratory pathways as the precardiac cells, but there are important differences. Pre-endocardial cells and pre-endothelial cells are known as angioblasts. The endocardial angioblasts are first detectable in the splanchnic mesoderm. Mesodermal cells are induced to enter the angioblast lineage by signals such as transforming growth factor beta (TGFβ) 2–4 and vascular endothelial growth factor (VEGF) signaling from the endoderm [10]. Endocardial angioblasts migrate anteriorly and to the midline with the premyocardial cell mass, but they do so as individual cells.

Formation of the Tube Heart

As the precardiac cell masses of the first heart field move steadily towards the midline, endocardial cells begin to

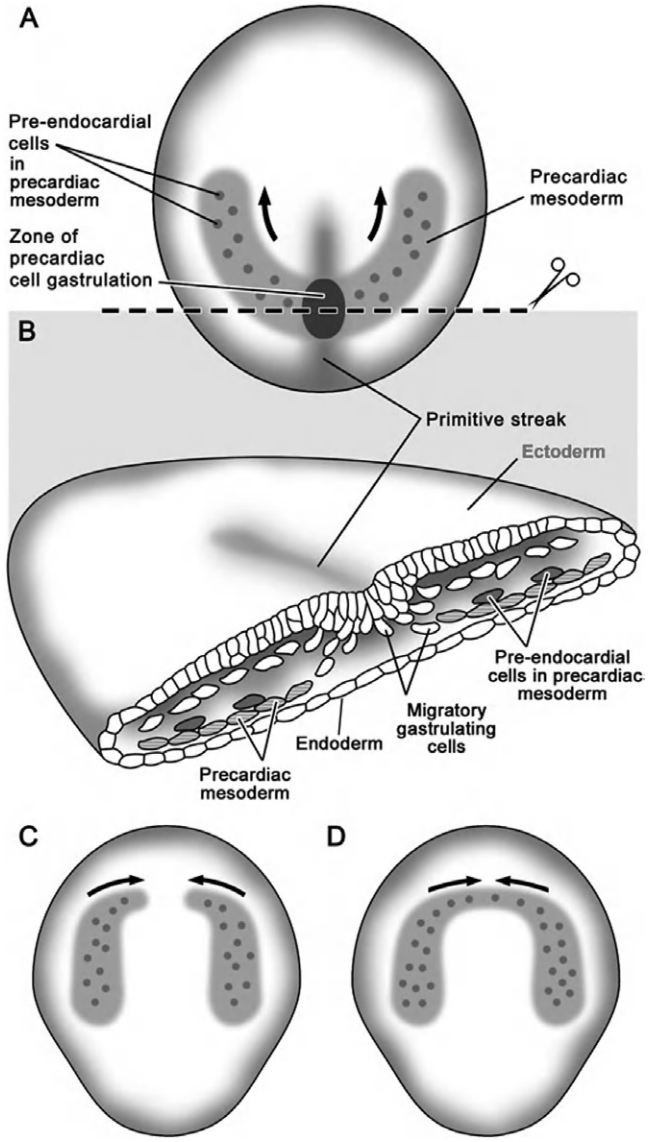

Figure 1.1 Simplified schema of gastrulation, precardiac cell migration, and formation of the heart forming fields. **A,** Cells destined to become cardiac cells migrate from the epiblast into the primitive streak through a broad region caudal to the most anterior portion of the primitive streak. The direction of migration of the gastrulated cells, as indicated by the arrows, is away from the midline and anteriorly on each side. **B,** The embryo in cross-section at the level indicated by the dotted line in **A**. The precardiac mesoderm forms an epithelial sheet closely associated with the endoderm. The pre-endocardial cells are scattered throughout the same region and can be distinguished immunohistochemically from the general precardiac mesoderm. **C,** and **D,** The two lateral precardiac mesoderm populations (also known as heart forming fields) will migrate anteriorly before turning towards the midline (**C**). They will meet in the midline, as shown in **D**, at a location immediately anterior to the anterior intestinal portal.

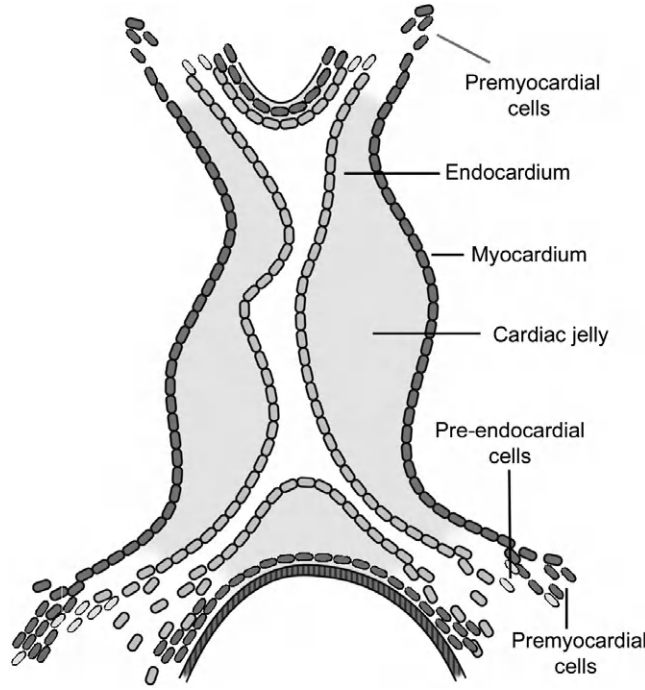

Figure 1.2 Formation of the tube heart is initiated by fusion of the bilateral precardiac mesoderm populations in the midline, resulting in formation of a myocardial tube surrounding an endothelial (endocardial) channel. The myocardial population of the cardiac tube at this stage consists of only the precursors of the future trabeculated portions of the left ventricle. Additional segments are added by ongoing migration of precardiac mesoderm into the tube heart.

form a network of tiny channels that will coalesce into a complex endocardial network surrounded by a myocardial mantle [22]. If the mesodermal sheets are prevented from meeting in the midline as a consequence of genetic [15] or mechanical manipulation [23], dual heart tubes will be formed that undergo some degree of further independent development. However, in normal development, the endothelial network quickly transforms into a single endothelial channel within a single myocardial tube (Figure 1.2) [7].

The tube heart at the time of its formation is connected to the foregut along its dorsal surface throughout its length by a structure called the dorsal mesocardium [24]. As looping proceeds, the dorsal mesocardium degenerates until it remains connected only at the atrial and arterial poles of the heart. The disintegration of the central portion of the dorsal mesocardium is a key event for looping to proceed normally, while the arterial and venous attachments provide "anchors" for the looping heart tube. The mesenchymal portion of the dorsal mesocardium known as the dorsal mesenchymal protrusion [25,26] protrudes into the atrium posteriorly and is a derivative of the second

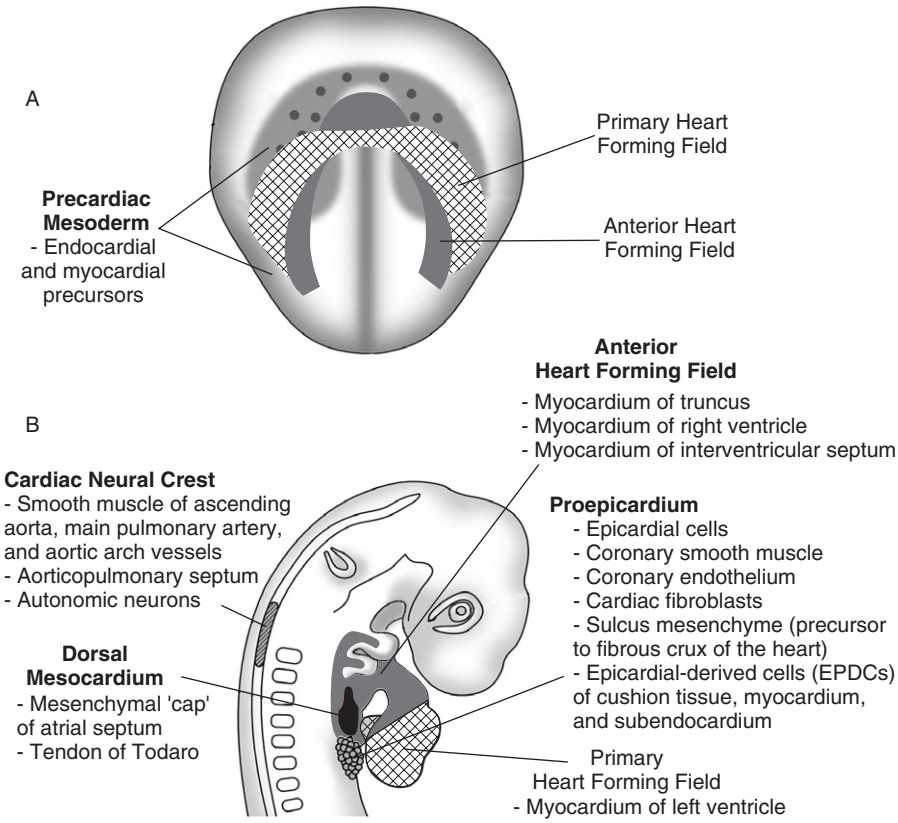

Figure 1.3 Normal heart development requires integration of cell populations from multiple sources. **A,** Precardiac mesoderm gives rise to the endocardium and the majority of cardiac cushion cells. Premyocardial cells give rise to the entire spectrum of cardiac myocyte phenotypes. The primary heart forming field will give rise to most of the myocardium of the atria and left ventricle. The anterior heart forming field will give rise to the myocardium of the outflow tract, right ventricle, and interventricular septum. **B,** Multiple extracardiac embryonic tissues provide critical cell populations to normal cardiac development. These cell populations include cardiac neural crest cells as well as cells from the proepicardium and the dorsal mesocardium.

heart field [25]. It is an important contributor to atrioventricular (AV) septation and serves as a conduit for the developing pulmonary veins. The dorsal mesocardium is also a pathway for cellular migrations as development proceeds, including neural crest-derived neural structures [27] and possibly cells derived from the ventral neural tube [28].

Soon after the formation of the cardiac tube the heartbeat is initiated and blood circulation can be observed (embryonic day 8.5 in the mouse and day 20 in the human). With the initiation of circulation the heart becomes the first organ to adopt its essential mature function in the embryo. At this point in cardiac organogenesis, however, the tube heart has not yet obtained its full complement of cell populations necessary for complete cardiac development. Early fate mapping studies [29–31] showed that the primary heart tube is derived from two bilateral fields of precardiac mesoderm, currently called the first heart field; this precardiac mesoderm was long considered the precursor tissue of the heart. Studies by others [32], however, strongly suggested that growth of the heart tube, specifically at the arterial pole, depended on the addition of cardiac tissue from a secondary pool of progenitor cells. It was not until the early twenty-first century that the nature of this additional cell population was elucidated. The combined studies of various laboratories [25,33–36] have provided significant new insights into the importance of this additional population of cells, called the second heart field, in the elongation and growth of the heart tube and in the formation of a mature four-chambered heart (Figure 1.3) [7]. Thus, these studies have demonstrated that the secondary heart field contributes at the arterial pole to the outflow tract and right ventricle and at the venous pole to parts of the atria and the dorsal mesenchymal protrusion.

The Tube Heart, Segments, and Segmental Identity

Traditionally, the heart tube has been regarded as containing the precursors of all of the cardiac segments. In reality, at the time the heartbeat is initiated the heart tube primarily consists of future left ventricular tissues [37,38]. Immunohistochemical, in situ hybridization, and cell fate tracing techniques have demonstrated that the outflow tract, the right ventricle [32], the AV junction segment [37], the atria [39], and the sinus venosus are added to the heart as looping proceeds. Indeed, these are the structures that are most important in the pathogenesis of the majority of forms of complex human congenital heart disease. Recent studies indicate that the outlet (truncal and conal) primordia [35,40] as well as the right ventricle and much of the

interventricular septum [35] and parts of the cardiac venous pole develop from the anterior/secondary heart field.

In prelooping and early looping stages the primitive heart tube consists of circumferential sheets of myocardial cells two to three layers thick surrounding an endothelial tube, these layers being separated by an acellular, extracellular matrix-rich space known as the cardiac jelly. As looping proceeds, the future segments can be distinguished morphologically by their position in the heart tube and by structural features, such as the striking accumulations of cardiac jelly in the AV canal and outflow segments. Segments can be distinguished physiologically by measurement of the differences in their velocity of muscular contraction and relaxation, their rates of spontaneous pacemaker activity, and the speed of electrical impulse conduction.

Segmental differentiation creates the physiological competence of the embryonic heart [41]. Unidirectional antegrade blood flow is maintained by organization of the tube heart into alternating regions of rapid and slow contractile properties [42]. The atrium has the fastest rate of spontaneous contractility and is the site of pacemaker activity. The wave of depolarization spreads from myocyte to myocyte from the atrium to the outflow tract, but the velocity of conduction is not uniform throughout the length of the heart tube. Atrial conduction is rapid, AV conduction is slow, ventricular conduction is rapid, and outlet conduction is slow. The zones of rapid conduction show rapid contraction–relaxation mechanical properties, while the slow zones of conduction demonstrate slow, sustained contractions. The result is a forceful contraction of the atria, followed by a sphincter-like contraction of the AV junction (prior to maturation of AV valves) that prevents the retrograde flow of blood during the forceful ventricular ejection phase. The cardiac cycle of the tube heart is completed by a sphincter-like contraction of the outflow tract (prior to maturation of the semilunar valves) to prevent retrograde blood flow from the aortic arches.

Genetic Determination of Cardiac Segmentation

In addition to functional differences, cardiac segments can also be distinguished by unique patterns of gene expression. However, despite the rapidly increasing number of markers that distinguish segments following heart tube formation, there has been less success in identifying segmental markers in the precardiac mesoderm. Data suggest that the final determination of lineage fate occurs in the precardiac mesoderm [9,31], but the timing and nature of the mechanisms are as yet poorly understood. Perhaps the best-studied determinants of the anterior–posterior axis in the gastrulating embryo are retinoids [43,44]. Retinoids are products of vitamin A metabolism, and manipulation of retinoid signaling pathways results in significant abnormalities in axial patterning in general and cardiac development in particular [45–49]. Abnormal development of atrial segments and systemic venous structures are observed in conditions of retinoid deficiency [50–52]. Excess retinoids create cardiac malformations, often involving the outflow tract [53,54], and result in ventricular expression of several genes that are normally largely restricted to the atria at these stages of normal development [55–57]. The spatial and temporal patterns of retinoid signaling in early cardiac development are highly correlated with the presence of retinaldehyde dehydrogenase 2 (RALDH2), a key enzyme in the retinol (vitamin A) to retinoic acid pathway [58–60]. Retinoid signaling pathways are clearly key mechanisms of segmental differentiation within the heart, but it is likely that other pathways yet to be determined are also involved.

Transgenic mice provide some of the most interesting data regarding differences between the genetic pathways regulating different regions of the heart. In these experiments, regulatory portions from one gene are used to drive the expression of a second gene whose product can readily be detected in the tissues. The DNA resulting from the combined portions of the two genes is injected into the male pronucleus of fertilized mouse eggs, and frequently the DNA is incorporated into the mouse nuclear DNA. The eggs are implanted in a female mouse and generally allowed to proceed through development until birth. The newborn animals bearing the new DNA (the "transgene") can be identified by analysis of their DNA. If the transgene is present, the animal will be bred and its offspring analyzed for the pattern of expression of the transgene.

Use of this technology has demonstrated several features of segmental and regional gene expression in the heart [61]. The genetic elements that determine regional patterns of gene expression are modular, in that genes expressed widely in the heart often have discrete portions of their regulatory DNA responsible for subsets of the overall pattern. For instance, a transgene driven by a 10-kilobase (kb) segment of the *Gata6* gene exhibits expression throughout the atria, AV junction, and left and right ventricles, excluding only the outflow tract; a smaller 2.3-kb fragment of the same gene drives expression only in the AV junction (Figure 1.4) [7,62]. The segmental and regional boundaries of gene expression determined by a specific genetic element may be variable during development, and transgenes expressed widely in the primitive tube heart can be restricted in their expression in the adult heart. Finally, the fact that some transgenes are differentially activated spatially and temporally in the heart is a striking confirmation of the nonequivalence of these tissues at the most basic level of gene regulation (Figure 1.4) [7].

Gene knockout experiments in mice also provide insight into the genetic regulatory networks critical to segmental differentiation. The requirement of the transcription factor HAND2 for normal development of the primitive right

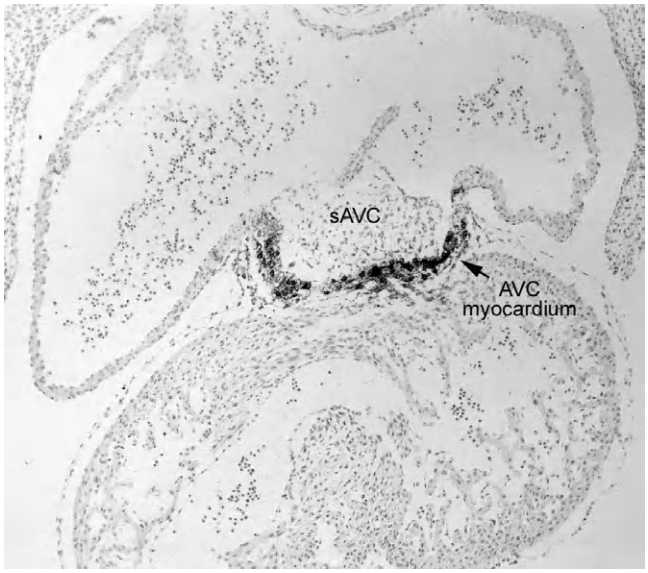

Figure 1.4 Section of an 11.75 embryonic day mouse embryo from a line carrying a transgene that expresses the LacZ reporter gene under the control of a portion of the GATA-6 promoter. At this stage of development expression of the LacZ gene, which produces the dark-staining cells indicated, is limited to atrioventricular canal myocardium. (sAVC, superior atrioventricular endocardial cushion; AVC, atrioventricular canal.) (Courtesy of A. Wessels and J. Burch.)

ventricle in mice is an especially compelling example of the apparent dependence of specific segments on specific genetic regulatory pathways [63].

A relatively new transgenic technique that has revolutionized the understanding of the developing heart is the use of Cre-lox mouse model systems [64]. In this approach mice are generated that contain the coding sequence for the Cre recombinase enzyme under the regulation of a gene sequence of interest. When these Cre mice are crossed with mice that carry sequences flanked by lox P sites, one can specifically delete these "Floxed" sequences and, depending on the nature of the Cre and Flox constructs, achieve, for instance, tissue-specific gene deletions [65] or cell fate tracing [25].

It is beyond the scope of this chapter to discuss in detail how each of the above techniques has advanced our insight into normal and abnormal cardiac development. For the interested reader there are some excellent recent reviews that discuss the use of these strategies [66,67].

Looping

As the heart tube extends due to addition of cardiac tissue to the arterial and venous poles, the heart tube bends to the right. As morphogenesis continues, the loop becomes more complex. The left ventricle moves inferior and anterior to the atrium, the right ventricle slightly anterior and to the right of the left ventricle. The bending of the heart tube is the first morphologic demonstration that the left and right sides of the embryo will not be morphologic mirror images, inextricably linking cardiac development to the correct establishment of the three body axes [68,69].

All vertebrate and most invertebrate body plans demonstrate fundamental asymmetries about the three body axes of anterior–posterior (A–P), dorsal–ventral (D–V), and left–right (L–R). At the molecular level, the axes are determined by asymmetric propagation of signaling events occurring very early in development. The process of L–R axis determination as it concerns heart development has been recently reviewed and broadly conceptualized as requiring three steps involving the initiation, elaboration, and interpretation of the sidedness signal [70,71]. The first step requires initiation of polarity along the A–P, D–V, and L–R axes. The initiating signals for these events are unknown in mammalian embryos. The second step is an elaboration and amplification of the initial L–R asymmetry through a variety of cellular signaling mechanisms. As is true in general for developmental processes, most of the molecules involved in elaborating the L–R signaling process in mice have easily recognized counterparts in birds. However, in a remarkable twist on that theme, some of the molecules required for left-sidedness in mice are determinants of right-sidedness in birds [72]. The molecules responsible for these processes in humans are poorly understood. The third step is the interpretation of the asymmetric signals elaborated in the second step by the cells and tissues of developing organs. The developmental fates of paired structures as to whether to form with mirror symmetries (such as the limbs), or as paired but unequal structures (such as the cardiac atria) is thus the result of both proper signal delivery to the organ primordia and proper reaction of the organ primordia to the signal.

As a measure of the complexity of the impact of genetic mechanisms on L–R axis determination on cardiac development, many genetic models of abnormal cardiac looping have now been described in mice [73]. Some are primarily models of abnormal directionality of looping, while others also show perturbation of the alignment of cardiac segments. Mouse models of globally randomized situs [74,75], situs inversus [76], situs defects affecting different embryonic organs to different degrees [77], and situs defects with preferential bilateral right- or left-sidedness have all been described [73]. Many of the genes implicated in the mouse models are candidate genes for heterotaxies in the human population [78].

The left and right atria have their molecular identities determined by L–R signaling mechanisms. Molecular distinctions between left and right atria are established early

after the atrial segment appears and are genetically dependent on L–R signaling mechanisms [79–81]. It is interesting to note, however, that there is often an increased incidence of transposition of the great arteries in mouse models of abnormal L–R axis determination [73], suggesting a possible element of L–R signaling in normal outflow development.

The mechanisms by which genetic signals result in regulated bending of the heart tube are unknown. Looping movements are intrinsic to the heart and will occur if the heart is isolated from the embryo, with or without beating [82,83]. The deformation of the straight heart tube into a looped structure likely results from some type of mechanical force [84]. However, the source of the required deforming force is not known. A simple explanation would be that myocytes replicate faster in the larger curvature of the loop and more slowly in the lesser curvature, and data suggesting a contribution of regional differences in growth have been presented [85,86]. However, cytochalasin B, an inhibitor of actin polymerization and therefore an inhibitor of cytoskeletal rearrangements, is also capable of either abolishing looping or reversing the direction of looping, according to whether it has been universally applied or selectively applied [87]. This suggests that the required asymmetric mechanical tension may be generated within the cells of the tube heart in response to as yet unknown regulatory signals.

Looping, Convergence, and Septation – Key Landmarks

Looping determines not only the sidedness of the heart but also the correct relationship of the segments of the heart to each other. Imaginary but useful divisions can be assigned to the morphogenetic steps leading from the more-or-less straight heart tube to the looped but still tubular heart, and from the looped heart to the heart poised for septation. Therefore, in this chapter, looping describes the initial period of growth, bending, and twisting of the heart tube. Looping begins and ends with the AV junction connected solely to the left ventricle and the outflow tract connected only to the right ventricle. The second phase of looping, sometimes called convergence, is the process of bringing the right atrial inflow over the right ventricle and the aortic outflow tract over the left ventricle, in the process aligning the outflow septal ridges for fusion with the primitive muscular septum and AV cushions. Ventricular septation is the process of closing the primary interventricular foramen while bringing the interventricular septum into continuity with the conus septum. Descriptions of these processes require recognition of a relatively small number of critical landmarks present in the embryonic heart during the looping and convergence stages of development (Figure 1.5) [7,88].

The looped heart has an inner curvature and an outer curvature. By nature of the tight angulation of the inner curvature the primitive atrial, AV, ventricular, and outflow segments are in close proximity for the remainder of cardiac development. As the region where the right ventricle acquires its inflow and the left ventricle acquires its outflow, the inner curvature of the heart is arguably the most critical, complex, and dynamic site in normal cardiac development.

On the lumenal surface of the heart, the fold in the heart at the inner curvature results in a small muscular ridge inside the heart between the AV junction and the outflow tract called the ventriculoinfundibular flange or ridge. Other key landmarks are the two major endocardial cushions of the AV junction and the two endocardial ridges of the outflow tract. The inferior endocardial cushion is attached to the dorsal AV myocardium and the superior endocardial cushion is attached to the ventral atrioventricular myocardium. As convergence proceeds, small right and left lateral AV endocardial cushions will become visible. The two outflow tract endocardial cushions form extended spiral ridges from the end of the truncus distally to the body of the right ventricle caudally. The endocardial cushion ridge ending in the anterior right ventricle is called the septal endocardial ridge. The endocardial ridge terminating posteriorly in the right ventricle is called the parietal endocardial ridge. The parietal endocardial ridge makes contact with the right lateral endocardial cushion, which itself will become continuous with the superior endocardial cushion. The septal endocardial ridge will make contact with the inferior endocardial cushion. As the endocardial cushions fuse during normal septation, they create, together with the mesenchymal cap of the primary atrial septum and the dorsal mesenchyme protrusion, the central AV mesenchymal complex extending from the AV junction to the distal extent of the myocardial outflow tract. At the most basic level the process of fusion of mesenchymal tissues can be thought of as a tissue zipper that septates the heart [26]. The reason that the endocardial cushion tissues of the conus septum cannot be found on inspection of the mature heart is that these mesenchymal structures are replaced by myocardium in the process known as myocardialization [89]. With respect to human congenital heart disease, this is a critical series of events, as disease phenotypes such as complex transposition, truncus arteriosus, and a number of tetralogy phenotypes all derive from aberrations of these normal developmental steps.

The left and right ventricular lumens are in continuity through the primary interventricular foramen. From the right ventricle, blood passes into the outflow tract of the heart. A myocardial cuff extends along the outflow tract to the junction with the aortic sac at the level of the pericardial reflection.

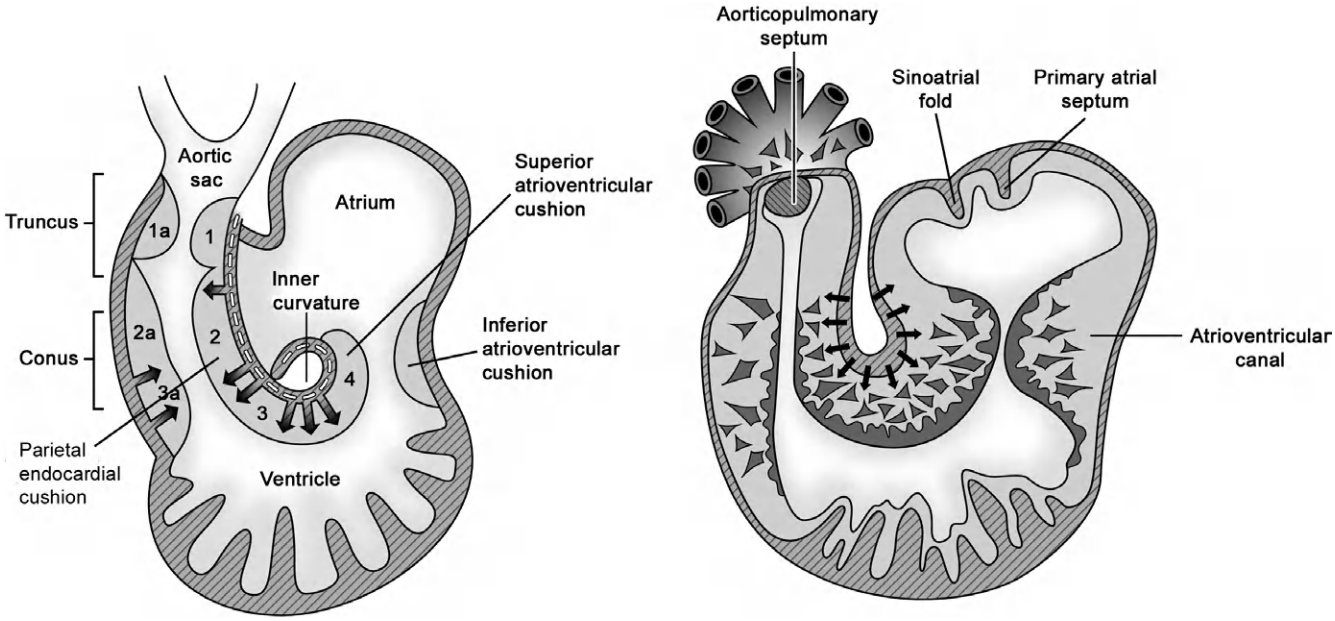

Figure 1.5 Highly simplified representation of key cardiac landmarks in early cardiac development. On the left, the cartoon illustrates the relative positions of the endocardial cushions at approximately HH stage 24. The truncal cushions are indicated as 1 and 1a, the distal conal cushions by 2 and 2a, the proximal conal cushions by 3 and 3a, and the superior atrioventricular cushion by 4. The arrows indicate the future sites of myocardialization. At the inner curvature, normal development results in loss of the myocardial sleeve and retention of the primitive fibrous continuity between the parietal endocardial cushion and the superior atrioventricular cushion. This is reflected by the fibrous continuity of the mitral valve and the aortic valve observed in the normal mature heart. In the cartoon on the right, the myocardialization of the inner curvature is indicated by the arrows; the mesenchymal invasion of the endocardial cushions is indicated by the polygonal cells. (After Mjaatvedt CH, Yamamura H, Wessels A, Ramsdell A, Turner D, *et al.* (1999) Mechanisms of segmentation, septation, and remodeling of the tubular heart: endocardial cushion fate and cardiac looping. In: Harvey RP, Rosenthal N, editors. *Heart Development*. San Diego: Academic Press. pp. 159–175 [88].)

During convergence, the angle of the inner curvature of the heart becomes more acute. The right AV junction is formed by rightward expansion of the AV junction, while at the same time the major (or midline) AV endocardial cushions are approaching each other in the center of the lumen of the AV junction. The outflow endocardial ridges, although unfused, define distinct aortic and pulmonary channels. The aortic channel moves leftward and anterior of its original position. Because of the combined rightward expansion of the AV orifice and the leftward movement of the aortic outflow tract the acute angle of the inner curvature now defines the region where the AV junction and the outflow tract are in continuity. These same morphogenetic movements result in rotation of the outflow ridges to a plane that is closer to parallel to that of the growing muscular septum.

Endocardial Cushion Development and Myocardialization

When the tube heart initially forms, the myocardial and endocardial cell layers are separated by an acellular substance traditionally called "cardiac jelly" [90]. Cardiac jelly can be regarded as a basement membrane, as it lies between two juxtaposed epithelia (the myocardium and the endocardium) and contains traditional basement membrane proteins. The initial production and distribution of these molecules is largely controlled by factors produced by the associated AV myocardium [91,92]. Cardiac jelly condenses into opposing swellings at the outflow and AV regions of the early, looped heart. The resulting endocardial cushions function in combination with the specialized contractile properties of the AV junction and outflow tract myocardium to prevent reversal of blood flow [93]. The AV endocardial cushions also function as the substrate for the formation of the mesenchymal tissues of the crux of the heart, including the AV valves and central fibrous body [94]. Endocardial cushions of the embryonic outflow tract participate in the formation of the aorticopulmonary septum, semilunar valves, and conus septum [95]. During morphogenesis of the endocardial cushions, the mesenchymal cell population that populates the originally acellular cardiac jelly is derived from the endothelial cells of the heart [67,96] along with a population of epicardially

derived cells that also migrates into the AV cushions, but not the outflow tract cushions [97].

Endothelial invasion of the cardiac jelly results in a true transdifferentiation of cell phenotype, from a cell within a typical epithelium to an independently migratory, fibroblast-like mesenchymal cell [98–100]. This process has been compared to cellular changes during malignant transformation and is at least partially under the control of TGFβ-mediated signaling processes [101,102]. Only endocardium from the outflow tract and AV cushions are competent to undergo transformation, and only outflow tract and AV junction myocardium are able to induce transformation [101,103]. Not all the endocardial cells of the AV and conotruncal regions participate in these changes; as migration proceeds, residual endocardial cell populations undergo divisions to replenish their numbers. The mesenchymal cells also replicate actively to populate the cushions [99]. Recent data suggest that a similar process may result in an endothelial-to-mesenchymal transformation contributing to the neointima of atheromatous plaques [104].

Myocardialization is the process in which the mesenchyme of the endocardial cushions is replaced by myocardium [89]. All of the septal structures inside the heart – the interventricular septum, the atrial septum, and the conal septum – are created in part by fusion of nonmyocardial mesenchymal cushions. Myocardialization is responsible for the formation of the myocardial conus septum and the inlet and anterior outlet portions of the interventricular septum. In humans, the AV membranous septum is the only nonmyocardial septal structure derived from endocardial cushion tissue. The myocardialization of the conal cushions appears, based on Cre-lox cell fate studies, to primarily involve myocardial cell invasion of the cushion tissue. The mechanisms controlling this process are unclear [89,105,106].

Atrial Septation

Atrial septation and connection of the common pulmonary vein to the left atrium are closely related events in the normal heart [81]. Recent investigations in mouse, chick, and human embryos highlight the importance of the dorsal mesocardium to these events. At the site where the dorsal mesocardium is in continuity with the atrium (approximately the level of the lung buds) there is a protrusion of mesenchymal tissue into the atrium. This tissue has been recognized for many years and by a variety of names, including "spina vestibuli," "endocardial proliferation of the dorsal mesocardium," "sinus venosus tissue," and, most recently, the "dorsal mesenchymal protrusion" – the terminology adopted herein. Unlike other mesenchymal tissues in the AV junction, the dorsal mesenchymal protrusion is not derived from an epithelial-to-mesenchymal transformation, but rather is a derivative of the second heart field [25,26]. The dorsal mesenchymal protrusion extends into the atrial cavity and is contiguous with the mesenchymal cap on the leading edge of the septum primum. Together with the two major atrioventricular cushions, the dorsal mesenchymal protrusion and the cap eventually fuse to form the atrioventricular mesenchymal complex. This process is essential for normal atrioventricular septation (Figure 1.6) [7,81]. Recent papers strongly suggest that perturbation of the development of the dorsal mesenchymal protrusion might be one of the major mechanisms in the pathogenesis of atrioventricular septal defects.

Based on the expression of several molecular markers that distinguish between left and right atrial myocardium [81], the myocardial portion of the septum primum is derived from left atrial myocardium. Growth of the septum primum occurs by lengthening of its myocardial portion. As described above, the mesenchymal cap on the leading edge of the septum primum is mesenchymal, the cells being derived by endothelial-to-mesenchymal transformation similar to that seen in the endocardial cushions [67]. As growth of the septum primum proceeds, it brings the mesenchymal cap of the septum, as well as the dorsal mesenchymal protrusion into contact with the two major AV endocardial cushions (Figure 1.7) [25,26]. The primary interatrial foramen is closed by fusion of these mesenchymal tissues as they form the AV mesenchymal complex [26]. Knowledge of this process is critical towards understanding the pathogenesis of complete common AV canal, as well as understanding the tissue relationships relevant to its repair.

Before the closure of the primary interatrial foramen occurs, the foramen secundum appears in the body of the septum primum. In humans, this process is initiated by the appearance of small fenestrations that increase in number and size until they coalesce into a definitive foramen secundum [81].

The septum secundum forms as an infolding of the atrial roof in the intervalvar space between the left venous valve of the sinus venosus and the septum primum. The septum secundum also marks the site of boundary between left atrial and right atrial tissues. As a result, the left atrial myocardium of the septum secundum exhibits left atrial markers while the right atrial myocardial surface of the septum secundum exhibits right atrial markers [81].

Interventricular Septation

As the primary interventricular foramen initially provides all of the inflow to the right ventricle and the entire outflow for the left ventricle, its correct closure is critical to normal cardiac development. Closure of the primary interventricular foramen is accomplished through coordinated growth of the muscular interventricular septum and fusion of

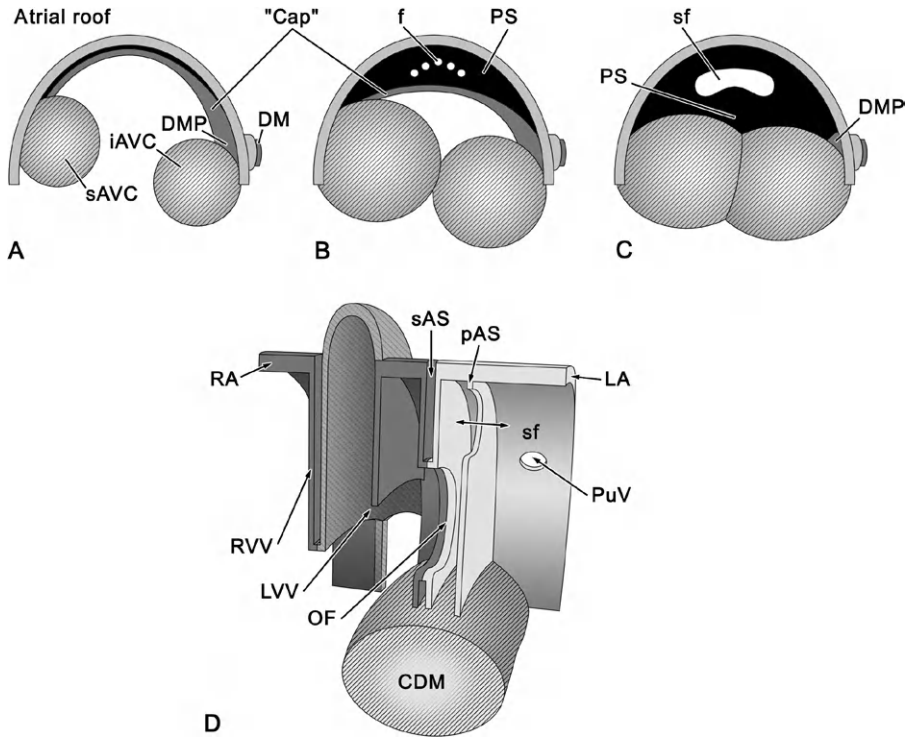

Figure 1.6 Sequence of events in atrial septation in human development. **A,** Heart at approximately 4.5 weeks of development. The leading edge of the septum primum is covered by a mesenchymal cap that is in continuity with the protrusion of the dorsal mesocardium into the atrial cavity. The superior and inferior atrioventricular cushions (sAVC and iAVC) are also in continuity with the mesenchymal cap. (DM, dorsal mesocardium; DMP, dorsal mesocardial protrusion.) **B,** Heart at ~6 weeks development. The septum primum with its mesenchymal cap is approaching the fusing inferior atrioventricular cushion and superior atrioventricular cushion. Fenestrations (f) are appearing in the muscular septum primum (PS). **C,** At ~6–7 weeks of development the fusion of the sAVC, iAVC, and cap of the septum primum is complete. The multiple fenestrations in the septum primum coalesce, forming the secondary foramen (sf). **D,** The secondary atrial septum (sAS) is created by infolding of myocardium at the junction of left and right atrial myocardium. Use of molecular markers distinguishing different populations of sinoatrial myocardial cells shows that the right-sided fold of the sAS and left venous valve (LVV) are derived from right atrial (RA) myocardium, while the left-sided fold of the sAS and primary atrial septum (pAS) are derived from left atrial (LA) myocardium. The right venous valve (RVV) is formed by infolding at the site of juncture of sinus venosus (SV) myocardium and RA myocardium, resulting in an RA molecular phenotype on the atrial surface and a SV molecular phenotype on the luminal surface. (CDM, endocardial cushion-derived mesenchyme; PuV, common pulmonary vein; OF, foramen ovale.) (After Wessels A, Anderson RH, Markwald RR, *et al.* (2000) Atrial development in the human heart: an immunohistochemical study with emphasis on the role of mesenchymal tissues. Anat Rec 259, 288–300 [81].)

endocardial cushions in the AV junction and the outflow tract.

Growth of the muscular interventricular septum is closely associated with dynamic changes in patterning of the ventricular myocardium [107]. When the heart tube initially forms and early after looping, its myocardial layers are but a few cells thick. After looping, the ventricular chambers enlarge caudally in a pouch-like fashion. The pouches are located on the greater curvature of the looped heart and quickly develop a series of circumferential ridges on their internal surfaces (Figure 1.8) [7,107].

The myocytes of the primitive trabecular ridges differ from the subjacent compact myocardium in that the myocytes of the compact myocardium are actively proliferating, while the trabecular myocytes have withdrawn from the cell cycle and are not dividing [107]. The "germinal layer" of compact myocardium provides increases in the numbers of ventricular wall myocytes, but the initial major increases in myocardial mass occur through increase in the trabecular component of the myocardium [107]. The compact myocardium "feeds" cells into the ventricular junctions of the developing trabeculae; this is a relationship that persists throughout embryonic myocardial growth [107].

The primitive trabecular ridges become fenestrated and sheet-like as they expand. Trabeculae are believed to

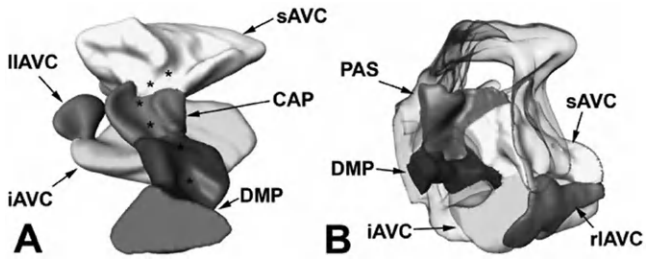

Figure 1.7 Three-dimensional reconstructions demonstrating the spatiotemporal relationships of the atrioventricular mesenchymal tissues during mouse heart development. Computer-generated three-dimensional reconstructions (AMIRA software) based on stained serial sections of mouse hearts **A** at embryonic day 11.5 and **B** at embryonic day 13. These panels show how the respective bodies of mesenchyme fuse with each other to accomplish atrioventricular septation. **A,** The mesenchymal tissues are viewed from above, while all other cardiac tissues are digitally removed to facilitate the study of the relationship of the mesenchymal components. At this stage, the individual mesenchymal components have not fused completely yet. The asterisks mark the groove within these tissues where the myocardial part of the septum primum is located (removed for reconstruction). **B,** The AV tissues are viewed as if one was standing in the right atrium. At this stage, all the mesenchymal tissues have fused. This panel demonstrates how the dorsal mesenchymal protrusion forms a wedge between the major AV cushions at the same time forming the base of the septum primum. At this stage the atrial cap cannot be distinguished any longer from the other endocardially derived mesenchymal tissues (for more detailed description see Snarr *et al.* [25,26]. (CAP, mesenchymal cap on the primary atrial septum; DMP, the dorsal mesenchymal protrusion; iAVC, inferior AV cushion; llAVC, left lateral AV cushion; PAS, primary atrial septum [septum primum]; rlAVC, right lateral AV cushion; sAVC, superior AV cushion.) (Reproduced with permission from Snarr *et al.* [26].)

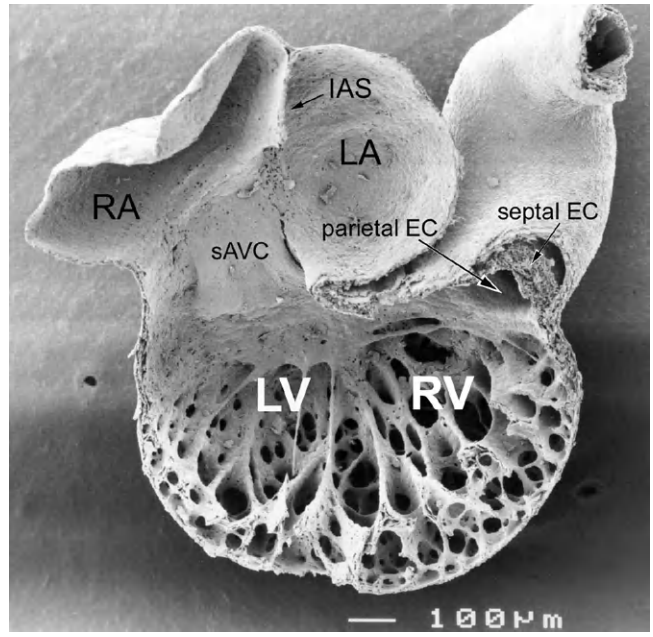

Figure 1.8 Scanning electron micrograph of a section through the right and left ventricles of an embryonic chick heart. The pleat-like ridges characteristic of early myocardial trabeculum formation are easily appreciated. At this stage, the inner curvature of the heart separates the atrioventricular inflow from the right ventricle and the outflow tract from the left ventricle. assume several physiologic functions in the primitive heart. They enhance contractile function of the ventricles [108]. The surface area of the endocardium is greatly increased by the presence of trabeculae, which is believed to improve nutrient and gas exchange with the developing myocardium before the development of a true coronary vasculature [109]. The trabeculae have been asserted to be the conduction system equivalent to (and possibly precursors to) the distal bundle branches and Purkinje fibers in the developing heart [42]. Trabeculae also help to direct the flow of blood in the preseptated heart [110]. Thus, the infrequent, yet important echocardiographic finding of ventricular noncompaction bears important implications.

In the chick heart, the primitive muscular septum is initially formed by a coalescence of trabeculae. In the mammalian heart, the primitive muscular septum appears to be the product of infolding of the compact myocardium produced by growth of the ventricular apices. Perhaps as a consequence, the interventricular groove is a more distinctive feature of mammalian hearts than avian hearts. The leading edge of the primitive muscular septum in humans is readily identified by the HNK1-Leu7 antibody that characterizes the primary ring (Figure 1.9) [7,111,112]. Use of this antibody in human embryos clearly demonstrates that the myocardial precursors of the right ventricle and right ventricular septum, including the inflow segment, are derived in their entirety from myocardial cell populations distal to the original primary interventricular foramen [113].

The primitive muscular interventricular septum is initially a crescent-shaped structure that extends at its posterior limit to the inferior endocardial cushion and at its anterior limit to the superior endocardial cushion. Part of the process of closure of the primary interventricular foramen consists of expansion of the superior and inferior endocardial cushions towards each other, where they will make contact and fuse at approximately 6 weeks' gestation in the human. The mechanism of fusion of the endocardial cushions in spite of the continuous mechanical activity of the heart is not known, but certainly deserves respect.

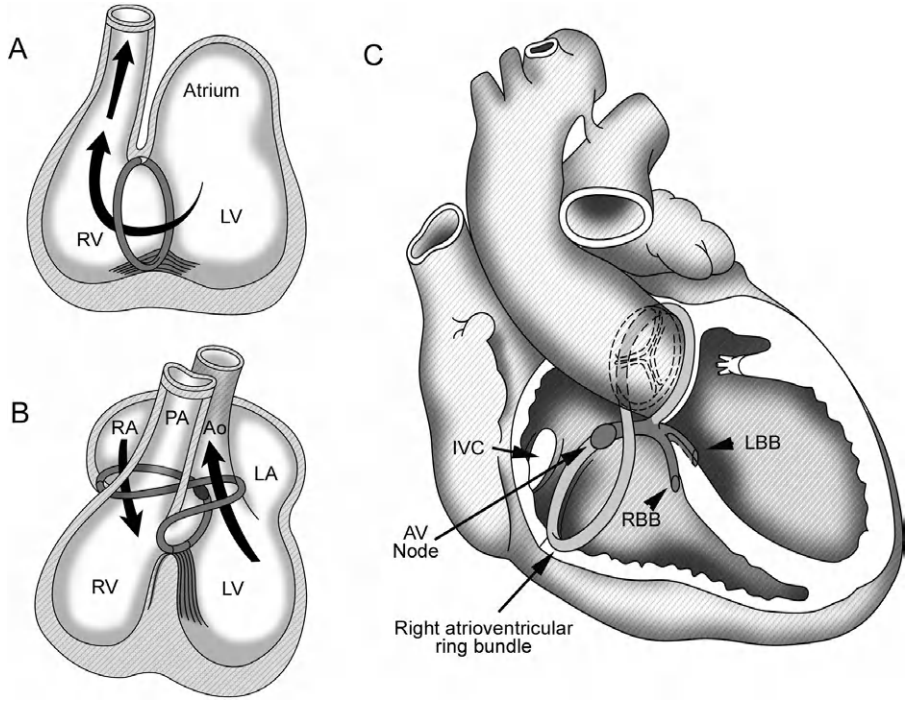

Figure 1.9 These diagrams demonstrate the development of the conduction system from a ring of myocardium detected in human embryonic heart by their expression of a carbohydrate epitope recognized by the antibodies Gln2, HNK1, and Leu7. **A,** Human heart at roughly 5 weeks' gestation. A ring of myocardium surrounding the primary interventricular foramen is detected. Note that the superior aspect of the ring is at the junction of atrioventricular (AV) myocardium and ventricular myocardium. **B,** In the human heart of roughly 7 weeks' development, convergence has resulted in expansion of the small segment of AV junctional myocardium to the right, accompanying the rightward expansion of the AV inlet. The leftward movement of the outlet results in the looping of the ring around the aortic root. As the muscular ventricular septum begins to grow, strands of ring tissue can be found extending from the major aspect of the ring on the crest of the septum down the septal walls towards the expanding apices of the right and left ventricles. **C,** The mature cardiac conduction system of AV node, bundle of His, and right bundle branch (RBB) and left bundle branch (LBB) is derived from the primitive ring tissue. In addition, remnants of the primitive ring in the adult heart can be found on the atrial side of the tricuspid valve fibrous annulus as well as in retroaortic myocardium. (RV; right ventricle, LV, left ventricle; RA, right atrium; LA, left atrium; PA, pulmonary artery; Ao, aorta; IVC, inferior vena cava.) (After Wessels A, Vermeulen JL, Verbeek FJ, *et al.* (1992) Spatial distribution of "tissue-specific" antigens in the developing human heart and skeletal muscle. III. An immunohistochemical analysis of the distribution of the neural tissue antigen G1N2 in the embryonic heart; implications for the development of the atrioventricular conduction system. San Diego: Academic Press. pp. 195–207 [112].)

Further growth of the interventricular muscular septum results in fusion of the crest of the septum with the fused cushion. The boundaries between the original muscular septum and endocardial cushion-derived portions of the septum become obscured by myocardialization except for the membranous septum between the left ventricle and right atrium. Normal inlet septum development is primarily determined by interactions between the inferior endocardial cushion-derived tissue and the muscular ventricular septum, while the smooth anterior interventricular septum is derived from interactions between the superior endocardial cushion and the muscular septum. The membranous septum is the approximate site of final union between the muscular septum and the superior and inferior endocardial cushions [114].

The Atrioventricular Junction Segment and Atrioventricular Valve Development

The electrophysiologic and physiologic properties of the junctional myocardium between the primitive atria and ventricles are critical to the preseptated heart, as previously discussed. However, myocardial continuity between the AV junctional myocardium, the atrial myocardium, and the ventricular myocardium must be interrupted for the development of the fibrous crux of the heart and the correct

function of the conduction system. This is accomplished by formation of a layer of fibrous insulation called the annulus fibrosis that will completely interrupt myocardial continuity between the AV myocardium and the ventricular myocardium, with the exception of the penetrating bundle of His specialized myocardium. In the mature heart the remnants of AV junction myocardium become incorporated into the myocardium of the definitive atrium [94].

Fibrous interruption of AV myocardial continuity results from the fusion of mesenchymal cell populations of the AV endocardial cushions with a mesenchymal cell population found in the atrioventricular sulcus on the external surface of the looped heart. Atrioventricular sulcus mesenchyme cells are brought to the heart in the course of the epicardial cell migration (see Figure 1.3) [7], as discussed in greater detail later in this chapter in connection with coronary artery development. Morphologic studies suggest that the sulcus mesenchyme actively invaginates into the endocardial cushions [115]; the mechanisms driving mesenchymal invagination and the parting of the myocardial layer are unknown. Interruption of myocardial continuity begins at 52 to 60 days of gestation in the human heart and is normally "complete" by the fourth month of gestation [94]. Failure to form the insulating tissues of the AV junction may underlie clinical pre-excitation syndromes. Interestingly, isolated myocytes possibly representing remnants of the embryonic junctional myocardium, originally present between the sulcus mesenchyme and the endocardial cushion mesenchyme, have been identified bridging the fibrous insulation of normal neonatal hearts [116]. This location is different from that noted for parietal accessory atrioventricular bundles [117], which are described as subepicardial and, therefore, seem to represent a different myocardial path through the sulcus mesenchyme-derived fibrous tissue. No structures similar to parietal accessory AV connections are noted in the course of normal development. Thus, the possibility that these accessory connections develop postnatally should be considered. The relationship between pre-excitation pathways in general and normal morphologic events requires further investigation.

Atrioventricular valve development may be tied to the process of sulcus tissue ingrowth, as the hinge points of the definitive leaflets are normally found at the point of juncture between the endocardial cushion tissues and the invaginating sulcus tissue. Atrioventricular valve leaflets are formed by separation of endocardial cushion tissue and myocardium from the ventricular walls in the poorly understood process of delamination [105,118,119]. Other events occurring at the same time that certainly influence normal valvar morphogenesis and may contribute to the delamination process include coarsening of the ventricular trabeculae, incorporation of trabeculae into the compact myocardium, and apical expansion of the ventricular cavity.

At the time of delamination, the atrial surfaces of the valve leaflets are composed of endocardial cushion tissue while the ventricular surfaces are primarily myocardial. The myocardial layer provides continuity with the evolving subvalvar tension apparatus. As leaflet morphogenesis proceeds, the myocardial component is eliminated by unknown processes. Initially, the ends of the AV leaflets are connected to the compact ventricular myocardium either directly or via trabecular outgrowths of the myocardium. As development proceeds, papillary muscles are derived by two mechanisms: from initially independent, preexisting trabeculae coalescing together to form papillary muscles; and from delamination of myocardium into myocardial structures that join with trabeculae or form of themselves the papillary muscles. The mitral valve papillary muscles are derived from a single large trabecula that then separates into the two independent papillary supports [119]. Thus the surgically challenging group of patients with parachute mitral valve derivatives are likely due to deficiencies in this process. Tricuspid valve papillary muscles develop independently from each other and via different mechanisms; the anterior papillary muscle of the tricuspid derives from an early coalescence of trabeculae detectable at 6 weeks' gestation, the septal leaflet papillary muscle is a product of delamination during the tenth to twelfth week of gestation, and the posterior papillary muscle complex is still a relatively indistinct structure at 12 weeks' gestation [105]. Chordae are formed by progressive fenestration and fibrous differentiation of trabeculae and/or the initially solid individual valve leaflets; there is disagreement with respect to the derivation of chordae from myocardium or endocardial cushion tissue [105,107,118].

As previously noted, there are four endocardial cushions in the AV junction. The superior and inferior cushions are the most prominent endocardial cushion masses from their first appearance, but there are also important contributions from the lateral endocardial cushions, which are visible only after Carnegie Stage 17 (approximately 42 days) [94,118]. The left lateral cushion contributes to the posterior (mural) leaflet of the mitral valve. The right lateral cushion, which becomes continuous anteriorly with the septal endocardial cushion of the outflow tract, contributes to the formation of the anterior and inferior leaflets of the tricuspid valve.

Atrioventricular valve morphogenesis is one of the most prolonged aspects of human cardiac development. Recognizable elements of the tricuspid valve begin formation at 5–6 weeks' gestation. The AV endocardial cushions are actively reconfiguring at this time, with fusion of the superior and right lateral AV endocardial cushions to each other. The conal cushions are also completing their fusion during this time. The fused outflow septum then expands apically to reach the inner curvature of the heart, anterior to the fusing superior and right lateral endocardial

cushions. In this position the fused outflow cushions will become adherent to the myocardium of the ventriculoinfundibular fold, establishing the anterior position of the conus septum with respect to the atrioventricular valvular structures, and also forming the crista supraventricularis [105]. Despite the overall advanced stage of cardiac morphogenesis at this point, the tricuspid valve leaflets are still very primitive in appearance and not freely mobile. The inferior leaflet is fully delaminated by the end of the eighth week of gestation, the anterior leaflet by the eleventh week, and the septal leaflet in the twelfth week. The commissure separating the anterior and septal leaflets is not complete until the septal leaflet is fully delaminated [105].

In development of the mitral valve, the inferior and superior AV cushions begin to fuse at roughly 5 weeks' gestation; even before fusion, the enlarged trabecular complex that will evolve into the two mitral papillary muscles can be seen connecting the superior and inferior cushions [118,119]. The left lateral cushion, the precursor to the posterior leaflet, is visible by the seventh week of gestation. At approximately this time initial delamination of the mitral valve structures becomes detectable and continues until the tenth week of development. Between the tenth and fourteenth weeks of development myocardial elements of the leaflets are eliminated, papillary muscles achieve their adult appearance, and chordae differentiate [118,119].

Development of the Conduction System

The sinoatrial node first becomes detectable at approximately 10.5 days in mouse development, roughly equivalent to Carnegie stage 14 (approximately 32 days) of human development, at the medial wall of the right common cardinal vein and extending cranially to the junction of the anterior and common cardinal veins. This corresponds to what will become the portion of the superior vena cava between the orifice of the azygous vein and the right atrium in the adult [120].

In the human embryo the AV node becomes detectable histologically at approximately Carnegie stage 15 (approximately 33 days) [121]. It is located in the posterior portion of the AV canal in the myocardium under the ventricular margin of the inferior endocardial cushion and is included in the primary ring [94]. The primitive AV node is in direct continuity with the AV and ventricular myocardium. From the earliest stages a cellular tract destined to become the bundle of His can be noted extending from the main mass of AV nodal tissue to the ventricular subendocardium. The AV sulcus mesenchyme will invaginate to make contact with the endocardial cushion mesenchyme inferiorly to the main mass of the developing AV node while encasing the future bundle of His in the fibrous insulating tissue at the crux of the heart [94].

The proximal bundle branches are detected in the human by antibodies to the primary ring antigen Gln2/HNK1/Leu7 (Figure 1.9) [7,111,112]. Differentiation of conduction tissue in the ventricles appears to occur by a process of recruitment of "working" myocardium into the conduction lineage and to be associated with withdrawal from the cell cycle [122,123]. Numerous observations support the contention that the trabeculae of the primitive heart are the initial conduction pathways connecting the proximal bundle branches with the ventricular free walls [124]. Subsets of trabeculae probably remain as elements of the conduction tissue in the mature heart.

The cellular morphology of Purkinje fibers is extremely variable between species [125]. In some species intramural Purkinje fibers are very difficult to distinguish by morphologic criteria. Molecular markers that unambiguously identify intramural Purkinje fibers across species are not known [124]. However, in all animals in which they have been studied, intramural Purkinje fibers are late-appearing structures in comparison to the central AV node–His bundle–bundle branch conduction tissues. In the developing sheep heart, where Purkinje fibers are easily distinguished by morphologic criteria from "working" ventricular myocytes, intramural Purkinje fibers are not seen until 60 days' gestation, while the AV node becomes visible as early as 27 days' gestation [126]. In this species, morphologic differentiation of the conduction tissue clearly progresses outward from the AV node.

Purkinje fibers in the chick embryo myocardium can be recognized by specific expression of the gap junction protein Cx42. Use of this marker shows that chick embryo Purkinje fibers are only detectable at day 10 of chicken development. In this model ventricular myocytes are recruited to differentiate into Purkinje cells only in the vicinity of developing coronary arteries [123]. Data suggest that endothelin signaling may be an important determinant of this process [127].

Morphogenesis of the Outflow Tract

Landmarks in the Outflow Tract

The morphologic terminology for the outflow tract used in this chapter follows that proposed by Pexieder [128]. The outflow tract is relatively short in the early phases of looping, after which it becomes elongated, with a distinct bend. The site of the bend is the primary external landmark dividing the truncus from the conus portions of the outflow tract: separate structures. The external landmarks for the entire region are the ventriculoinfundibular fold proximally and the aortic sac distally. The aortic sac–outflow junction is identified by flaring of the root of the aortic sac, the reflection of the pericardium, and the distal limit of the cardiac jelly and myocardium. The proximal end of the

outflow tract lumen is marked by myocardial ridge on the inner surface of the ventriculoinfundibular fold, the ventriculoinfundibular flange. The septal outflow ridge and parietal outflow ridge spiral from the right ventricle to the distal outflow tract, with a distinct change in their direction noted at the site of the bend in the outflow tract. As septation proceeds, the myocardial outflow tract shortens.

At the base of the heart the conal ridges are continuous with the AV endocardial cushions. During remodeling of the conus the mesenchymal (fibrous) continuity of the cushions will be retained between the mitral and aortic valves but will be lost between the tricuspid and pulmonary valves. The mechanisms through which outflow tract remodeling occurs are of great interest but remain largely undetermined. It is precisely these mechanisms that are of particular importance in understanding the pathogenesis of a large number of clinically challenging congenital heart disease phenotypes. Indeed, the normal processes of outflow tract remodeling are easily disrupted via pharmacologic, genetic, or experimental microsurgical manipulations, often resulting in persistence of a complete myocardial conus for both semilunar valves and a ventricular septal defect – double-outlet right ventricle (DORV) [129,130]. In one experimental model in which a clip was placed on a vitelline vein, the resulting malformation appeared to be secondary to altered embryonic blood flow; however, this model of altered blood flow does not explain the vast majority of congenital heart disease phenotypes [129,131,132]. Indeed, different teratogenic models are capable of resulting in different forms of conal abnormalities within the spectrum of DORV [129]. The frequency with which DORV is observed in experimental models presumably points to the requirement for integration of multiple processes for the embryonic heart to proceed beyond the "default" relationship of having both great arteries arising from the right ventricle. It also points out that the terminology "DORV" may undesirably lump an etiologically disparate group of defects into one final common pathway lesion. Thus, careful analysis of vessel morphology is required to accurately determine the cardiac phenotype. Alternatively, varieties of DORV may be forms of developmental arrest that represent final common morphologic pathways for a multitude of initial insults [130].

Aorticopulmonary Septation

The aorticopulmonary septum is initially formed as a condensation of mesenchyme in the roof of the aortic sac, between the fourth and sixth aortic arches (Figure 1.10) [7,130]. The extracardiac origin of this mesenchyme had been well recognized since the late 1970s [133] and in 1983 was identified by Kirby to be a population of neural crest cells [134]. Two prongs of mesenchymal condensations penetrate into the endocardial cushion ridges at the truncal end of the outflow tract. Septation moves towards the heart and is accomplished by fusion of the prongs of neural crest-derived mesenchyme. As the septum forms, the arterial trunks thus become separated by neural crest-derived smooth muscle cells [106]. As aorticopulmonary septation proceeds towards the heart and the trunks of the aorta and pulmonary artery become distinct, the distal extent of the myocardial sleeve remains at or below the septation complex. There is very little apoptosis detected in the distal

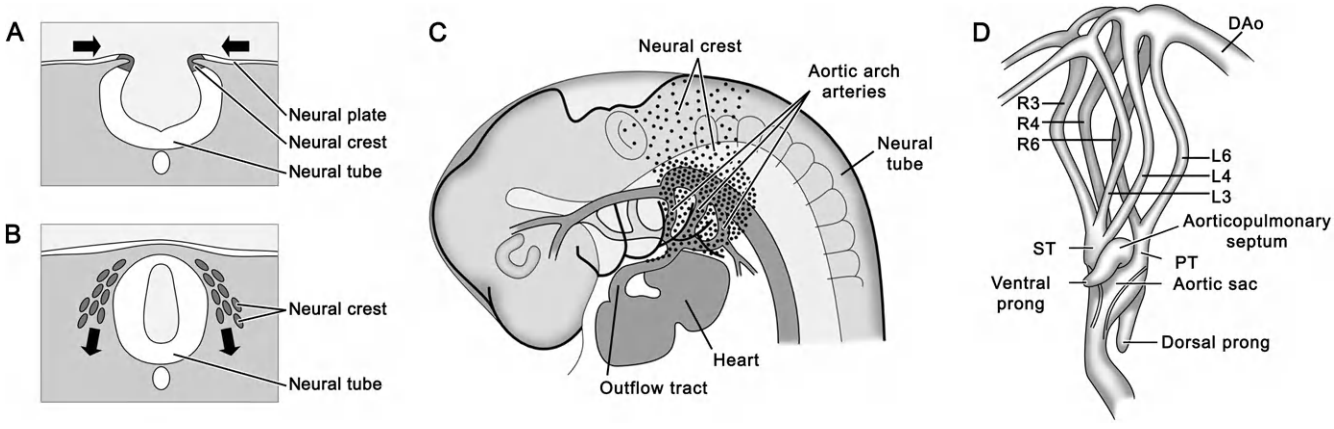

Figure 1.10 Features of the neural crest contribution to normal cardiac development. **A,** and **B,** The neural crest is a population of cells that is released to migrate throughout the embryo by fusion of the lateral neural plates to form the closed neural tube. **C,** The cardiac neural crest migrates via the aortic arch arteries into the outflow tract of the heart. **D,** The neural crest cells that form the aorticopulmonary septum form a condensed mass of cells between the fourth and sixth aortic arch vessels with two "prongs" that penetrate into the conal and truncal endocardial cushions. (PT, pulmonary trunk; ST, systemic trunk; DAo, descending aorta.) (Reproduced with permission from Kirby [130]. Contribution of neural crest to heart and vessel development. In: Harvey RP, Rosenthal N, eds. *Heart Development*. pp. 179–193. Copyright © 1999 Elsevier.)

truncal myocardium, so it is probable that the myocardium is not simply dying away [106]. It remains a topic of active debate whether subaortic conal myocardium retracts towards the heart or transdifferentiates into smooth muscle cells in the roots of the aorta and pulmonary artery [106,135,136]. In the absence of the aorticopulmonary septum, the outlet of the heart communicates with a common arterial trunk such as that seen in truncus arteriosus or in incomplete forms such as aorticopulmonary window.

Development of the Semilunar Valves

The semilunar valves develop at the juncture between the aorticopulmonary septum and the conus septum. They are derived from the parietal and septal conal ridges, the small intercalated ridges that form between the conal endocardial ridges, and the mesenchymal prongs of neural crest-derived mesenchyme that penetrate into the conal endocardial ridges. In the mouse, the neural crest cells of the mesenchymal prongs are marked by expression of the protein α-smooth muscle actin (ASMA) [106,137]. Cardiac neural crest cells can also be visualized using a variety of transgenic mouse model systems, the most frequently used being the Wnt1-cre mouse in combination with the Rosa26R-lacZ reporter mouse [67]. Fusion of the endocardial ridges occurs by contact of the ridges followed by disappearance of the endothelial cells at the site of contact. The ridges are then connected to each other by a whorl or knot-like structure of ASMA-positive cells, which is the forming aorticopulmonary septum.

Semilunar valve leaflet development begins shortly after septation. In mice, the initial process is outgrowth of unexcavated cusps of tissue corresponding to the future leaflets from the arterial surface of the distal endocardial ridges and intercalated cushions [138]. Valve sinuses are formed by active endothelial excavation of the outlet surface of the leaflets. The initial valve leaflets are thickened structures filled with an abundant extracellular ground substance densely populated with endocardial-derived mesenchymal cells bordered by a cuboidal endothelium on the arterial surface and a flattened, streamlined endothelium on the ventricular surface [139]. After the sinuses are fully excavated, the leaflets remodel into the delicate fibrous tissue characterizing mature semilunar valves [139]. Valve remodeling is a slow process that may be histologically incomplete at the time of birth [138,140]. The mechanisms of these processes are largely unexplored. The neural crest does not play as prominent a role as in aorticopulmonary septum formation – the only ASMA-positive neural crest-derived cells present in the semilunar valve leaflets as they develop are at the junctures of the leaflet commissures and the arterial wall of the great vessels [106]. These locations may hint at links between neural crest abnormalities and abnormalities of valve commissure formation or location.

A mouse model of both aortic and pulmonary valve aplasia secondary to ablation of the *Nfatc* gene has been described [141,142]. NFAT proteins are transcription factors known to be important mediators of intracellular calcium signaling in the immune system, nervous system, myocardium, and skeletal muscle [143]. NFAT signaling is initiated by calcineurin, the primary intracellular target of cyclosporine and FK506. During heart development, expression of the *Nfatc* gene is limited to a subset of cells in the endocardium, but beyond this observation the mechanism of contribution of NFATc to semilunar valve development is unknown. Although rare, aplasia of both semilunar valves has been described in humans as well [144,145]. Additionally, single semilunar valve dysplasia is one of the most common forms of congenital heart disease, either seen in isolation (e.g., bicuspid aortic valve) or in conjunction with other defects such as tetralogy of Fallot, tetralogy of Fallot with absent pulmonary valve syndrome, pulmonary atresia, and a wide variety of left ventricular outflow tract defects that include aortic valvar hypoplasia with hypoplastic left heart syndrome as its most severe manifestation.

A more complex model of abnormal semilunar valvulogenesis is found in mice deficient for *Sox4* [146]. These animals die in mid-gestation with semilunar valve insufficiency (as do NFATc-deficient embryos) and have been demonstrated to suffer from a spectrum of cardiovascular defects ranging from isolated lack of the infundibular septum to complete failure of conotruncal and aorticopulmonary septation. Additional extracardiac defects noted include tracheoesophageal fistulae. The outflow tract malformations noted in this model are hypothesized to result from abnormalities in signaling between neural crest (see below) and the outflow tract endocardial cushion cell populations. Unlike the models of common trunk associated with "pure" neural crest defects, *Sox4*-deficient mice exhibit variably severe defects in the numbers and relative differentiation of semilunar valve cusps.

Conus Septation

Formation of the conus septum is a multistep process. Initially the conal endocardial ridges are "simple" structures consisting of cardiac jelly bounded by endocardium and myocardium. As in the AV cushions, a subset of endocardial cells transdifferentiates into mesenchymal cells that then invade the cardiac jelly. The conal endocardial ridges subsequently enlarge and, with each sphincter-like contraction of the conal myocardium, are brought into apposition [93]. Fusion of the endocardial ridges, another poorly understood process, proceeds temporally from the distal conus to the base of the heart and results in an initially

mesenchymal conus septum. When the proximal conal cushions fuse they complete the separation of the subaortic and subpulmonary outflow tracts. The endocardial cushion tissue is then replaced by myocardial tissue in a process that is initially completed at the proximal conus septum and is last completed at the distal conus septum. The myocardialization of the conal cushions results in the formation of the supraventricular crest and the muscular outflow septum.

Mesenchymal neural crest prongs of the aorticopulmonary septation complex extend into the conal endocardial ridges, but unlike their role in aorticopulmonary septation they do not form the conal septum. The neural crest cells in the conal ridges disappear, possibly by an apoptotic mechanism, and their presence is speculated to be important in some way for regulating the subsequent process of myocardialization [147].

Morphogenesis of the Great Vessels and Coronary Circulation

The Neural Crest and Cardiac Development

Neural crest cells migrate into the heart through the aortic arches and are necessary for aorticopulmonary septation, outflow tract septation, and formation of the tunica media of the third, fourth, and sixth aortic arch vessels [130,134,148]. An additional population of neural crest cells differentiates into the entirety of the autonomic innervation of the heart. Other neural crest-derived structures in proximity to the developing heart and great vessels include the thymus, thyroid, and parathyroid glands.

The neural crest is a transient structure in vertebrate development originating in the dorsal-most region of the neural tube (Figure 1.10) [7,130,148,149]. The cells of the neural crest reside on the lateral margins of the neural plate and the right- and left-sided populations are brought into apposition by the folding of the neural plate into the neural tube. The cells then disperse and migrate along precise pathways to their multiple destinations. As with closure of the neural tube, this process is initiated cranially and extends caudally [148]. Specific regions of the neural crest seed cells via specific pathways to specific structures [150]. The neural crest cells that reach the outflow tract of the early heart migrate via the third, fourth, and sixth aortic arch vessels. The region of the neural crest contributing to cardiac and fourth aortic arch morphogenesis is sometimes called the "cardiac" neural crest [130,148].

Experimental ablation of the cardiac neural crest results in structural heart defects including DORV, truncus arteriosus, tetralogy of Fallot, and ventricular septal defects [149]. The most consistent impact of experimental neural crest ablation on the cardiovascular system in chick embryos is aberrant patterning of the aortic arch arteries, although no specific malformation of the aortic arch vessels is predominant in this model [130]. There are strong similarities between lesions observed following neural crest ablations in the chick embryo and the spectrum of cardiovascular anomalies in the DiGeorge syndrome [151,152]. Several cardiac teratogens in experimental animals have spectra of defects that are also comparable, such as bis-diamine in rats [153], alcohol in mice [154], nimustine hydrochloride in fetal rats and chick embryos [155,156], endothelin A blockade in chick embryos [157], and retinoic acid in humans [158]. Mouse genetic models of abnormal neural crest function include the Splotch mouse, caused by loss of the transcription factor PAX3 [159]. Endothelin signaling is particularly important in cardiac neural crest functioning, as demonstrated by the presence of aortic arch abnormalities and other neural crest-associated defects in mice bearing targeted disruptions of endothelin 1 (ET-1) [160,161], endothelin converting enzyme-1 (ECE-1) [162], and the endothelin-A (ETA) receptor [163,164]. Additional mouse models exhibiting cardiovascular features of cardiac neural crest deficiency include the trisomy 16 mouse and mice with targeted multigene deletions comparable to human chromosome 22q11 microdeletions [137,165].

Origins of the Outflow Tract Endothelium

In common with the endothelium of the aortic arch vessels, outflow tract endothelium is derived from precursors in lateral and paraxial mesoderm of the cranial region [166] corresponding to cells of the second heart field [35]. Similarly, the epicardium of the distal portion of the outflow tract is derived from a separate population of precursor cells than that of the remainder of the heart [167]. As previously noted, the outflow tract myocardium, the myocardium of the right ventricle, and interventricular septum originate from the second heart field [35]. Taken together, these data suggest a distinct developmental origin of the entirety of the cardiac outflow tract.

Epicardial Cell Migration and Development of the Coronary Arteries

The development of the epicardium is a relatively late event in the development of the heart, but its proper formation is essential for normal development of the coronary arteries, valves, and the interstitial fibroblast population of the myocardium. The epicardium migrates over the surface of the heart from villous projections in the region of the septum transversum in mammals [168–171]. The precursor tissue is histologically and functionally complex and has been called the proepicardium or proepicardial organ [172]. It is a transitory embryonic structure that gives rise to the epicardial cell layer and is also the

source of the nonmyocardial mesenchymal cells (i.e., fibroblasts, coronary smooth muscle cells) of the heart. The migrating cells eventually flatten over the surface of the myocardium and develop morphologic characteristics compatible with primitive epithelial cells. The flattening process also causes cells to occupy a greater surface area, bringing adjacent clusters of cells into contact with each other until a continuous sheet results. In the rodent, where the process is well studied, these events occur between days 9 and 11 of embryonic life, and the villous projections are markedly diminished by day 10.5 [171,172]. This is poorly understood in human development; while these important processes in rodent development are complete just before mid-gestation, in the human most are shifted towards the first 2 months of development (see [173] for comparison of developmental landmarks between human and mouse).

As the epicardial layer of cells extends over the heart, an extensive acellular extracellular matrix layer appears between the epicardium and the myocardium. If migration from the proepicardial organ is physically disrupted in chick embryos, then no epicardium develops and there is failure of the subepicardial extracellular matrix to form as well [174]. The subepicardial space becomes populated by mesenchymal subepicardial cells generally accepted to provide the precursors of cardiac fibroblasts, coronary vascular smooth muscle cells, and coronary endothelial cells. Recent publications using transgenic mouse models that allow the tracing of cells derived from the epicardium have also suggested that these cells may give rise to a population of myocytes localized in the interventricular septum [175,176]. The subepicardial extracellular matrix accumulates to its greatest degree in the AV groove. In addition to being a key site for coronary vasculogenesis, the mesenchymal cells that come to populate the AV groove matrix will form the majority of the fibrous insulating ring between the atria and the ventricles [94]. All of the cell populations just described as invading the myocardium and/or subepicardial extracellular matrix have come to be known as epicardial-derived cells (EPDCs) [97]. As identified by lineage markers, EPDCs migrate into the sulcus matrix and subsequently into the AV endocardial cushions. In addition to entering the AV cushions, EPDCs also migrate into the myocardium and subendocardium. Specific possible morphogenetic roles of the myocardial and subendocardial EPDCs have not been determined, but abnormalities of the compact myocardium, AV cushions, and coronary vasculature have all been documented in their absence [167].

The subepicardial space is the site of origin of the vascular plexus of the coronary vessel precursors. There are three sequential and overlapping phases of nutrient delivery to the myocardium during embryogenesis of the heart [109,177]. The first phase is associated with the development of an extensive network of intratrabecular sinusoids lined by endocardial cells through which nutrient flow to the myocardium likely occurs. The second phase is the development of a subepicardial plexus of endothelial-lined channels that penetrate the myocardium. A subset of these channels will communicate with the intratrabecular sinusoids. The third stage is regression and coalescence of the vascular subepicardial network into muscular arterial channels. As soon as the vessels are readily identifiable they are noted to penetrate into the ventricular and atrial walls, where they establish a mid-myocardial network. The vessels spread to the ventral surface of the heart and follow the sulci (especially the AV sulcus) to the outflow tract where they form a plexus in the myocardial sheath surrounding the truncus arteriosus. Coalescence of vessels and capillary outgrowth from the peritruncal plexus results in penetration of the wall of the aorta by the definitive proximal coronary arteries [172,177–179]. Abnormalities of this process likely contribute to the pathogenesis of a number of surgically important disease phenotypes including intramural coronary ostia, abnormalities of coronary positioning in both normally related and transposed great vessels, and anomalous left coronary artery from the pulmonary artery syndrome.

Development of the Aortic Arch

The great vessels are the conduit for blood to flow from the heart to the body and, therefore, must be formed and functional at the time of initiation of embryonic circulation (approximately day 20–22 in humans). The vessels of the embryo are formed by a process called vasculogenesis. Vasculogenesis occurs by aggregation of pre-endothelial cells (angioblasts) into networks of small endothelial channels (in contrast to the process of building vessels by sprouting growth or branching, called angiogenesis). The dorsal aorta and aortic arches are created by fusion of independently formed regional vasculogenic networks. After communications between the networks are established the definitive lumen is formed through merging of the small endothelial passages into larger channels [180,181]. The channels are functional vessels composed of only endothelial cells. Mesenchymal cells in the descending aorta and neural crest cells in the aortic arch region will then be recruited to form the smooth muscle cells of the media of the developing arteries by an obscure process [182–184]. These enveloping events require signaling through extracellular proteins known as angiopoietins via the Tie1 (TIE) and Tie2 (TEK) receptors in endothelial cells [185]. The transcription factor KLF2 (LKLF) has also been shown to be necessary for formation of the tunica media in embryonic vessels [186].

The initial embryonic arterial circulation is morphologically bilaterally symmetric and consists of multiple pairs of aortic arch vessels connecting the heart outflow to the

paired dorsal aortae. The dorsal aortae are initially paired for the full length of the embryo. Fusion of the paired aortae into a single structure begins distally and progresses retrograde to the seventh somite. As development proceeds, the paired first, second, third, fourth, and sixth aortic vessels and the dorsal aortae undergo an intricate series of transformations. The first and second aortic arch vessels regress, remaining patent only as capillary structures. The dorsal aorta between the third and fourth aortic arch vessels (the carotid duct) regresses completely, leaving no remnant, resulting in the paired third aortic arch vessels becoming the only source of blood flow from the aortic sac/truncus complex to the head of the embryo. The third aortic arch vessels become the precursors of the definitive common carotid arteries. The right dorsal aorta completely regresses at the site of dorsal aortic bifurcation; this leaves the right fourth aortic arch vessel to become a short stub connecting the right seventh intersegmental (future subclavian) artery to the aortic sac/truncus complex. The right sixth aortic arch vessel becomes the right pulmonary artery. The left sixth aortic arch vessel becomes the left pulmonary artery and the ductus arteriosus connecting the pulmonary plexus-derived distal main pulmonary artery and left pulmonary artery to the left dorsal aorta at the junction of the left dorsal aorta and the left fourth arch vessel. The left dorsal aorta remains widely patent throughout its length but remodels so that the definitive left fourth aortic arch vessel, the ductus arteriosus, and the left seventh intersegmental artery (future left subclavian artery) all connect to the left dorsal aorta within a very short span. Understanding these developmental concepts and relationships is important in planning repair of great vessel abnormalities as well as vascular rings. Despite the generally superb imaging (echocardiography, computed tomography angiography, or magnetic resonance imaging) that accompanies patients with aortic patterning defects, one is occasionally surprised by intraoperative findings. A facile knowledge of great vessel developmental derivatives can help troubleshoot an intraoperative surprise and potentially limit the dissection required to reveal the relevant operative anatomy.

The vertebral arteries are derived from anastomoses between the seven cervical intersegmental arteries. After continuity is established between the intersegmental arteries their connections to the dorsal aorta regress (with the exception of the connection of the seventh intersegmental vessel that becomes the subclavian artery) creating the subclavian origin of the definitive vertebral arteries.

Neural crest cells are critical to the normal pattern of regression or maintenance of aortic arch vessel patency (Figure 1.10) [7,130]. When neural crest cells are physically ablated in chick embryos, vascular patterning is abnormal in 100% of experiments, although the specific pattern of ablation-induced abnormalities is not predictable [181]. Neural crest cells invade and replace the original tunica media of the aortic arch vessels, but it is not known by what subsequent mechanisms neural crest cells determine the future vascular pattern.

Several genetic models of abnormal aortic vessel patterning that are not yet linked to neural crest abnormalities have been identified in mouse and zebra fish. Knockout experiments in mice involving the closely related transcription factors mesoderm/mesenchyme forkhead 1 (MF1) and mesenchyme forkhead 1 (MFH1) demonstrate cardiovascular phenotypes that include coarctation of the aorta, interruption of the aortic arch, ventricular septal defects, and in the case of MF1, thickening and partial fusion of semilunar valve leaflets [187].

Development of the Pulmonary Veins

The earliest evidence of the formation of the common pulmonary vein in the embryo is the presence of a strand of endothelial cells in the dorsal mesocardium. The endothelial strand forms a lumen and initially is a midline structure. As the dorsal mesenchymal protrusion is developing and projecting into the atrial cavity on the right side of the primitive pulmonary vein, the relative position of the pulmonary vein changes as it occupies a position to the left of the middle [67]. The continued development of the dorsal mesenchymal protrusion, the myocardialization of this mesenchyme, and the concomitant growth of the septum primum eventually result in the connection of the pulmonary vein to the left atrium in normal development [81]. Therefore, the development of the pulmonary vein does not result from an outgrowth of the atrial wall. The remodeling of the original single common pulmonary vein orifice into the four separate orifices characteristic of the mature heart is a topic deserving of additional study. Initially, the walls of the pulmonary veins are not muscular. However, as development proceeds, myocardial sleeves are formed around these veins. Recent studies have revealed some of the molecular pathways that underlie this mechanism [188]. As pulmonary myocardium is a frequent site initiating atrial fibrillation, advancing our knowledge of this event is of high importance.

Development of the Systemic Veins

The embryonic systemic veins are also formed by vasculogenesis. Initially there are three bilaterally symmetric venous drainages: the vitelline, umbilical, and cardinal venous systems [189]. The vitelline veins drain the embryonic gastrointestinal tract and gut derivatives. The umbilical veins bring oxygenated blood from the placenta to the heart. The cardinal venous system returns blood from the embryonic head, neck, and body wall. All three of these drainages enter into the sinus venosus of the primitive heart tube. The adult venous pattern is established through

complex patterns of regression, remodeling, and replacement of these embryonic venous systems and their connections to the sinus venosus [190,191].

The sinus venosus is initially bilaterally symmetric, with right and left "horns" that provide connection for the right and left common cardinal veins, umbilical veins, and vitelline veins. However, the connections of the left-sided cardinal, vitelline, and umbilical venous systems with the left horn of the sinus venosus normally regress. This results in the coronary sinus remaining as the primary structural derivative of the left horn of the sinus venosus in the normal fetal and postnatal heart. When embryonic venous connections with the left venous horn fail to regress, persistence of the left superior vena cava is observed. The right horn of the sinus venosus normally accommodates the entirety of the systemic venous drainage except the portion from the heart returned via the coronary sinus. In addition, the portion of the mature right atrium between the orifices of the vena cavae is derived from the right horn of the sinus venosus.

The right and left vitelline veins are connected to each other via a plexus of veins that become the liver sinusoids. The left vitelline vein regresses after it loses connection with the left horn of the sinus venosus. Therefore, the entire venous system of the embryonic gut normally drains to the heart through the right vitelline vein. The connection of the right vitelline vein to the right sinus venosus persists into fetal and adult life as the terminal portion of the inferior vena cava.

The left umbilical vein also loses its connection with the left horn of the sinus venosus, but it is the right umbilical vein that regresses as a distinct structure. The left umbilical vein forms anastomoses with the ductus venosus (derived from the liver plexus of the vitelline veins). No derivatives of the embryonic umbilical venous drainage connect to the heart or persist following the closure of the ductus venosus in adult life.

The cardinal venous system initially consists of bilateral anterior cardinal veins and bilateral posterior cardinal veins. Fusion of the anterior and posterior cardinal veins at the level of the sinus venosus forms the common cardinal veins. The left anterior cardinal vein loses its connection with the left horn of the sinus venosus, but a small remnant on the surface of the heart normally persists as a passage of coronary venous blood to the coronary sinus and is known as the oblique vein of the left atrium. Another portion of the left anterior cardinal vein persists as the left internal jugular vein. As the left anterior cardinal vein loses connection with the heart it becomes connected to the right anterior cardinal vein via the intercardinal anastomosis that forms between the thyroid vein and the thymic vein; this connection will persist as the left brachiocephalic vein. The portion of the right anterior cardinal vein between the right atrium and the drainage of the left anterior cardinal vein proximally (via the intercardinal anastomosis) becomes the normal right superior vena cava.

The posterior cardinal veins are the only portions of the embryonic venous drainage that are destined to have a symmetrical fate. Both posterior cardinal veins will regress throughout most of their length and lose their direct connections with the sinus venosus. The posterior cardinal veins originally drain the body wall, gonadal, and renal structures. Their function in venous drainage of the body wall is supplanted by the supracardinal venous plexus, while the gonadal and renal venous drainage is captured by the subcardinal venous plexus.

The posterior cardinal, supracardinal, and subcardinal venous beds contribute the segments that form the definitive inferior vena cava (IVC) to the level of the vitelline vein-derived segment connecting to the right atrium origin. Remnants of the posterior cardinal veins in the fetal and adult circulation are limited to the most distal portion of the IVC (formed by anastomosis of the right and left posterior cardinal veins) and the common iliac veins. The posterior cardinal vein-derived IVC connects to the supracardinal segment of the IVC. The supracardinal venous system is the site of origin of the azygous and hemiazygous veins, which ordinarily connect to the IVC between the renal veins and the common iliac veins. The supracardinal segment of the IVC connects to the subcardinal segment of the IVC, which receives the drainage of the gonadal veins and renal veins before connecting to the vitelline venous channel into the heart.

In both the supracardinal and subcardinal venous systems the initial vascular structures are bilaterally symmetric, with the left-sided channels regressing and the right-sided channels persisting, resulting in the typical right sided location of the IVC. The mechanisms through which the definitive systemic venous structures are formed are very poorly understood. The frequency of venous drainage abnormalities in human and animal models of altered left-right axis differentiation [73] makes it clear that the mechanisms of venous morphogenesis are likely dependent on appropriate left-right signaling. This is a particularly important series of developmental relationship that persists in those cases of interrupted IVC with azygous continuation in which the hepatic veins drain directly into the right atrium.

CHAPTER 2

Nomenclature and Classification of Pediatric and Congenital Heart Disease

Jeffrey P. Jacobs
All Children's Hospital, Saint Petersburg, FL, USA

Background

Over the past five decades, tremendous progress had been made in the diagnosis and treatment of patients with pediatric and congenital cardiac malformations. Survival is now expected for many patients with lesions previously considered untreatable. In parallel with these advances, the science of nomenclature and classification of pediatric and congenital heart disease has also rapidly evolved. Part of this evolution of the science of Nomenclature and Classification is closely related to the rapid advancement in the science of analytical outcomes of the treatments of patients with pediatric and congenital cardiac malformations [1–124].

In the current era, research into nomenclature and classification is closely linked to research about databases that track outcomes. The nomenclature and classification is indeed the fundamental building block of any database designed to track outcomes. In order to perform meaningful multi-institutional analyses, it has been documented that any database must incorporate the following six essential elements:

1. use of a common language and nomenclature [3–36, 40,42–49,51,53,56,57,62–64,66,67,69,72,73,78-80,82–84, 96–108];
2. use of a database with an established uniform core data set for collection of information [1-36,38,40-43,49,53,55–57, 62,63,65,69,70,73,74,76,78–81,85–91,96–108,110,111,113, 116–124];
3. incorporation of a mechanism of evaluating case complexity [37,39,50,52–54,56–59,63,68,69,71,73,75,78–80,92,93, 109,112,115];
4. availability of a mechanism to assure and verify the completeness and accuracy of the data collected [60,61,63,69,73, 78–80,94];
5. collaboration between medical and surgical subspecialties [69,73,78–80];
6. standardization of protocols for life-long follow-up [73,77–80,95,114].

The aforementioned six elements are all based on utilization and implementation of a standardized international and universal system of nomenclature and classification. This system has been created and is named the International Pediatric and Congenital Cardiac Code (IPCCC) [82]. The IPCCC will be described in this chapter.

Although nomenclature and databases are separate topics, they are very closely related. Furthermore, many of the recent advances in the science of nomenclature and classification have been stimulated by the recent rapid advances in computer science and database development [42,62]. Although the concepts of nomenclature and database are closely and practically linked, the remainder of this chapter will focus specifically on the nomenclature and classification of pediatric and congenital heart disease.

Nomenclature is defined as the system of names used in a branch of learning or activity [125]. Classification is defined as an arrangement, according to some systematic division, into classes or groups based on some factor common to each [125]. Aristotle was the first known biologist to attempt to classify living things. In 1735, Linnaeus first published *Systema Naturae*, a work that eventually led to our currently used binomial nomenclature system for the classification of living species. With the Linnaean method, well over 1 million species are systematically divided in a hierarchical manner into kingdom, phylum, class, order, family, genus, and species [126].

To describe the heart, this chapter proposes the use of a ternary system composed of three elements:

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.
© 2013 Blackwell Publishing Ltd. Published 2013 by Blackwell Publishing Ltd.

1. the segmental anatomy of the heart;
2. the classification of the cardiac lesion;
3. the description of the cardiac lesion.

First, the segmental anatomy is described by the relations of the cardiac chambers to one another and the mechanism by which these chambers are connected. Second, the given cardiac lesion is classified according to major lesion type. Third, the cardiac lesion is described, fully or in part, according to the hierarchical nomenclature system developed by the IPCCC.

Segmental Anatomy

In order to properly describe any heart, it is essential to provide a description of both the relations of structures within the heart, and the manner in which they are joined together or connected. The first feature accounts for the broad interspatial relations between the various structures. This feature, nonetheless, is not always concordant with the fashion in which two cardiac structures are joined to each other, or in some instances, not joined together [127]. It is the structure of the cardiac components, and their relations, that form the basis of the segmental approach of Van Praagh and Vlad [128–130]. The sequential segmental approach of Anderson added junctional morphology to these considerations [127,131–133]. Others have now sought to combine the approaches, and advocate complete description of both relations and connections [67,72,134].

The Meaning of Left and Right

When discussing the morphology of the atria and the ventricles, and their connections and spatial relationships, the words "left" and "right" can be confusing [44,48,72]. In this chapter, we adhere to the following previously published rules that can be used to provide consistency and accuracy when describing anatomical phenotypes regarding the words "left" and "right." These rules are required, to provide consistency and accuracy when describing anatomical phenotypes [44,48,72].

For cardiac chambers, irrespective of the system of nomenclature utilized, unless otherwise stated, "left" refers to morphologically left, and "right" refers to morphologically right. In other words, "left" refers to those chambers that, in the normal individual, are positioned on the left side of the body, and "right" to those that, in the normal person, are right-sided. Thus, left ventricle means the morphologically left ventricle, left atrium refers to the morphologically left atrium, and right atrial appendage refers to the morphologically right atrial appendage, and so on. When discussing cardiac chambers, the words "left" and "right" do not imply sidedness or position. If one wishes to describe the position or sidedness of a cardiac chamber, it is necessary to use terms such as left-sided ventricle. The term left ventricle, therefore, merely means the morphologically left ventricle, and does not mean or imply left-sidedness or right-sidedness. Similarly, it does not imply connections to the right or left atrium, or the pulmonary or systemic circulations.

In contrast, when describing structures that are not cardiac chambers, such as the superior vena cava, and using the prefix "left" or "right," it is now the spatial position that is being described, rather than any other connection or phenotypic variation that may exist.

Cardiac Relations and Cardiac Connections (or Cardiac Alignments)

A description of both cardiac relations and cardiac connections is integral to a depiction of the segmental anatomy of the heart. Cardiac relations describe the broad interspatial relations between the various cardiac structures. Cardiac connections describe the specific mechanism by which two cardiac structures connect to each other regardless of their interspatial relations [127]. Cardiac relations and cardiac connections can be characterized according to the segmental approach of Van Praagh and Vlad [128–130], the sequential segmental approach advocated by Anderson and colleagues [127,131–133], or both [67,72,134].

The essence of the original segmental approach of Van Praagh was analysis of the topological arrangement, or cardiac relations, of the atrial chambers, the ventricular mass, and the arterial trunks [72,135]. When Anderson and colleagues [136] sought to further develop this innovative methodology, they also emphasized the importance of describing the manner in which the basic segments were united, or joined together, across their junctions; in other words, the cardiac connections or alignments [72]. Very rarely the segmental topological arrangements do not correspond with the way the chambers and arterial trunks are united across their junctions [137]. It is essential, therefore, that any system of nomenclature distinguishes between segmental topologies and junctional variations [67,72,137]. This goal is important for all hearts, and especially those found in patients with heterotaxy. It may be accomplished either via the European approach of Anderson and colleagues, or the Bostonian approach developed by Van Praagh and his colleagues, as long as care is taken to specify both these features [26,67,72].

The Segmental Approach of Van Praagh

The segmental approach developed by Van Praagh and colleagues [128–130], documents the anatomy of the cardiac components, and the relations of the three major cardiac segments, namely, the atrial chambers, the ventricles, and the arterial trunks, in a venoarterial sequence. Letters are coded in braces, also known as curly brackets "{}" to describe the segments as follows:

1. the atrial "situs" (the sidedness of the atrial chambers);
2. the ventricular "loop" (the ventricular topology);
3. the relationship of the arterial trunks in space.

In this system, the atrial situs is coded with a single letter code:

- "S" for "situs solitus," otherwise known as normal arrangement;
- "I" for "situs inversus," or the mirror-imaged arrangement;
- "A" for "situs ambiguus";
- "X" for unknown.

"Situs ambiguus is defined as an abnormality in which there are components of situs solitus and situs inversus in the same person. Situs ambiguus, therefore, can be considered to be present when the thoracic and abdominal organs are positioned in such a way with respect to each other as to be not clearly lateralized and thus have neither the usual, or normal, nor the mirror-imaged arrangements [72]."

"Heterotaxy is synonymous with 'visceral heterotaxy' and 'heterotaxy syndrome.' Heterotaxy is defined as an abnormality where the internal thoraco-abdominal organs demonstrate abnormal arrangement across the left–right axis of the body. By convention, heterotaxy does not include patients with either the expected usual or normal arrangement of the internal organs along the left–right axis, also known as 'situs solitus,' nor patients with complete mirror-imaged arrangement of the internal organs along the left–right axis also known as 'situs inversus' [72]."

The ventricular loop is also coded with a single letter code dependent on the topology and chirality, or handedness, of the ventricular mass:

- "D" for D-loop;
- "L" for L-loop;
- "X" for those instances where the looping cannot be determined.

The relationship of the arterial trunks is also coded with a single letter code:

- "S" for normally related great arteries;
- "I" for inverted, or mirror-imaged normally related great arteries;
- "D" for D-transposed or D-malposed great arteries, with the aorta to the right of the pulmonary trunk;
- "L" for L-transposed or L-malposed great arteries, with the aorta to the left of the pulmonary trunk;
- "A" for the aorta directly anterior to the pulmonary trunk.

In this system, a normal heart is coded {S,D,S}. This coding system employing three letters does not specify the way the cardiac chambers within the segments are joined together, a feature that many describe as the type of "atrioventricular and ventriculoarterial connections." This feature, known in the school using the approach of Van Praagh as "atrioventricular and ventriculo-arterial alignments" [67], is separately specified.

The Sequential Segmental Approach of Anderson

The sequential segmental approach developed by Anderson and colleagues [127,131–133], documents the anatomy of the cardiac components, as well as the connections (or junctions) between them.

The atrial chambers, on the basis of the morphology of their appendages, are classified as one of four types. "Isomerism" describes the situation in which morphologically right structures, or morphologically left structures, are found on both sides of the body in the same individual:

- usual or normally arranged;
- mirror-imaged;
- isomerism of the morphologically left atrial appendages;
- isomerism of the morphologically right atrial appendages.

The arrangements at the atrioventricular junctions are classified by both types of atrioventricular connections and modes of atrioventricular connections. Types of atrioventricular connections describe how the atrial and ventricular chambers are joined together:

- concordant;
- discordant;
- biventricular and mixed;
- double-inlet left ventricle;
- double-inlet right ventricle;
- absent right atrioventricular connection;
- absent left atrioventricular connection.

Modes of atrioventricular connections describe the structure of the valve, or valves, guarding the junctions:

- two perforate valves;
- one single perforate valve with an absent atrioventricular connection;
- one perforate along with one imperforate valve;
- a common atrioventricular valve;
- an absent valve with an unguarded orifice.

An imperforate valve is a structure formed by union of valvar leaflets so as to block completely the existing junction between adjacent structures, either an atrium and a ventricle, or a ventricle and an arterial trunk. Such an imperforate valve is different from a muscular wall of a chamber, because perforating the valve recreates the initial channel present between the adjacent structures. Either an atrioventricular valve or an arterial valve can be imperforate. In addition, either or both atrioventricular valves may override or straddle the ventricular septum.

The arrangements at the ventriculoarterial junctions are also classified by both types of ventriculoarterial connections and modes of ventriculoarterial connections. Types of ventriculoarterial connections describe how the ventricular chambers and great arteries are joined together:

- concordant;
- discordant (transposition);
- double-outlet right ventricle;
- double-outlet left ventricle;
- single outlet–common arterial trunk;
- single outlet–solitary aortic trunk with pulmonary atresia;

• single outlet–solitary pulmonary trunk with aortic atresia;
• single outlet–solitary arterial trunk.

Modes of ventriculoarterial connections describe the structure of the valve, or valves, guarding the junctions:

• two perforate valves;
• one single perforate valve with an absent ventriculoarterial connection;
• one perforate along with one imperforate valve;
• a common ventriculoarterial valve (truncal valve);
• an absent valve with an unguarded orifice.

An imperforate valve is a structure formed by union of valvar leaflets so as to block completely the existing junction between adjacent structures, either an atrium and a ventricle, or a ventricle and an arterial trunk. Such an imperforate valve is different from a muscular wall of a chamber, because perforating the valve recreates the initial channel present between the adjacent structures. Either an atrioventricular valve or an arterial valve can be imperforate. In addition, either or both ventriculoarterial valves may override the ventricular septum.

Although Anderson did not include the side of the aortic arch in his analysis, many physicians have used an "L" (left aortic arch) or "R" (right aortic arch) descriptor to incorporate the aortic arch side in the sequential segmental approach. Although use of abbreviations is not part of the traditional Andersonian approach, a normal heart could be described as [SCCL] (situs solitus, concordant atrioventricular connection, concordant ventricular arterial connection, left aortic arch). Specification of the arrangement of the atrial appendages, the atrioventricular connections, and the ventriculoarterial connections, does not specify nor imply the ventricular topology, or the relationships of the cardiac chambers or great arteries in space. These variables are separately specified.

Atrial Situs

The development of morphologically right-sided structures on one side of the body, and morphologically left-sided structures on the other side, is termed lateralization. Normal lateralization, the usual arrangement, is also known as "situs solitus." The mirror-imaged arrangement is also known as "situs inversus." The term "visceroatrial situs" is often used to refer to the situs of the viscera and atria when their situs is in agreement. The arrangement of the organs themselves, and the arrangement of the atrial chambers, is not always the same [127,129]. When the sidedness of the atrial chambers and the sidedness of the remaining organs are not harmonious, the sidedness of the organs and atrial chambers must be separately specified.

When considering the arrangement of the organs, the school of nomenclature that developed using the teachings of Van Praagh recognizes three patterns: situs solitus is the usual arrangement, situs inversus is the mirror-imaged variant of solitus, and the third pattern is situs ambiguus, which is defined as any situation where a combination of situs solitus and situs inversus occurs in the same individual.

In the normal atrial arrangement, or "atrial situs solitus," the morphologically right atrium is on the right, and the morphologically left atrium is on the left. In the mirror-imaged atrial arrangement, or "atrial situs inversus," the morphologically left atrium is on the right, and the morphologically right atrium is on the left. In terms of overall morphology, it is usually easy to differentiate the morphologically right atrium from the morphologically left atrium. This distinction can generally be made on the basis of the anatomy of the atrial appendages, the morphology of the atrial septum, and the drainage of the supradiaphragmatic portion of the inferior vena cava.

Typically, the morphologically right atrial appendage is broad and blunt, whereas the morphologically left atrial appendage is narrow, pointed, and fingerlike. Uemura and colleagues [138] showed that the extent of the pectinate muscles relative to the vestibules of the right- and left-sided atrioventricular junctions distinguished between the morphologically right and left atrial appendages. In the normal morphologically right atrium, which of course is right-sided, the pectinate muscles extend all round the vestibule, and reach to the cardiac crux. In the normal left-sided morphologically left atrium, these pectinate muscles are confined within the tube-like left atrial appendage, and the smooth vestibule is confluent with the smooth-walled body of the left atrium. In patients with mirror-imaged arrangement, or "situs inversus," this morphological pattern is itself mirror-imaged.

The morphologically right side of the atrial septum contains the rim of the oval fossa, or "limbus of the fossa ovalis," whereas the morphologically left side of the interatrial septum is made up of the flap valve of the oval fossa. When the organs themselves are lateralized, the supradiaphragmatic termination of the inferior caval vein provides an extremely reliable landmark for the morphologically right atrium [127]. During echocardiographic examinations, the arrangement of the atrial chambers, also known as "atrial situs," is often inferred by documenting the location of the inferior vena cava within the abdomen, specifically by determining its relationship to the descending thoracic aorta in subcostal short and long axis views. In the normal atrial arrangement, or atrial "situs solitus," the aorta and inferior vena cava typically lie apart, on opposite sides of the spine, with the aorta on the left. This arrangement is mirror-imaged in atrial "situs inversus," with the aorta on the right and the inferior vena cava on the left. The rules as stated above, however, are reliable only in the setting of usual or mirror-imaged arrangements. In the

setting of heterotaxy, these relationships do not pertain [139]. When there is isomerism of the right atrial appendages, or "asplenia syndrome," the aorta and inferior vena cava are almost always on the same side of the spine, with the vein slightly anterior. In the setting of isomerism of the left atrial appendages, or "polysplenia syndrome," the inferior vena cava usually does not connect directly with the right atrium, its suprarenal course often being interrupted, with the blood returning to the heart through the azygos or hemiazygos veins, such that the aorta is midline and the azygos vein is located in a posterolateral position [139].

"Isomerism" describes the situation in which morphologically right structures, or morphologically left structures, are found on both sides of the body in the same individual. In chemistry, two compounds can have the same chemical structure, but be mirror images of each other. These compounds are called enantiomers, or isomers, giving the arrangements of enantiomerism, or stereoisomerism. Such isomerism has long been known to exist in the lungs of patients with heterotaxy. Evidence of such isomerism also has been noted in the heart. Van Mierop and colleagues [140,141] described the existence of right isomerism in the setting of asplenia syndrome, while Moller and colleagues [142] pointed to the presence of bilateral left-sidedness in the setting of polysplenia syndrome.

The presence of isomerism of the appendages within the atrial chambers, therefore, can be determined by the examination of the extent of the pectinate muscles relative to the atrioventricular junctions. The atrial chambers as a whole, however, are not isomeric. It is erroneous to describe "atrial isomerism," although this incorrect term is used widely and loosely. It is only the appendages that are isomeric in the setting of heterotaxy.

Some cardiac morphologists, however, do not accept the concept of isomerism of the atrial appendages. They prefer to use the term atrial situs ambiguus to describe this subset of patients. Furthermore, in the living patient, it may be difficult to document the extent of the pectinate muscles relative to the atrioventricular junctions. Because of this difficulty, it should be noted that, in heterotaxy, bronchopulmonary anatomy usually is consistent with the structure of the appendages, and can aid in the documentation of heterotaxy. Most patients with heterotaxy, also have splenic abnormalities and the anatomy and structure of the spleen are often used to stratify patients with heterotaxy. Splenic anatomy, however, shows less correlation with the arrangement of the atrial appendages when compared with bronchopulmonary anatomy.

The morphology of the lungs, and the relation between the bronchial tree and the pulmonary arteries, therefore, are useful in determining "situs." The arrangement of the atrial appendages is highly consistent with bronchopulmonary morphology [127,143]. In the majority of patients with heterotaxy, when attention is paid to the lungs and bronchial tree, the left-sided structures are seen to be the mirror-images of their right-sided counterparts. A morphologically right lung typically has three lobes, and a morphologically left lung typically has two lobes. Furthermore, the right side tends to have an eparterial bronchus, whereas the bronchus on the left side is typically hyparterial. An eparterial bronchus is one that branches superior to the first lobar division of the pulmonary artery, in contrast to a hyparterial bronchus that branches inferior to the first lobar division of the respective pulmonary artery. Tracheobronchial anatomy can be assessed from examination of the chest radiograph [127,144,145]. Isomerism is consistent with a ratio of less than 1 to 1.6 between the lengths of the two main bronchi, whereas lateralization has a ratio of more than 1 to 1.6. Examination of chest radiographs, therefore, may provide one of the simplest techniques for differentiating isomerism from lateralization in a living patient, albeit that this can now be shown with even greater detail using tomographic techniques. Bronchial tomography has been used to measure bronchial length, and comparison of measured bronchial length with the age of the patient has been used to determine the presence of right versus left bronchial isomerism [127,143,146]. Nevertheless, although the correlation between bronchial morphology and the structure of the atrial appendages is highly consistent, it is not absolute. In patients with heterotaxy, the anatomy of the atrial appendages does not always correspond with the bronchial arrangement [147–149].

Splenic anatomy is often used to stratify patients with heterotaxy [142,150]. In most instances, right isomerism is associated with absence of the spleen, and left isomerism is associated with multiple spleens. This association between splenic anatomy and the arrangement of the atrial appendages, however, is weaker than the correlation between the arrangement of the atrial appendages and bronchial morphology. Moreover, absence of the spleen, or presence of multiple spleens, is not always easily documented. Multiple spleens are not always easy to differentiate from one spleen with spleniculi [142,150,151]. A rudimentary spleen cannot easily be differentiated from one that is absent [152]. Splenic anatomy can be difficult to determine both clinically and at autopsy [127].

Although not all patients with multiple spleens have isomerism of the left atrial appendages, and not all patients with absence of the spleen have isomerism of the right atrial appendages, it has become customary for many pediatric cardiologists to stratify heterotaxy into the subsets of "asplenia syndrome" and "polysplenia syndrome" [142,150]. Because a syndrome includes a constellation of findings, each of which may not be present in all instances, and because the splenic arrangement does not always fit

with the expected patterns of the remaining thoracoabdominal organs, investigators may at times be comfortable with describing the presence of the spleen in patients known to have "asplenia syndrome" [142].

Ventricular Loop

The morphologically right ventricle typically possesses coarse trabeculations in its apical component, while the morphologically left ventricle typically exhibits fine apical trabeculations. Ventricular topology, or "looping of the heart," describes the chirality, or handedness, of the ventricular mass. With right hand ventricular topology, or "D-loop," the right ventricle wraps around the left ventricle such that the palmar surface of the right hand can be placed on the septal surface of the right ventricle with the thumb in the inlet and the fingers in the outlet. With left hand ventricular topology, or "L-loop," it is the palmar surface of the left hand that fits on the right ventricular septum in this fashion.

The concept of looping refers to the formation of the ventricular loop in the embryo. The loop normally rotates to form a D-loop. In order to describe the fashion in which the atrial chambers are joined to the ventricular mass, this being the feature known variously as the atrioventricular connections or alignments, it is essential in any given patient; first, to note the atrial arrangement, and second, to describe the specific ventricular topology.

Atrioventricular Connection

The term "atrioventricular connections," or "atrioventricular alignments," refers to the mechanism of union between the atrial and the ventricular myocardium. As already discussed, in any patient, in order to describe the fashion in which the atrial chambers are joined to the ventricular mass, it is essential to first, note the atrial arrangement, and second, to describe the specific ventricular topology.

The arrangements at the atrioventricular junctions are classified by both types of atrioventricular connections and modes of atrioventricular connections. Types of atrioventricular connections describe how the atrial and ventricular chambers are joined together. Modes of atrioventricular connections describe the structure of the valve, or valves, guarding the junctions. The atrial chambers can be joined to the ventricles in biventricular or univentricular fashion. Biventricular atrioventricular connections can be of the following types:

- concordant;
- discordant;
- biventricular and mixed.

Univentricular atrioventricular connections can be of the following types:

- double-inlet left ventricle;
- double-inlet right ventricle;
- absent right atrioventricular connection;
- absent left atrioventricular connection.

The right atrium is connected to the right ventricle, and the left atrium to the left ventricle in *concordant atrioventricular connections*. In *discordant atrioventricular connections*, the right atrium is connected to the left ventricle, and the left atrium to the right ventricle.

When both atria connect to one ventricle, the term double-inlet atrioventricular connection is used. Absent right atrioventricular connection and absent left atrioventricular connection refer to absence of one atrioventricular connection.

In cases of heterotaxy (isomerism of the atrial appendages or situs ambiguus) in the setting of univentricular atrioventricular connections, the description of the atrioventricular connection is exactly the same as for patients without heterotaxy (those patients with usual or mirror-imaged arrangement of the atrial appendages). In cases of heterotaxy (isomerism of the atrial appendages or situs ambiguus) in the setting of biventricular atrioventricular connections, the atrioventricular connection was previously described as *ambiguous*. This terminology was utilized because a biventricular atrioventricular connection is by definition ambiguous in cases of isomerism or situs ambiguus. In the setting of heterotaxy, when the atrial chambers are joined to the ventricles in biventricular fashion, this anatomical phenotype is unique. When the appendages are isomeric, and the atria are joined to the ventricles in biventricular fashion, then irrespective of whether the isomeric appendages are morphologically left or right, and irrespective of the ventricular topology, half of the heart will be joined in concordant fashion, and the other half joined together in discordant fashion. In the setting of heterotaxy, therefore, biventricular atrioventricular connections or alignments are, of necessity, mixed. In the past, biventricular atrioventricular connections in the setting of heterotaxy were described as ambiguous; in the current era, biventricular atrioventricular connections in the setting of heterotaxy are described as *biventricular and mixed*.

Analysis of the way the atrial myocardium is joined to the ventricular mass gives only half of the necessary information concerning the morphology of the atrioventricular junctions. It is also necessary to take account of the structure of the valve or valves guarding the junctions; in other words, the mode of the atrioventricular connection or alignment.

Ventriculoarterial Connection

The arrangements at the ventriculoarterial junctions are classified by both types of ventriculoarterial connections and ventriculoarterial modes of connections. Types of ven-

triculoarterial connections describe the ventricular chambers and the manner in which the great arteries are joined together. Modes of ventriculoarterial connections describe the structure of the valve, or valves, guarding the junctions.

In concordant ventriculoarterial connections, the right ventricle is connected to the pulmonary artery and the left ventricle to the aorta. In discordant ventriculoarterial connections, the right ventricle is connected to the aorta and the left ventricle to the pulmonary artery. Both great vessels arise entirely or predominately from one ventricle in double-outlet ventriculoarterial connection [27,28]. In single-outlet connection, only one great artery is connected to the heart.

Modes of ventriculoarterial connection include two perforate valves, a single perforate valve, one perforate and one imperforate valve, and a common (truncal) valve. The distinction between a single perforate valve, one perforate valve, and one imperforate valve is best understood by considering the example of pulmonary atresia with ventricular septal defect (PA-VSD). If the right ventricle is in continuity with the pulmonary artery but the pulmonary valve is imperforate, the ventriculoarterial connection type is concordant, and the mode is one perforate and one imperforate valve. If there is no pulmonary trunk (or only a fibrous remnant of the pulmonary trunk), the ventriculoarterial connection type is single-outlet–solitary aortic trunk with pulmonary atresia, and the mode is single perforate valve [127].

The Position of the Heart and the Orientation of Its Apex

The position of the heart in the chest, and the orientation of the cardiac apex, must also be described separately, because these features can vary independently from each other, and have no definitive relationship to other cardiac relations and connections. The ventricular mass may be right-sided, left-sided, or midline. The cardiac apex may also be right-sided, left-sided, or midline. These features take on added importance when planning the route or pathway of an extracardiac Fontan connection. The terms "dextrocardia," "levocardia," "mesocardia," "dextroversion," and "levoversion" have been used over the years in various fashions by various authors [153].

"Dextrocardia" is usually considered synonymous with a right-sided ventricular mass, while "dextroversion" is frequently defined as a configuration where the ventricular apex points to the right. In a patient with the usual atrial arrangement, or situs solitus, dextroversion, therefore, implies a turning to the right of the heart. In the same context, "levocardia" has most often been used synonymously with a left-sided ventricular mass, and "levoversion" is frequently defined as a configuration where the ventricular apex points to the left. "Mesocardia" is the term used to account for the ventricular mass occupying the midline. One must be cautious, however, about the use of such terms, because others have used variations of this terminology, suggesting terms such as "dextrorotation," "mixed dextrocardia," or "pivotal dextrocardia" in attempts to compress all the information into a single term. These variations are not universally understood, and should be avoided. The proper description of a heart, irrespective of the system used, should include a description of the position of the heart in the chest and the orientation of the cardiac apex. These features can vary significantly in heterotaxy, and they are not always in harmony. For example, one might encounter a patient where the cardiac mass may be located predominantly in the right chest, but with its apex pointing to the left, in other words, "dextrocardia with levoversion." The separate description of the location of the cardiac mass and the direction of the cardiac apex is not merely an academic exercise, as these features can profoundly impact planned surgical interventions.

Classification of Cardiac Lesions

The description of the segmental anatomy of the heart includes a complete description of the following variables:

1. situs;
2. ventricular topology (ventricular loop);
3. atrioventricular connections (type and mode);
4. ventriculoarterial connections (type and mode);
5. the relationships of the arterial trunks in space;
6. the position of the heart and the orientation of its apex.

After the description of the segmental anatomy of the heart, the cardiac lesions must be classified and ultimately described. Cardiac lesions historically have been classified by incidence [154–157] (Table 2.1) [134] and by differentiation of cyanotic and acyanotic lesions (Table 2.2) [134]. Table 2.2 provides information useful in conceptualizing a classification system for congenital heart lesions [134]. Only seven major lesion groups compose approximately 80% of congenital heart disease, a fact to be considered in developing a congenital heart disease nomenclature and classification system. The incidence of any given lesion, however, varies from center to center depending on a variety of factors, including institutional expertise and institutional acuity level. The classification of lesions into cyanotic and acyanotic groupings can be further refined by subdivision of the major groups into subsets based on underlying pathophysiological mechanisms (Table 2.3) [134]. In the cyanotic group, right-to-left shunting with decreased pulmonary blood flow and intracardiac mixing of oxygenated and desaturated blood are two causative mechanisms of cyanosis. The two most common pathophysiological entities in acyanotic congenital heart

Table 2.1 Common lesions in congenital heart disease and approximate incidence.

Ventricular septal defect (20%)
Atrial septal defect (10%)
Patent ductus arteriosus (10%)
Coarctation of the aorta (10%)
Congenital aortic stenosis (10%)
Tetralogy of Fallot (10%)
Pulmonary stenosis (10%)
Transposition of the great arteries (5–8%)
Pulmonary atresia (5%):
with intact ventricular septum
with ventricular septal defect
Atrioventricular septal defect (2–5%)
Tricuspid atresia (3%)
Truncus arteriosus (3%)
Total anomalous pulmonary venous connection (2%)
Hypoplastic left heart syndrome (2%)
Interrupted aortic arch (1%)
Ebstein anomaly (0.5%)
Mitral stenosis (rare)
Aortopulmonary window (rare)

Table 2.2 Acyanotic versus cyanotic lesions in congenital heart disease and approximate incidence.

Aortopulmonary window (rare)
Left-sided obstructive lesions
Coarctation of the aorta (10%)
Congenital aortic stenosis (10%)
Interrupted aortic arch (1%)
Mitral stenosis (rare)
Cyanotic
Right-to-left shunts
Tetralogy of Fallot (10%)
Pulmonary stenosis (10%)
Pulmonary atresia (5%):
with intact ventricular septum
with ventricular septal defect
Tricuspid atresia (3%)
Ebstein anomaly (0.5%)
Complex mixing defects
Transposition of the great arteries (5–8%)
Total anomalous pulmonary venous connection (2%)
Truncus arteriosus (3%)
Hypoplastic left heart syndrome (2%)

disease are left-to-right shunting and left-sided obstructive lesions.

Although traditionally popular, the classification systems shown in Tables 2.2 and 2.3 are problematic [134]. In many lesions, the direction of shunting changes gradually, often with changes in pulmonary vascular resistance. Furthermore, cyanosis can evolve gradually; several lesions that initially are acyanotic can become cyanotic. For example, ventricular septal defect is initially associated with acyanosis with left-to-right shunting; however, as pulmonary vascular resistance gradually increases, the direction of shunting can change to right-to-left, and the patient can become cyanotic. Furthermore, the common physiological characterization of tetralogy of Fallot (TOF) as either cyanotic ("blue") or acyanotic ("pink") is of limited usefulness because it describes the condition of a patient at a point in time, rather than the cardiac malformation itself. In most infants with tetralogy and adequate or generous antegrade pulmonary blood flow, with the acquisition of right ventricular hypertrophy, progressive or periodic cyanosis eventually develops [13].

Because of the aforementioned limitations, alternative classification systems must be considered. The lesions of congenital heart disease can be classified with a segmental system that starts with the great veins and proceeds to the great arteries. This segmental system can accommodate the incidence of various lesions and can meet the needs of surgeons, cardiologists, and pathologists. All lesions of congenital heart disease are distributed into one of the six segments listed in Table 2.4 [134] (and further subdivided in Table 2.5) [134]. Almost any given cardiac lesion in congenital heart disease can be placed into one of these subdivisions, as shown in Table 2.6 [134], which classifies the most common congenital cardiac lesions. Certain lesions involve more than one subdivision or even segment; the system functions by placing the lesion in the subdivision most involved.

Table 2.4 Segmental system of classification of lesions of congenital heart disease: level 1.

I. Great veins
II. Atria
III. Atrioventricular junction
IV. Ventricles
V. Ventriculoarterial junction
VI. Great arteries

Table 2.5 Segmental system of classification of lesions of congenital heart disease: level 2.

I. Great veins
Systemic veins
Pulmonary veins
II. Atria
Right atrium
Atrial septum
Left atrium
III. Atrioventricular junction
Right atrioventricular valve
Common atrioventricular valve
Left atrioventricular valve
IV. Ventricles
Right ventricle
Ventricular septum
Left ventricle
Single ventricle
V. Ventriculoarterial junction
Right ventriculoarterial valve
Common ventriculoarterial valve
Left ventriculoarterial valve
Both ventriculoarterial valves
VI. Great arteries
Pulmonary artery
Aorta
Both great arteries
Coronary arteries

Description of Cardiac Lesions

After being classified into a major group of lesions, a cardiac lesion may be further described according to the hierarchical nomenclature system developed and maintained by The International Society for Nomenclature of Paediatric and Congenital Heart Disease (ISNPCHD) [80,82]. This system is named the International Paediatric and Congenital Cardiac Code (IPCCC) [80,82] and was developed to fill the need for a standardized nomenclature to be used in databases worldwide, allowing for shared meaningful data. Its form is driven by the need to be inclusive of extant classification systems, rather than exclusive. Furthermore, the system is hierarchical in nature, so that it allows user centers to choose a level of detail applicable to the center's needs but allows data sharing with other centers that choose to code with a higher or lower level of detail.

During the 1990s, both The European Association for Cardio-Thoracic Surgery (EACTS) and The Society of Thoracic Surgeons (STS) created databases to assess the outcomes of congenital cardiac surgery. Beginning in 1998, these two organizations collaborated to create the International Congenital Heart Surgery Nomenclature and Database Project [3–36]. By 2000, a common nomenclature, along with a common core minimal data set, were adopted by The European Association for Cardio-Thoracic Surgery and The Society of Thoracic Surgeons, and published in the Annals of Thoracic Surgery [3–36]. In 2000, The International Nomenclature Committee for Pediatric and Congenital Heart Disease was established. This committee eventually evolved into the International Society for Nomenclature of Paediatric and Congenital Heart Disease. The working component of this international nomenclature society has been The International Working Group for Mapping and Coding of Nomenclatures for Paediatric and Congenital Heart Disease, also known as the Nomenclature Working Group. By 2005, the Nomenclature Working Group cross-mapped the nomenclature of the International Congenital Heart Surgery Nomenclature and Database Project of The European Association for Cardio-Thoracic Surgery and The Society of Thoracic Surgeons with the European Paediatric Cardiac Code of the Association for European Paediatric Cardiology, and therefore created the International Paediatric and Congenital Cardiac Code, which is available for free download from the internet at http://www.IPCCC.net [80,82].

The initial hierarchical nomenclature levels of the IPCCC for the more common lesions shown in Table 2.6 [134] are displayed in Table 2.7 [134]. Most lesions have several

Table 2.6 Segmental system of classification of lesions of congenital heart disease: level 3.

I. Great veins
Systemic veins
  Systemic venous anomaly, superior vena cava
  Systemic venous anomaly, inferior vena cava
Pulmonary veins
  Total anomalous pulmonary venous connection
  Partial anomalous pulmonary venous connection
  Cor triatriatum
  Pulmonary venous stenosis

II. Atria
Right atrium
Atrial septum
  Atrial septal defect
Left atrium

III. Atrioventricular junction
Right atrioventricular valve
  Tricuspid stenosis
  Tricuspid regurgitation
  Ebstein anomaly of the tricuspid valve
Common atrioventricular valve
  Atrioventricular canal defect (atrioventricular septal defect)
Left atrioventricular valve
  Mitral stenosis
  Mitral regurgitation

IV. Ventricles
Right ventricle
  Tetralogy of Fallot
  Double-chamber right ventricle
Ventricular septum
  Ventricular septal defect
Left ventricle
  Single ventricle
  Single ventricle, double-inlet left ventricle
  Single ventricle, double-inlet right ventricle
  Single ventricle, mitral atresia
  Single ventricle, tricuspid atresia
  Single ventricle, unbalanced atrioventricular canal defect
  Single ventricle, heterotaxia syndrome
  Single ventricle, other
  Hypoplastic left heart syndrome

V. Ventriculoarterial junction
Right ventriculoarterial valve
  Pulmonary stenosis
  Pulmonary insufficiency
  Pulmonary atresia with intact ventricular septum
  Pulmonary atresia with ventricular septal defect
Common ventriculoarterial valve
  Truncus arteriosus
Left ventriculoarterial valve
  Aortic stenosis
  Aortic insufficiency
  Aortic atresia
  Sinus of Valsalva aneurysm
  Aortic-left ventricular tunnel
Both ventriculoarterial valves
  Transposition of the great arteries
  Double-outlet right ventricle
  Double-outlet left ventricle

VI. Great arteries
Pulmonary artery
  Pulmonary arterial stenosis
  Pulmonary artery sling
Aorta
  Aortic coarctation
  Interrupted aortic arch
Both great arteries
  Patent ductus arteriosus
  Aortopulmonary window
  Vascular ring
  Pulmonary arterial origin from ascending aorta (hemitruncus)
Coronary arteries
  Anomalous origin of coronary artery from pulmonary artery

further levels of hierarchical analysis and description; these are published in the April 2000 supplement to the Annals of Thoracic Surgery [3–36] and on the Internet at http://www.IPCCC.net. The myriad of detailed coding choices presented in this system appear daunting in print but are manageable with computer-generated coding, in which only short lists of coding possibilities (two hierarchical levels) are seen at any given time.

Consensus Definitions

In addition to developing and maintaining the IPCCC, the ISNPCHD has published consensus definitions for several complex congenital cardiac malformations, including the functionally univentricular heart [64], hypoplastic left heart syndrome [66], congenitally corrected transposition [67], and heterotaxy [72]. On 9 July 2007, the ISNPCHD created two new committees so that the Society now has the following three committees:

1. The International Working Group for Mapping and Coding of Nomenclatures for Paediatric and Congenital Heart Disease, also known as the Nomenclature Working Group (NWG);

2. The International Working Group for Defining the Nomenclatures for Paediatric and Congenital Heart Disease, also known as the Definitions Working Group (DWG);

Table 2.7 Segmental system of classification and nomenclature of lesions of congenital heart disease: level 4.

I. GREAT VEINS
Systemic veins
  Systemic venous anomaly, SVC
    Abnormal RSVC
    Absent RSVC
    Bilateral SVC
    CS ostial atresia or stenosis (CS draining cephalad through LSVC)
    Levoatrial-cardinal vein
    Other (specify)
    Retroaortic innominate vein
    SVC occlusion
    SVC stenosis
  Systemic venous anomaly, IVC
    Abnormal RIVC
    Biatrial drainage of IVC
    Cor triatriatum dexter
    IVC occlusion
    IVC stenosis
    LIVC
    Other (specify)
    Separate entry of hepatic veins (RIVC to right-sided atrium)
Pulmonary veins
  Total anomalous PV connection
    Type 1 (supracardiac)
    Type 2 (cardiac)
    Type 3 (infracardiac)
    Type 4 (mixed)
  Partial anomalous PV connection
    Nonscimitar
    Scimitar
  Cor triatriatum
    Accessory atrial chamber receives all PV and communicates with LA
    Accessory atrial chamber receives all PV and does not communicate with LA
    Accessory atrial chamber receives part of the PV (subtotal cor triatriatum)
  Pulmonary venous stenosis
    Congenital
      Congenital, diffusely hypoplastic
      Congenital, long segment focal (tubular) stenosis
      Congenital, discrete stenosis
    Acquired
      Acquired, postoperative
      Acquired, not postoperative

II. ATRIA
Right atrium
Atrial septum
  Atrial septal defect
    Common atrium (single atrium)
    Coronary sinus
    PFO
    Primum
    Secundum
    Sinus venosus
Left atrium

III. ATRIOVENTRICULAR JUNCTION
Right AV valve
  Tricuspid stenosis
    Congenital
      Valvar hypoplasia
      Abnormal subvalvar apparatus
      Double-orifice valve
      Parachute deformity
      Other
    Acquired
      Status post cardiac surgery
  Tricuspid regurgitation
    Congenital
      Primary annular dilatation
      Prolapse
      Leaflet underdevelopment
      Absent papillary muscle or chordae
      Other
    Acquired
      Status post cardiac surgery
  Ebstein anomaly of the tricuspid valve
    Ebstein anomaly, type I
    Ebstein anomaly, type II
    Ebstein anomaly, type III
    Ebstein anomaly, type IV
    Ebstein anomaly, "left-sided" Ebstein anomaly
    Ebstein anomaly, atypical Ebstein-like anomalies associated with hypoplastic right heart syndrome
    Ebstein anomaly, other
Common AV valve
  AV canal defect (AVSD)
    AVC (AVSD), partial (incomplete) (PAVSD) (ASD, Primum)
    AVC (AVSD), intermediate (transitional)
    AVC (AVSD), complete (CAVSD)
Left atrioventricular valve
  Mitral stenosis
    Congenital
      Subvalvar
      Valvar
      Supravalvar
      Mixed
      Other
    Acquired
      Status post cardiac surgery
  Mitral regurgitation
    Congenital
      Subvalvar
      Valvar
      Mixed
      Other
    Acquired
      Status post cardiac surgery

(*Continued*)

Table 2.7 (*Continued*)

IV. VENTRICLES

Right ventricle
- Tetralogy of Fallot
  - TOF, pulmonary stenosis
  - TOF, pulmonary atresia
  - TOF, common atrioventricular canal (TOF/CAVSD)
  - TOF, absent pulmonary valve
- Double-chamber right ventricle
  - DCRV, no VSD
  - DCRV, VSD
    - VSD to lower RV chamber
    - VSD to upper RV chamber
    - VSD to lower and upper RV chamber

Ventricular septum
- VSD
  - VSD, multiple
  - VSD, type 1 (subarterial) (supracristal) (conal septal defect) (infundibular)
  - VSD, type 2 (perimembranous) (paramembranous) (conoventricular)
  - VSD, type 3 (inlet) (AV canal type)
  - VSD, type 4 (muscular)
  - VSD, type: Gerbode type (LV-RA communication)

Left ventricle

Single ventricle
- Single ventricle, double-inlet left ventricle
  - DILV {S,L,L}, outlet chamber (bulboventricular foramen)
  - DILV {S,D,D}, outlet chamber (bulboventricular foramen)
  - DILV {S,D,N} (Holmes heart)
  - DILV, DOLV
  - DILV, DORV
- Single ventricle, double-inlet right ventricle
  - DIRV, DORV
  - DIRV, outlet chamber (bulboventricular foramen)
  - DIRV, other
- Single ventricle, mitral atresia
  - Mitral atresia, DORV
  - Mitral atresia, {S,D,N}
  - Mitral atresia, {S,L,L} (corrected transposition)
- Single ventricle, tricuspid atresia
  - Type 1a (no TGA, pulmonary atresia)
  - Type 1b (no TGA, pulmonary hypoplasia, small VSD)
  - Type 1c (no TGA, no pulmonary hypoplasia, large VSD)
  - Type 2a (D-TGA, pulmonary atresia)
  - Type 2b (D-TGA, pulmonary or subpulmonary stenosis)
  - Type 2c (D-TGA, large pulmonary artery)
  - Type 3a (L-TGA, pulmonary or subpulmonary stenosis)
  - Type 3b (L-TGA, subaortic stenosis)
- Single ventricle, Unbalanced AV canal defect
  - Single ventricle, unbalanced AV canal, right dominant
  - Single ventricle, unbalanced AV canal, left dominant
- Single ventricle, heterotaxia syndrome
  - Heterotaxia syndrome, DORV, CAVC (CAVSD), Asplenia
  - Heterotaxia syndrome, DORV, CAVC (CAVSD), Polysplenia
  - Heterotaxia syndrome, single LV
- Heterotaxia syndrome, other
- Single ventricle, other
  - Single ventricle, other, mostly LV
  - Single ventricle, other, mostly RV
  - Single ventricle, other, indeterminate
- Hypoplastic left heart syndrome
  - HLHS, aortic atresia + mitral atresia
  - HLHS, aortic atresia + mitral stenosis
  - HLHS, aortic atresia + VSD (well developed mitral valve and LV)
  - HLHS, aortic stenosis + mitral atresia
  - HLHS, aortic stenosis + mitral stenosis
  - HLHS, aortic stenosis + mitral valve hypoplasia
  - HLHS, hypoplastic AV + MV + LV (HLHC)

V. VENTRICULOARTERIAL JUNCTION

Right ventriculoarterial valve
- Pulmonary stenosis
  - Pulmonary stenosis, subvalvar
  - Pulmonary stenosis, valvar
  - Pulmonary stenosis, supravalvar
- Pulmonary insufficiency
- Pulmonary atresia with intact ventricular septum
  - No coronary fistulas/sinusoids
  - Coronary fistulas/sinusoids: non-RV-dependent coronary circulation
  - Coronary fistulas/sinusoids: RV-dependent coronary circulation
- Pulmonary atresia with VSD
  - Type A (native PAs present, no MAPCA)
  - Type B (native PAs present, MAPCA present)
  - Type C (no native PAs, MAPCA present)

Common ventriculoarterial valve
- Truncus arteriosus
  - With confluent or near confluent PAs (large aorta type) (Van Praagh A1, A2; Colette and Edwards I, II, III)
  - With absence of one PA (large aorta type with absence of one PA) (Van Praagh A3)
  - With interrupted aortic arch or coarctation (large PA type) (Van Praagh A4)

Left ventriculoarterial valve
- Aortic stenosis
  - Aortic stenosis, subvalvar
  - Aortic stenosis, valvar
  - Aortic stenosis, supravalvar
- Aortic insufficiency
  - Congenital
  - Acquired
- Aortic atresia
- Sinus of Valsalva aneurysm
  - Sinus of Valsalva aneurysm, Left sinus
  - Sinus of Valsalva aneurysm, Right sinus
  - Sinus of Valsalva aneurysm, Non-coronary sinus
- Aortic-LV tunnel
  - Type I: simple tunnel
  - Type II: aortic wall aneurysm
  - Type III: intracardiac aneurysm
  - Type IV: aortic wall aneurysm and intracardiac aneurysm

Table 2.7 (*Continued*)

Both ventriculoarterial valves
- Transposition of the great arteries
  - TGA: IVS
  - TGA: IVS, LVOTO
  - TGA: VSD
  - TGA: VSD, LVOTO
- Double-outlet right ventricle
  - DORV, VSD type
    - Subaortic VSD + no PS
    - Doubly committed VSD + no PS
  - DORV, TOF type
    - Subaortic VSD + PS
    - Doubly committed VSD + PS
  - DORV, TGA type
    - Subpulmonary VSD + no PS (Taussig-Bing)
    - Subpulmonary VSD + PS
    - *DORV, remote VSD (uncommitted VSD)*
    - Common atrioventricular canal (CAVSD) + PS
    - Common atrioventricular canal (CAVSD) + no PS
    - No CAVSD + PS
    - No CAVSD + no PS
  - DORV, IVS
- Double-outlet left ventricle
  - DOLV, subaortic VSD
  - DOLV, subpulmonary VSD
  - DOLV, doubly committed VSD
  - DOLV, noncommitted VSD
  - DOLV, IVS
  - DOLV, Ebstein anomaly

VI. GREAT ARTERIES

Pulmonary artery
- PA stenosis
  - PA stenosis (hypoplasia), main (trunk)
  - PA stenosis (hypoplasia), branch
- PA sling
  - With tracheal stenosis
  - With tracheomalacia
  - With tracheal stenosis and tracheomalacia
  - Without tracheal stenosis or tracheomalacia

Aorta
- Aortic coarctation
  - COA, isolated
  - COA, with VSD
  - COA, with complex intracardiac anomaly
- Interrupted aortic arch
  - Type A: interruption distal to the left subclavian artery
  - Type B: interruption between the left carotid and left subclavian arteries
  - Type C: interruption between the innominate and left carotid arteries

Both great arteries
- Patent ductus arteriosus
  - PDA, normal origin and insertion
  - PDA, abnormal origin and insertion
- Aortopulmonary window
  - Type 1 proximal defect
  - Type 2 distal defect
  - Type 3 total defect
  - Intermediate type
- Vascular ring
  - Double aortic arch
  - Right aortic arch – left ligamentum or left PDA
  - Innominate artery compression
  - Vascular ring, other
  - PA origin from ascending aorta (hemitruncus)
    - Left PA
    - Right PA

Coronary arteries
- Anomalous origin of coronary artery from PA
  - Anomalous left coronary from the PA (ALCAPA)
  - Anomalous right coronary from the pulmonary artery (ARCAPA)
  - Anomalous circumflex from the pulmonary artery (ACxPA)
  - Anomalous left and right coronaries from the pulmonary artery (both) ALCAPA and ARCAPA)

ASD, atrial septal defect; AV, atrioventricular; CAVSD, complete atrioventricular septal defect; COA, coarctation of the aorta; CS, coronary sinus; DCRV, double-chamber right ventricle; DILV, double-inlet left ventricle; DIRV, double-inlet right ventricle; DOLV, double-outlet left ventricle; DORV, double-outlet right ventricle; HLHC, hypoplastic left heart complex; HLHS, hypoplastic left heart syndrome; IVC, inferior vena cava; IVS, intact ventricular septum; LA, left atrium; LIVC, left inferior vena caval; LSVC, left superior vena cava; LV, left ventricle; LVOTO, left ventricular outflow tract obstruction; MAPCA, major aortopulmonary collateral arteries; MV, mitral valve; PA, pulmonary artery; PAVSD, partial atrioventricular septal defect; PDA, patent ductus arteriosus; PFO, patent foramen ovale; PS, pulmonary stenosis; PV, pulmonary vein; RA, right atrium; RIVC, right inferior vena cava; RSVC, right superior vena cava; RV, right ventricle; {S,D,D}, {S,D,N}, {S,L,L}, Van Praagh descriptors of segmental anatomy – see text for detailed explanation; SVC, superior vena cava; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

3. The International Working Group for Archiving and Cataloguing the Images and Videos of the Nomenclatures for Paediatric and Congenital Heart Disease, also known as the Archiving Working Group (AWG), and the Congenital Heart Archiving Research Team (CHART).

The NWG will continue to maintain, preserve, and update the IPCCC, as well as provide ready access to it for the international pediatric and congenital cardiology and cardiac surgery communities, related disciplines, the healthcare industry, and governmental agencies, both electronically and in published form. The DWG will write definitions for the terms in the International Paediatric and Congenital Cardiac Code, building on the previously published definitions from the NWG [64,66,67,72]. The AWG will enable the linkage of images and videos to the IPCCC. The images and videos will be acquired from cardiac morphologic specimens and imaging modalities such as echocardiography, angiography, computerized axial tomography, and magnetic resonance imaging, as well as intraoperative images and videos. An image and video archive will be created, based on the IPCCC, and this archive will be linked to CTSNet (http://www.ctsnet.org), and the new Congenital Portal of CTSNet (http://www.ctsnet.org/portals/congenital/index.html).

Examples of some of the consensus definitions of nomenclature developed by the ISNPCHD are provided below. By the time the next edition of this book is published, the DWG will have developed consensus definitions for the majority of terms in the nomenclature of pediatric and congenital cardiac disease.

The term "functionally univentricular heart" describes a spectrum of congenital cardiovascular malformations in which the ventricular mass may not readily lend itself to partitioning that commits one ventricular pump to the systemic circulation, and another to the pulmonary circulation.

A heart may be functionally univentricular because of its anatomy or because of the lack of feasibility or lack of advisability of surgically partitioning the ventricular mass. Common lesions in this category typically include double inlet right ventricle (DIRV), double inlet left ventricle (DILV), tricuspid atresia, mitral atresia, and hypoplastic left heart syndrome. Other lesions which sometimes may be considered to be a functionally univentricular heart include complex forms of atrioventricular septal defect, double outlet right ventricle, congenitally corrected transposition, pulmonary atresia with intact ventricular septum, and other cardiovascular malformations. Specific diagnostic codes should be used whenever possible, and not the term "functionally univentricular heart". See The International Society for Nomenclature of Paediatric and Congenital Heart Disease (ISNPCHD) http://www.ipccc.net/.

The version of the IPCCC derived from the International Congenital Heart Surgery Nomenclature and Database Project of the EACTS and STS uses the term "single ventricle" as synonymous for the functionally univentricular heart [24,64].

The consensus of the EACTS and STS Congenital Heart Surgery Database Committees was that the nomenclature proposal for single ventricle hearts would encompass hearts with double-inlet atrioventricular connection (both DILV and DIRV, hearts with absence of one atrioventricular connection (mitral atresia and tricuspid atresia), hearts with a common atrioventricular valve and only one completely well developed ventricle (unbalanced common atrioventricular canal defect), hearts with only one fully well developed ventricle and heterotaxia syndrome (single ventricle heterotaxia syndrome), and finally other rare forms of univentricular hearts that do not fit in one of the specified major categories [24,64].

In the version of the IPCCC derived from the nomenclature of the International Congenital Heart Surgery Nomenclature and Database Project of the EACTS and the STS, patients classified in this section of the nomenclature, therefore, include all those who would be coded using the Short List for "Single Ventricle," specifically [24,64]:

- Single ventricle;
- Single ventricle, DILV;
- Single ventricle, DIRV;
- Single ventricle, heterotaxia syndrome;
- Single ventricle, mitral atresia;
- Single ventricle, tricuspid atresia;
- Single ventricle, unbalanced AV canal.

Despite the recognition that hypoplastic left heart syndrome is a common form of functionally univentricular heart, with a single or dominant ventricle of right ventricular morphology, the EACTS-STS version of the IPCCC includes an entirely separate section for consideration of hypoplastic left heart syndrome. Also, it is recognized that a considerable variety of other structural cardiac malformations, such as pulmonary atresia with intact ventricular septum, biventricular hearts with straddling atrioventricular valves, and some complex forms of double-outlet right ventricle (DORV), may at times be best managed in a fashion similar to that which is used to treat other functionally univentricular hearts. Nomenclature for description of those entities, however, is not included in this Single Ventricle section of the EACTS-STS version of the IPCCC [24,64].

"Hypoplastic left heart syndrome is synonymous with the term hypoplasia of the left heart and is defined as a spectrum of cardiac malformations with normally aligned great arteries without a common atrioventricular junction, characterized by underdevelopment of the left heart with significant hypoplasia of the left ventricle including atresia, stenosis, or hypoplasia of the aortic or mitral valve, or both valves, and hypoplasia of the ascending aorta and aortic arch." [66]

"Hypoplastic left heart syndrome without intrinsic valvar stenosis or atresia is synonymous with the term hypoplastic left heart complex and is defined as a cardiac malformation at the milder end of the spectrum of hypoplastic left heart syndrome with normally aligned great arteries without a common atrioventricular junction, characterized by underdevelopment of the left heart with significant hypoplasia of the left ventricle and hypoplasia of the aortic or mitral valve,

or both valves, in the absence of intrinsic valvar stenosis or atresia, and with hypoplasia of the ascending aorta and aortic arch." [66]

"The Norwood operation is synonymous with the term 'Norwood (Stage 1)' and is defined as an aortopulmonary connection and neoaortic arch construction resulting in univentricular physiology and pulmonary blood flow controlled with a calibrated systemic-to-pulmonary artery shunt, or a right ventricle to pulmonary artery conduit, or rarely, a cavopulmonary connection." [66]

"Congenitally corrected transposition is synonymous with the terms 'corrected transposition' and 'discordant atrioventricular connections with discordant ventriculo-arterial connections,' and is defined as a spectrum of cardiac malformations where the atrial chambers are joined to morphologically inappropriate ventricles, and the ventricles then support morphologically inappropriate arterial trunks." [67]

"Heterotaxy is synonymous with 'visceral heterotaxy' and 'heterotaxy syndrome.' Heterotaxy is defined as an abnormality where the internal thoraco-abdominal organs demonstrate abnormal arrangement across the left-right axis of the body. By convention, heterotaxy does not include patients with either the expected usual or normal arrangement of the internal organs along the left-right axis, also known as "situs solitus," nor patients with complete mirror-imaged arrangement of the internal organs along the left-right axis also known as "situs inversus." [72]

"Isomerism in the context of the congenitally malformed heart is defined as a situation where some paired structures on opposite sides of the left–right axis of the body are, in morphologic terms, symmetrical mirror images of each other." [72]

"Left isomerism in the context of the congenitally malformed heart is defined as a subset of heterotaxy where some paired structures on opposite sides of the left–right axis of the body are symmetrical mirror images of each other, and have the morphology of the normal left-sided structures." [72]

"Right isomerism in the context of the congenitally malformed heart is defined as a subset of heterotaxy where some paired structures on opposite sides of the left–right axis of the body are symmetrical mirror images of each other, and have the morphology of the normal right-sided structures." [72]

"Isomerism of the left atrial appendages is a subset of heterotaxy where the atrial appendages on both sides of the body have the appearance of the morphologically left atrial appendage." [72]

"Isomerism of the right atrial appendages is a subset of heterotaxy where the atrial appendages on both sides of the body have the appearance of the morphologically right atrial appendage." [72]

"Situs ambiguus is defined as an abnormality in which there are components of situs solitus and situs inversus in the same person. Situs ambiguus, therefore, can be considered to be present when the thoracic and abdominal organs are positioned in such a way with respect to each other as to be not clearly lateralized and thus have neither the usual, or normal, nor the mirror-imaged arrangements." [72]

"Asplenia literally means absent spleen." [72]

"Asplenia syndrome can be defined as a subset of heterotaxy with components of bilateral right-sidedness, usually associated with absence of the spleen." [72]

"Polysplenia literally means multiple spleens." [72]

"Polysplenia syndrome can be defined as a subset of heterotaxy with components of bilateral left-sidedness, usually associated with multiple spleens." [72]

"Ivemark syndrome is a term that, historically, is synonymous with asplenia syndrome." [72]

The NWG was consulted by the World Health Organization (WHO) Disease Classification Revision Committee to provide definitions of Eisenmenger for The International Classification of Diseases. The NWG provided definitions of the following four related terms:

- Eisenmenger defect is a membranous ventricular septal defect with anterior malalignment of the conal septum without outflow tract obstruction, as described by Eisenmenger in 1897. This terminology is no longer in common usage and many cardiologists would not be able to define the precise defect to which the term refers.
- Eisenmenger syndrome could briefly be described as, acquired severe pulmonary vascular disease associated with congenital heart disease.
- The term, Eisenmenger complex, represents an acquired condition that is the combination of an Eisenmenger defect (malalignment membranous VSD) with severe pulmonary hypertension and a right-to-left shunt. It may at times be used synonymously (incorrectly) with the term, Eisenmenger syndrome, the latter meaning severe pulmonary vascular disease associated with a VSD and/or other cardiac malformations. Other than for historical purposes however, the phrase, Eisenmenger complex, should be dropped as its definition is not widely agreed on or known.
- The term, Eisenmenger disease, may be used by some to be synonymous with Eisenmenger complex or Eisenmenger syndrome. The term is not used widely and should not be retained because of its ambiguity.

Nomenclature, Definitions, and Classification Controversies

Some cardiac lesions remain difficult to assign to one or another subset. Among the lesions subject to debate were:

1. ostium primum atrial septal defect;
2. tetralogy of Fallot–pulmonary atresia (TOF-PA);
3. double-outlet right ventricle (DORV);
4. single ventricle;
5. transposition of the great arteries (TGA).

Reasonable consensus has been achieved; however, it is likely that as the initiative for a comprehensive standardized nomenclature system progresses, continuing debate by surgeons, cardiac pathologists, and pediatric cardiologists will assure that the system will evolve to achieve a uniform nomenclature that crosses geographic boundaries and specialty preferences [5].

Ostium Primum Atrial Septal Defect (Partial Atrioventricular Canal)

Ostium primum atrial septal defect (partial atrioventricular canal) is defined as a crescent-shaped hole in the inferior portion of the atrial septum just above the atrioventricular valve with varying degrees of left atrioventricular valve regurgitation owing to a cleft in the anterior leaflet of the mitral valve [6,8]. The controversy surrounding this lesion revolves not around the definition or the moniker but in how to classify the lesion as it relates to surgical outcome and long-term disability [158,159]. Most surgeons believe repair of an ostium primum defect with a cleft anterior mitral leaflet (partial atrioventricular canal with a cleft of the left atrioventricular valve or partial atrioventricular

septal defect with cleft of the left atrioventricular valve) has potential consequences regarding mitral valve function and cardiac arrhythmia. Therefore, including ostium primum atrial septal defect (partial atrioventricular canal) with other forms of atrial septal defect for the purpose of risk stratification yields a disparate analysis. Ostium primum atrial septal defect (partial atrioventricular canal) is consequently best analyzed with the other atrioventricular canal defects (complete atrioventricular canal and intermediate atrioventricular canal) when risk stratification models or outcome reports are considered. Subsets of analysis can be developed for each of the subtypes of atrioventricular canal: complete, intermediate or transitional, and partial or incomplete.

Tetralogy of Fallot with Pulmonary Atresia Versus Pulmonary Atresia with Ventricular Septal Defect

The distinction between TOF-PA and PA-VSD can be arbitrary and has led to nomenclature and identification controversies. The surgical considerations and outcomes, however, are very similar regardless of the name given this entity. For the most part, these lesions are repaired by closure of the VSD and placement of a right ventricle-to-pulmonary artery conduit. Postoperative complications are related to right ventricular dysfunction, residual VSDs, residual pulmonary stenosis, and the need for replacement of the conduit. The Congenital Heart Surgery Nomenclature and Database Project decided to group TOF-PA patients with PA-VSD patients, preferring to classify these patients as having PA-VSD [13,15].

Pulmonary atresia, as defined in the context of TOF by the International Congenital Heart Surgery Nomenclature and Database Project [15], is the lack of luminal continuity between the right ventricle and the pulmonary trunk [160]. Pulmonary atresia also occurs with corrected transposition [161]. In that case, there is lack of luminal continuity between the left ventricle and the pulmonary trunk. A broad definition of *pulmonary atresia* [15], therefore, is the lack of luminal continuity and the absence of blood flow from a ventricle or a rudimentary chamber to the pulmonary artery. In the severe form of pulmonary atresia, the pulmonary arteries are partially or completely absent. Pulmonary atresia can occur in biventricular hearts with an intact ventricular septum or VSD and in hearts with a univentricular atrioventricular connection. That pulmonary atresia can occur with almost any form of congenital heart disease is supported by the results of the classic studies by Van Praagh and associates [161,162]. *Ventricular septal defect* is defined as an opening or hole in the interventricular septum [7,163,164]. From these two definitions, it follows that *PA-VSD* is a group of congenital cardiac malformations in which there is lack of luminal continuity and absence of blood flow from either ventricle to the pulmonary artery in a biventricular heart that has an opening or a hole in the interventricular septum. In the severe form of PA-VSD, the native pulmonary arteries are partially or completely absent [15].

Because the term PA-VSD has been frequently used interchangeably with TOF-PA, it is useful to define the latter [15]. *Tetralogy of Fallot–pulmonary atresia* is a congenital cardiac malformation characterized by the following features: (1) extreme underdevelopment of the right ventricular infundibulum, (2) a large-outlet, subaortic VSD, (3) marked anterior and leftward displacement of the infundibular septum, which often is fused with the anterior wall of the right ventricle; the result is complete obstruction of blood flow into the pulmonary artery [15,160]. Tetralogy of Fallot–pulmonary atresia, therefore, is a specific type of PA-VSD with the intracardiac malformation more accurately defined [15]. The presence or absence of multiple aortopulmonary collateral arteries does not change these definitions. Other types of intracardiac anatomy in PA-VSD include DORV and TGA with complete atrioventricular septal defect [165].

In most cases of PA-VSD, the intracardiac anatomical features are those of TOF. A rudimentary infundibulum may be identified with careful inspection; this structure is partially or completely fused with the anterior wall of the right ventricle. This configuration usually is the case in the presence of a main pulmonary artery. The presence of a main pulmonary artery can serve as a guide to intracardiac diagnosis depending on to which ventricle the artery is attached and whether the structure found has a lumen or is a fibrous cord. If the main pulmonary artery or fibrous cord originates from the right ventricle and the aorta also arises entirely or predominately from the right ventricle, the diagnosis is DORV with pulmonary atresia (DORV-PA). If, on the other hand, the main pulmonary artery or fibrous cord originates from the left ventricle along with the aorta, the defect is double-outlet left ventricle with pulmonary atresia. If the main pulmonary artery or fibrous cord originates from the left ventricle and the aorta arises from the right ventricle, the defect is TGA with pulmonary atresia (TGA-PA). In many patients with PA-VSD, however, no main pulmonary artery or fibrous cord originates from the heart. In these cases, the precise intracardiac diagnosis cannot be made with certainty. For example, if no main pulmonary artery or fibrous cord originates from the heart and the aorta arises entirely from the right ventricle, it is impossible to establish whether DORV-PA or TGA-PA is present. In these situations, the malformation is simply called by its general name, PA-VSD.

Tetralogy of Fallot Versus Double-Outlet Right Ventricle

Another area of controversy centers on differentiation of TOF and DORV [13]. Some authors [166,167] use the term DORV when the pulmonary artery arises from the right ventricle and more than 50% of the aorta arises from the

right ventricle. Other authors [168] use the term DORV only when the pulmonary artery arises from the right ventricle and 90% or more of the aorta arises from the right ventricle. Still others [169] use the term DORV only when there is absence of fibrous continuity between the aortic and mitral valves. Double-outlet right ventricle is defined by the International Congenital Heart Surgery Nomenclature and Database Project [27] as a type of ventriculoarterial connection in which both great vessels arise entirely or predominately from the right ventricle. In a commentary on the difficulties encountered by the nomenclature project in achieving consensus, Marshall Jacobs stated, "It is inescapable that some hearts will be called TOF at some centers and DORV at other centers [13]."

Double-Outlet Right Ventricle Versus Transposition of the Great Arteries

Double-outlet right ventricle with subpulmonary VSD and TGA-VSD can be differentiated from one another by site of origin of the pulmonary artery [27]. Because DORV is a type of ventriculoarterial connection in which both great vessels arise entirely or predominantly from the right ventricle [170], hearts with DORV and subpulmonary VSD are considered a subset of DORV. If the aorta arises entirely or predominately from the right ventricle, the pulmonary artery arises entirely or predominately from the left ventricle, and there is a subpulmonary VSD, the defect is considered a subset of TGA-VSD [171,172].

Double-outlet right ventricle with subpulmonary VSD is further delineated by the presence or absence of associated pulmonary stenosis. Hearts with DORV and subpulmonary VSD without pulmonary stenosis are considered to be Taussig–Bing type (Taussig–Bing syndrome). The very rare hearts with DORV and subpulmonary VSD and pulmonary stenosis are not of the Taussig–Bing type. In surgical series of DORV [172,173], subpulmonary VSDs are present in approximately 30% of patients. These VSDs are usually unrestrictive, lie anteriorly and superiorly beneath the pulmonary valve in the interventricular septum, and are within the limbs of the septomarginal trabecula.

Single Ventricle

The commonly used terms, *single ventricle* and *univentricular heart*, are debated by anatomists and pathologists. In an attempt to derive a classification useful and relevant to surgical therapy, the Nomenclature and Database Project limited hearts considered univentricular or as single ventricles to be those in which the atrial chambers connect to only one well developed, dominant ventricle. The well developed ventricle has an inlet portion that supports the subvalvar tensor apparatus, a trabecular zone, and an outlet portion to a great artery. Also often present is an incomplete, rudimentary, or hypoplastic ventricle that may lack an atrioventricular connection [24].

In 2000, The International Congenital Heart Surgery Nomenclature and Database Project defined single-ventricle anomalies as cardiac malformations characterized by the lack of two completely well developed ventricles. Anderson prefers the term *functionally single ventricle* rather than *single ventricle* because these hearts generally have a functional single ventricle and a diminutive or hypoplastic ventricle.

In 2006, the NWG of the ISNPCHD addressed the definition of single ventricle as well [64]. The following five paragraphs are taken directly from their manuscript titled: "Classification of the Functionally Univentricular Heart: Unity from mapped codes" and document the rich history behind the terms single ventricle and functionally univentricular heart:

> "The debate about the proper nomenclature for the functionally univentricular heart goes back several decades. The approach taken at Boston Children's Hospital from the 1970s is summarized by the following passage, authored by Donald C. Fyler, in the textbook 'Nadas' Pediatric Cardiology: [1]' [174]
>
> > 'At Boston Children's Hospital, a single ventricle is defined as the presence of two atrioventricular valves with one ventricular chamber or a large dominant ventricle associated with a diminutive opposing ventricle. [2-4] The term double-inlet ventricle is also used to describe this group of anomalies. While the concept of a univentricular heart [5-8] fits the physiologic idea of a common mixing chamber and has pathologic merits as well, lumping patients with mitral atresia, tricuspid atresia, and others into one category adds confusion rather than contributing to classification. The easy distinction between a single atrioventricular valve and two atrioventricular valves has been a reproducible basis for clinical impressions extending over many years. To change nomenclature would require significant benefits that are not apparent at the present time.'" [175–181]
>
> "The concept of the 'univentricular heart' as discussed above by Fyler is essentially the one evolved by a group of European morphologists and clinicians, albeit with strong support from Freedom in Toronto.[5-7] The evolution of their system, however, depended on emphasizing that, in the hearts under discussion, it was the atrioventricular connection, rather than the heart itself, which was truly univentricular. Thus, in one of the cited works,[8] the situation was summarized as follows:
>
> > 'In most hearts with double-inlet connection it is not the ventricles that are univentricular; it is the AV connection. The concept of a univentricular AV connection, then, appropriately groups hearts with double-inlet along with those having absence of one AV connection. It distinguishes this entire group from those other hearts with biventricular AV connections (each atrium connected to its own ventricle). The term "univentricular AV connection" is thus a collective one for all those hearts in which the atria connect to only one ventricle.'" [178–181]
>
> "With ongoing experience, it has now become clear that many of these hearts with biventricular atrioventricular connections can also lead to a situation which, in terms of physiology, is functionally univentricular. Thus, in the initial review of this supplement, Jacobs and Anderson[9] explain how the term 'functionally univentricular heart' allows for the grouping together of hearts in which 'one chamber was incapable independently of supporting either the pulmonary or the systemic circulation.' This approach is based upon the concept of '*appreciating that the entire ventricular mass was functionally univentricular whenever one or other ventricle was incapable, for whatever reason, of supporting either the systemic or the pulmonary*

circulation."[9] The endpoint of this evolutionary journey, therefore, is an approach that permits description of the patients possessing functionally univentricular hearts based upon a clear understanding of the cardiac phenotype, and a detailed description of this cardiac phenotype." [64,182]

Therefore, as stated previously, the functionally univentricular heart is defined as a spectrum of congenital cardiovascular malformations in which the ventricular mass may not readily lend itself to partitioning that commits one ventricular pump to the systemic circulation, and another to the pulmonary circulation. The version of the IPCCC derived from the International Congenital Heart Surgery Nomenclature and Database Project of the EACTS and STS uses the term "single ventricle" as synonymous for the functionally univentricular heart.

Transposition of the Great Arteries

Malposition of the great arteries is defined as all defects with abnormal position of the great vessels regardless of the ventricular origin. Transposition of the great arteries (TGA) is defined as right ventricular origin of the aorta and left ventricular origin of the pulmonary artery [26,183]. The term *transposition* is synonymous with either *ventriculoarterial discordance* or *discordant ventriculoarterial connection* [26,184,185]. Subtypes of malposition of the great arteries include the following lesions:

1. double-outlet right ventricle (DORV);
2. double-outlet left ventricle (DOLV);
3. anatomically corrected malposition (concordant ventriculoarterial connections with parallel great arteries) [26];
4. physiologically uncorrected TGA (atrioventricular concordance with ventriculoarterial discordance);
5. corrected TGA (atrioventricular discordance with ventriculoarterial discordance) [25,183].

Transposition of the great arteries as a subset of malposition includes both corrected TGA and physiologically uncorrected TGA because the great arteries arise from the wrong ventricles in both lesions [25].

The term congenitally corrected TGA was introduced in 1961 to differentiate the naturally occurring condition from surgically repaired transposition [186]. Congenitally corrected TGA is probably the most accepted term in current use for this anatomic complex, but inclusion of the modifier "congenitally" makes it cumbersome, and acceptance is by no means universal [26]. Acceptable synonyms include *corrected TGA*, *atrioventricular and ventriculoarterial discordance*, *atrioventricular discordance with transposition*, *double discordance*, and *discordant transposition*.

In 2000, the Nomenclature and Database Project defined *corrected TGA* [26] as a malformation in which (1) the two ventricles are connected inappropriately to the atria and (2) the great arteries are transposed. Thus the systemic venous atrium (right atrium) is connected to the morphologically left ventricle and the pulmonary venous atrium (left atrium) is connected to the morphologically right ventricle. In addition, the aorta originates from the right ventricle and the pulmonary artery from the left ventricle. As a result of the abnormal (discordant) connections at both levels, the defect is "physiologically corrected" with systemic venous blood flow to the pulmonary circulation and pulmonary venous blood flow to the systemic circulation. In clinical practice, because of frequently associated defects (e.g., VSD, left ventricular outflow tract obstruction, left atrioventricular [tricuspid] valve abnormalities [typically regurgitation], PA-VSD, and conduction abnormalities), corrected transposition often is far from physiologically correct. The term *physiologically corrected transposition* is therefore of little practical use [26].

In 2006, the NWG of the ISNPCHD published the following definition: "Congenitally corrected transposition is synonymous with the terms 'corrected transposition' and 'discordant atrioventricular connections with discordant ventriculo-arterial connections', and is defined as a spectrum of cardiac malformations where the atrial chambers are joined to morphologically inappropriate ventricles, and the ventricles then support morphologically inappropriate arterial trunks." [67].

Use of the term *d-TGA* to refer to physiologically uncorrected TGA is not precise, not acceptable, and should be discouraged [25]. Likewise, use of the term *l-TGA* to refer to corrected TGA is not precise, not acceptable, and should be discouraged [25,26]. The terms *d-TGA*, *a-TGA*, and *l-TGA* define the spatial arrangements of the great arteries and should not be used to define transposition. The term *d-TGA* refers only to hearts in which the aortic valve is to the right of the pulmonary valve. In *l-TGA* the aortic valve is to the left of the pulmonic valve, and in *a-TGA* the aortic valve is directly anterior to the pulmonic valve.

Many clinicians incorrectly use the terms *TGA*, *d-TGA*, and *complete transposition* synonymously. The term *d-TGA* refers only to hearts with TGA in which the aortic valve is to the right of the pulmonary valve. This anatomic arrangement is the most common variant of TGA, found in more than 80% of cases reported by Van Praagh [25]. The terms *complete transposition* and *incomplete transposition* are obsolete. In the past, double-outlet right or left ventricle was termed incomplete transposition. All malpositions of the great arteries now classified as transposition are "complete" transpositions. Thus complete transposition may refer to either physiologically uncorrected TGA or corrected TGA, because in both cases the great arteries arise from the wrong ventricle and thus are completely transposed. Used as a modifier, "complete" is redundant and should be avoided [25].

Although *d-TGA* represents the most common spatial relation of the great arteries in uncorrected TGA, all cases of *d-TGA* are not physiologically uncorrected TGA, and not all cases of physiologically uncorrected TGA are *d-TGA*

[25]. Physiologically uncorrected TGA includes hearts with the segmental anatomy {S,D,D}, {S,D,A}, and {S,D,L} as well as {I,L,L} and {I,L,D}. Van Praagh stated that in hearts in which one is not able to define the atrial situs, it is impossible to say whether there is atrioventricular concordance. Yet many cases of situs ambiguus – {A,L,L} or {A,D,D} – behave as physiologically uncorrected TGA and are managed with arterial switch [25].

The term *l-TGA* typically has been used synonymously with corrected TGA; however, not all cases of *l-TGA* are physiologically corrected TGA [25]. Furthermore, corrected TGA includes hearts with the segmental anatomy {S,L,L}, {S,L,D}, and {I,D,D}. Van Praagh and colleagues [187] introduced the term *l-TGA* in the 1960s to describe TGA with a left-sided (usually anterior) aorta. In most cases, this situation coexists with atrioventricular discordance with an L-loop ventricular arrangement in which the morphologically left ventricle is right-sided and the morphologically right ventricle is left-sided. Because the association of *l-TGA* with an L-loop is so close, many clinicians incorrectly believe that the presence of *l-TGA* is indicative of *corrected TGA*. Since the terms *l-TGA* and *corrected TGA* were introduced, many morphologists and clinicians have tended to use the terms as though they are synonymous. Some patients with corrected TGA and an L-loop, however, have an aorta that lies anterior and to the right of the pulmonary artery {S,L,D}. Furthermore, patients with corrected TGA and situs inversus also can have an aorta that lies anterior and to the right of the pulmonary artery {I,D,D} [25,26].

The terms *d-TGA*, *a-TGA*, and *l-TGA* cannot be used to imply or define the presence of corrected TGA or uncorrected TGA. They merely define the spatial arrangements of the great arteries in TGA. They are important modifiers, however, because the spatial relations of the great vessels may closely correlate with the anatomic features of the coronary arteries [25].

"Regardless of the original intent of these terms, many people use '*d-transposition*' to refer to the combination of d-looped ventricles and transposition, and '*l-transposition*' to imply the combination of l-looped ventricles and transposition, without reference to the position of the arterial roots. In this use, {S,D,L} transposition is a form of d-transposition, and {I,L,D} is form of l-transposition. Using this interpretation, the terms, 'd-transposition' and 'l-transposition' refer to d-loop transposition and l-loop transposition. This usage adds even more confusion, because it is apparent that universal agreement does not exist as to whether or not the 'd' and 'l' refer to arterial position or ventricular looping. This point alone potentially represents the worst problem with the terms 'd-transposition' and 'l-transposition,' and further justifies the recommendation to avoid these terms." [67]

Summary

This chapter provides a ternary system for describing any heart. First, the segmental anatomy of the heart is described. Second, all cardiac lesions are classified as to their major lesion type. Third, each lesion is further described according to the hierarchical nomenclature system initially developed by the International Congenital Heart Surgery Nomenclature and Database Project [3–36] and subsequently unified with other nomenclature systems including the European Paediatric Cardiac Code to become refined by the International Paediatric and Congenital Cardiac Code (IPCCC) [80,82].

Further debate by surgeons, anatomists, and pediatric cardiologists is expected to result in nomenclature changes and continued evolution of this nomenclature system. We are now closer than ever to achieving the goal of establishing a uniform nomenclature system that crosses geographic boundaries and specialty preferences.

CHAPTER 3

Physiology of the Fetal and Neonatal Circulations and Fetal Cardiac Surgery

Ashok Muralidaran,[1] Vadiyala Mohan Reddy,[2] and Frank L. Hanley[1]

Fetal Circulation

Blood flow in a normal adult is in series, a sequential flow of blood from the systemic venous system to the right heart, to the lungs, and to the left heart where well oxygenated blood is eventually pumped back into the systemic circulation. In the fetus, the right and left hearts control different proportions of the total blood volume, thus acting in a parallel fashion. The total fetal cardiac output is thus a sum of both of the ventricles' output – the combined ventricular output (CVO) or the biventricular output. The general pattern favors the streaming of well oxygenated blood from the placenta to the heart and the brain; and the less oxygenated blood streams into the umbilical arteries and, finally, back to the placenta.

Fetal Intra- and Extracardiac Shunts

Three important shunts help accomplish the streaming of blood that we previously described: the ductus venosus, the foramen ovale, and the ductus arteriosus. This is illustrated in Figure 3.1 [1].

A good fraction of the oxygenated placental blood returning via the umbilical vein (UV) is diverted directly into the inferior vena cava (IVC) via the ductus venosus (DV), thus bypassing the liver parenchyma [2]. When this well oxygenated blood reaches the right atrium it is preferentially shunted across to the left atrium via the foramen ovale, thus making its way via the left ventricle to the coronary and cerebral circulations. The venous return from these circulations and the upper body drains via the superior vena cava into the right atrium, streaming directly into the right ventricle with almost no blood traversing the foramen ovale [2]. The right ventricle then pumps this deoxygenated blood into the main pulmonary artery, the majority of it flowing into the descending aorta via the ductus arteriosus, supplying the abdominal viscera, the lower body, and the umbilical arteries with reoxygenation at the placenta. The lower body venous return is via the IVC to the right atrium, being split between the shunt across the foramen ovale and the normal flow via the tricuspid valve to the right ventricle [3]. Figure 3.2 illustrates the flows in the main vessels, shunts, and chambers as a proportion of the biventricular output [1]. Note the minimal flow to the lungs in the fetus later transitioning to support a full cardiac output in the neonate.

Venous Return

The richly oxygenated UV blood splits in half as it enters the liver, being distributed equally between the DV and the liver parenchyma [4]. The DV blood flows into the IVC streaming dorsal and leftward to that of the blood returning from the lower body, facilitating its preferential route into the left atrium (LA) and hence, the brain and myocardium [5]. The other half that enters the liver does so preferentially via the left portal vein, contributing to about 80% of the total hepatic blood flow. The remaining 20% is split between the portal vein (15%) and the hepatic arteries (5%) [4].

The crista dividens – the lower border of the septum secundum – forms the cephalad margin of the foramen ovale (FO) lying to the right of the atrial septum, overriding the IVC orifice. It splits the IVC stream into an anterior and rightward portion flowing into the right atrium (RA) and

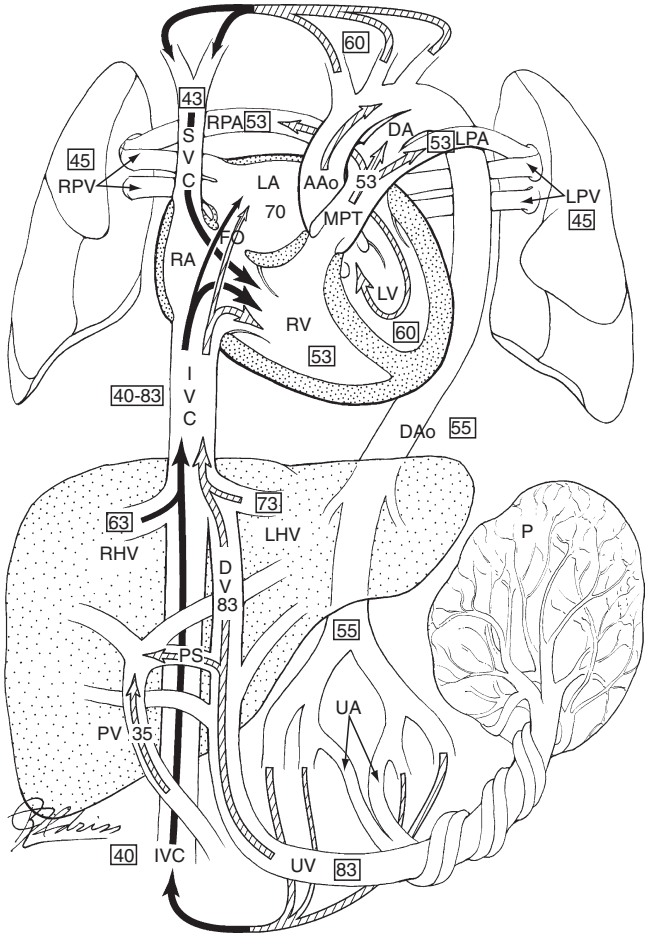

Figure 3.1 Diagrammatic representation of normal fetal circulation, major flow patterns, and blood hemoglobin oxygen saturations. (AAo, ascending aorta; DAo, descending aorta; DV, ductus venosus; FO, foramen ovale; IVC, inferior vena cava; LA, left atrium; LHV, left hepatic vein; LPA, left pulmonary artery; LPV, left pulmonary veins; LV, left ventricle; MPT, main pulmonary trunk; P, placenta; PS, portal sinus; PV, portal vein; RA, right atrium; RHV, right hepatic vein; RPA, right pulmonary artery; RPV, right pulmonary veins; RV, right ventricle; UA, umbilical arteries; UV, umbilical vein).

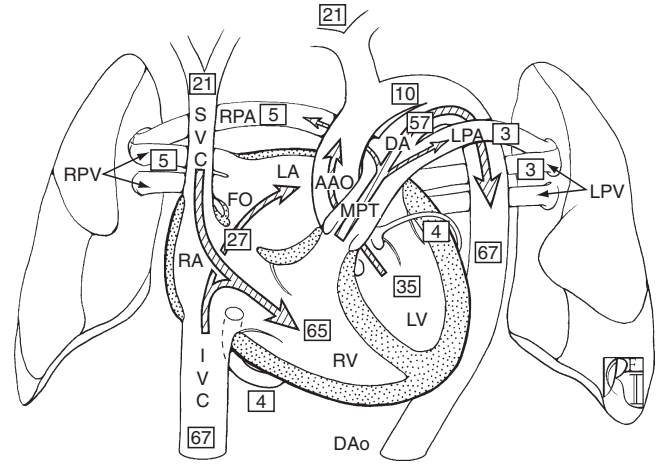

Figure 3.2 Representative values for percentages of fetal cardiac output (combined ventricular output) returning to and leaving the heart in normal fetal lambs. (AAo, ascending aorta; DAo, descending aorta; DV, ductus venosus; FO, foramen ovale; IVC, inferior vena cava; LA, left atrium; LHV, left hepatic vein; LPA, left pulmonary artery; LPV, left pulmonary veins; LV, left ventricle; MPT, main pulmonary trunk; P, placenta; PS, portal sinus; PV, portal vein; RA, right atrium; RHV, right hepatic vein; RPA, right pulmonary artery; RPV, right pulmonary veins; RV, right ventricle; UA, umbilical arteries; UV, umbilical vein).

a posterior and leftward stream that flows into the LA. The latter stream is predominantly composed of the UV return that flowed via the DV. Intermixing does occur, in that some DV blood flows into the RA and some deoxygenated IVC blood flows into the LA, but the left atrium has a significantly higher saturation than the right (Figure 3.1) [1].

Blood returning to the heart via the SVC is preferentially streamed into the tricuspid orifice by the crista interveniens situated in the posterolateral wall of the RA. The coronary sinus flow is also directed toward the tricuspid valve and hence, the right ventricle (RV). The pulmonary venous return is to the LA, mixing with the blood crossing the FO.

Cardiac Output, Oxygenation, and Distribution

The RV is the dominant ventricle in the fetus. It predominantly perfuses the lower body, the abdominal organs, and the placenta. As illustrated in Figure 3.2 [1], the RV contributes approximately 65% and the LV, 35% of CVO [6]. Composed of the SVC, the coronary sinus and the predominantly lower body return from the IVC, this overwhelmingly deoxygenated blood is pumped by the RV mostly to the descending aorta via the ductus arteriosus, with only 8% of the RV output reaching the lungs. This preferentially distributes the deoxygenated blood for reoxygenation in the placenta.

The LV perfuses the ascending aorta, resulting in 21% of the CVO reaching the brain and upper body and 10% reaching the descending aorta via the isthmus. As shown in Figure 3.1 [1], the blood streaming into the LV has a relatively high saturation rate of 60%. Hence, there is some saturated blood from the LV entering the descending aorta that may perfuse the placenta contributing to the physiological "left-to-right" shunt equivalent in the fetus [7]. Individual organ blood flows are shown in Figure 3.3 [2] as proportions of the CVO.

Table 3.1 [1] shows some representative fetal blood gas values. Although the systemic arterial partial pressure of oxygen (pO_2) of the fetus is low, because of the fetal hemoglobin and the consequent left shift of the hemoglobin–oxygen dissociation curve, hemoglobin O_2 saturation (or

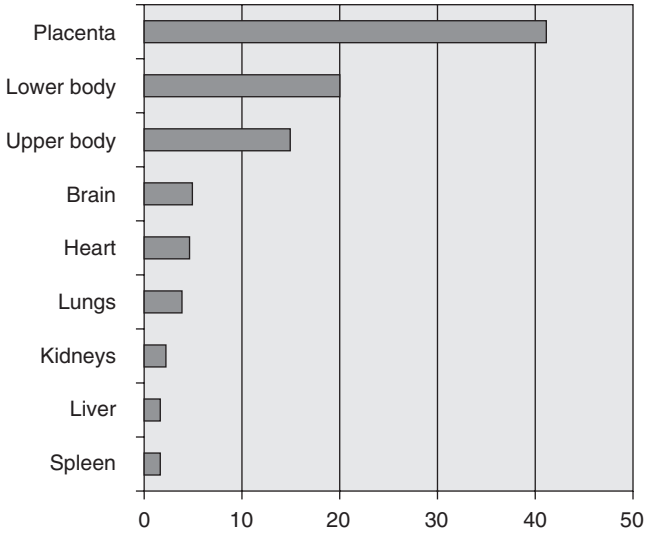

Figure 3.3 Average combined cardiac output distributed to different organs or parts in eight different fetal animals. (Adapted with permission from Rudolph, *et al.* [2].)

Table 3.1 Normal fetal pH and blood gas data. Reproduced with permission from Heymann [1].

	Umbilical vein	Descending aorta	Ascending aorta
pH	7.40–7.45	7.35–7.40	7.37–7.42
pO_2 (torr)	28–33	20–24	22–26
pCO_2 (torr)	45–50	48–53	46–51

at the same hemoglobin saturation, the oxygen content) is higher in the fetus than the adult. Fetal O_2 consumption is significantly less as the work of breathing is absent and thermoregulation requirements *in utero* are far less [8].

Intracardiac and Vascular Pressures

Fetal vascular pressures (shown in Figure 3.4 [1]) also reflect the preferential streaming patterns described previously. The high flow from the placenta results in the UV having a 3–5 mmHg higher pressure than the IVC. The RA pressure is higher than the LA and along with the kinetic energy of blood streaming via the IVC, contributes to the shunting of blood across the FO [3]. The ductus arteriosus offers little resistance to flow and pressures in the main pulmonary trunk; the pulmonary arteries and the RV are only slightly higher (1–2 mmHg) than the aorta and the LV.

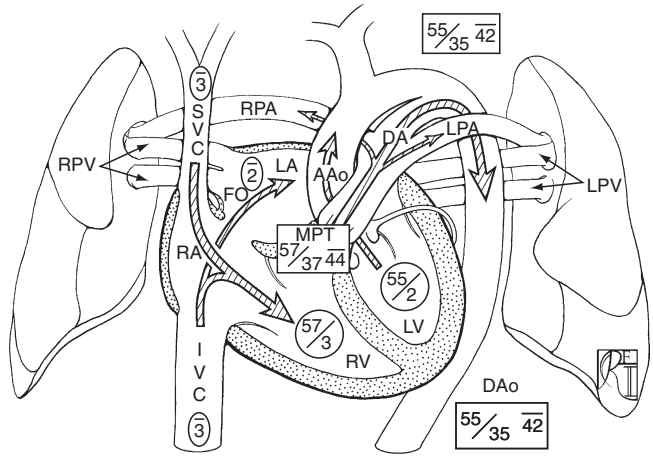

Figure 3.4 Representative values for vascular pressures in normal fetal lambs. (AAo, ascending aorta; DAo, descending aorta; DV, ductus venosus; FO, foramen ovale; IVC, inferior vena cava; LA, left atrium; LHV, left hepatic vein; LPA, left pulmonary artery; LPV, left pulmonary veins; LV, left ventricle; MPT, main pulmonary trunk; P, placenta; PS, portal sinus; PV, portal vein; RA, right atrium; RHV, right hepatic vein; RPA, right pulmonary artery; RPV, right pulmonary veins; RV, right ventricle; UA, umbilical arteries; UV, umbilical vein).

Circulatory Changes at Birth

The Transition

At birth, the pattern of circulation changes from the fetal "parallel" type to the adult "series" type, leading to more efficient oxygen uptake and delivery [9]. This happens with rapid establishment of pulmonary circulation, loss of placental circulation, and the closure of the ductus venosus, the foramen ovale, and eventually the ductus arteriosus. There is a rapid increase in O_2 consumption probably related to the work of breathing and thermoregulation, with an increase in cardiac output, a decrease in pulmonary vascular resistance, and an increase in pulmonary blood flow. The consequent increase in pulmonary venous return to the LA coupled with a decrease in IVC flow to the RA from cessation of placental UV return reverses the pressure difference between the LA and the RA, closing the flap valve of the FO. Pressures are also reversed across the DA, with a left-to-right flow reversal being established before it closes.

Closure of the Ductus Arteriosus

In the fetus, the patency of the ductus arteriosus is maintained by prostaglandin E2 (PGE_2) and prostacyclin (PGI_2) [10]. The initial functional closure which occurs within 12 hours of birth is thought to be mediated by the increase in systemic pO_2, though other vasoactive substances may also be contributory [11]. A reduction in circulating prostaglan-

din levels is implicated in persistent ductal closure. Eventually there is fibrous replacement of the musculature of the ductus arteriosus with formation of the ligamentum arteriosum.

Pulmonary Circulation

The high fetal pulmonary vascular resistance (PVR) is attributed to vasoconstriction in the thick medial layer of the small branches [12]. With increasing gestation, there is growth of new arteries, an increase in the cross-sectional area of the vascular bed, a drop in the PVR, and a slight increase in pulmonary blood flow [12]. Hypoxia is a major vasoconstrictive factor, as are acidosis and the leukotrienes [13,14].

A diverse group of vasoactive substances causes fetal and perinatal pulmonary vasodilatation – bradykinin, histamine, acetylcholine, PGE_1, PGE_2, prostaglandin D2 (PGD2), PGI_2, and catecholamines, to name a few [15]. Their effects are mediated by the endothelial release of secondary substances like nitric oxide (NO). A baseline relaxation of the fetal pulmonary vasculature has been attributed to NO [16].

Ventilation causes a mechanical stretch-induced production of PGI_2 in the fetal lung, with a drop in PVR that is accentuated with oxygen [17]. A calcium-dependent potassium channel activation has been hypothesized to mediate this effect of oxygen [18]. At birth, a combination of ventilatory stretch, increased alveolar oxygen tension, local NO, and PGI_2 production blend to produce a dramatic fall in PVR and a resultant striking increase in pulmonary blood flow. A role for ventilation-induced local mast cell degranulation and release of histamine and PGD_2 has also been suggested in contributing to postnatal pulmonary vasodilation [19].

Myocardial Performance

The immature fetal myocardium displays significant structural and hence functional differences from that of the adult. Not only are myocardial cells smaller, smooth, and rounded as opposed to being rod-shaped as in the adult, the cytoplasm has proportionately more water and lower myofibril content and they are not all arranged parallel to the cellular axis [20]. This may account for the differences in force generation and in the fetal myocardium being stiffer and less compliant.

The Frank-Starling mechanism is intact in the fetus at least at low atrial pressures but studies have differed on ventricular performance at higher atrial filling pressures [21–24]. Increases in arterial pressure significantly depress cardiac function in the fetus [24]. It does appear that in the fetus the preload and afterload are interrelated. The enhancement in stroke volume occurring after increasing the filling pressure by volume loading is stifled by a simultaneous augmentation in the afterload.

It is a matter of great interest how the neonatal left ventricle transitions from a low-pressure, low-output chamber to functioning at systemic pressures controlling a full cardiac output abruptly at birth. Changes in contractility, increase in beta adrenergic receptor density, and postnatal thyroid hormone changes have been suggested to aid in this transition [25,26].

Fetal Surgery

With expanding knowledge of fetal physiology and mechanisms of congenital lesions, fetal surgical therapy was the next logical clinical step. A succinct review of the initial two decades of fetal surgery with particular respect to the San Francisco center is provided by Dr. Harrison in a personal perspective [27].

Currently for congenital diaphragmatic hernia, the management strategy has shifted away from open fetal surgery to open or endoscopic tracheal occlusion to hasten lung growth and maturity. Endoscopic laser ablation of the communicating vessels is offered in select cases of twin-to-twin transfusion syndrome. Trials are being conducted comparing conventional postnatal care and intrauterine treatment of meningomyelocele [28]. The EXIT procedure stands for *ex utero* intrapartum treatment, where fetuses with certain congenital pulmonary lesions or prenatally diagnosed neck tumors are carefully managed at birth. During a controlled surgical delivery, the umbilical-placental circulation is maintained while the airway is secured, or the neonate is placed on extracorporeal membrane oxygenation (ECMO). A detailed discussion of fetal surgery in general is beyond the scope of this chapter.

Fetal Cardiac Surgery

Animal Models of Congenital Lesions

Advances in fetal echocardiography provided early and accurate information about structural cardiac defects and the attendant physiological derangements [29]. Thus, a flurry of research began in the 1970s exploring the possibilities of intrauterine cardiac repair. Dr. Rudolph's group pioneered the research in fetal cardiovascular physiology by creating models of cardiac lesions in fetal lambs that included banding of the aorta to simulate stenosis and placing an inflated balloon in the left atrium to create an inflow limitation [30]. A combination of these resulted in a lesion similar to hypoplastic left heart syndrome (HLHS). Turley and associates performed a banding model of aortic and pulmonary stenosis and attempted intrauterine repair

[31]. A model of pulmonary stenosis and intrauterine repair with improvement in fetal hemodynamics was also reported [32]. These studies were performed without cardiopulmonary bypass. Not only was placing the fetus on cardiopulmonary bypass essential to further advance research in fetal cardiac surgery; but equally important was addressing the issues of the nature of the bypass circuit, the fetus' systemic reaction to extracorporeal circulation, the placental and fetal-maternal interactions during bypass, and fetal cardioplegia.

Cardiopulmonary Bypass and the Placenta

In one of the early attempts at establishing fetal extracorporeal circulation, Hawkins and associates placed fetal lambs on bypass at hypo- and normothermia and conducted the study at varying flow rates [33]. Placental dysfunction evidenced by a combined metabolic and respiratory acidosis was manifest on bypass and this remains a formidable barrier to success to date. The exact mechanism of post-bypass placental failure is yet to be elucidated, but has stimulated much research.

Understanding Placental Hemodynamics

To better comprehend the placental vasculature, Assad, Lee, and Hanley placed the isolated *in situ* lamb placenta on bypass and studied the placental vascular resistance and compliance to varying flow rates [34,35]. They quantified the large capacitance of the placental vessels and calculated the precise perfusion rates and pressures required to create, and hence, avoid increased placental vascular resistance. In their studies, a high flow rate was required to sustain placental function, and hence, as a corollary, lower flow induced dysfunction.

A fetal lamb model testing this hypothesis revealed high bypass flow rates (300–400 mL/kg/min) as being relatively better than low rates (100–125 mL/kg/min) in offsetting placental dysfunction, although it eventually occurred in all animals [36]. The normal fetal lamb cardiac output is approximately 400 mL/kg/min and in most studies the small cannula sizes in the circuit and slow gravity venous drainage limited high flow rates. A novel use of a vacuum-assisted venous drainage in fetal bypass has been studied with improvement in bypass flows but with a modest overall result [37].

The Fetal Stress Response

Bradley, Hanley and associates performed a seminal study which demonstrated altered organ perfusion during fetal bypass documenting significantly deranged flows to the placenta correlating with the observed increase in placental vascular resistance [38]. A role for the fetal stress response with a humoral etiology for placental dysfunction was postulated and tested in further studies. Adding indomethacin to the bypass prime significantly abated the increase in placental vascular resistance suggesting the role for vasoactive prostaglandins [39,40]. In addition, when high spinal anesthesia was also administered to the fetal lamb, an abrogation of the fetal stress release of catecholamines was achieved, and in a study, resulted in acceptable placental perfusion during bypass [41]. With the previously mentioned techniques, fetal lambs have survived up to term in a chronic study [42]. Procedural complications of high spinal anesthesia and an adverse reaction to indomethacin in certain vascular beds preclude the application of this model to the human context. A recent study established a strong association of rising vasopressin (a known placental vasoconstrictor) levels with placental dysfunction during bypass thus underscoring the importance of the fetal stress response [43].

Role of the Endothelium in Placental Dysfunction

Champsaur and coworkers evaluated the various beneficial effects of pulsatile flow during fetal lamb bypass as opposed to the conventional continuous flow obtained with roller pumps. In their earliest study, they documented higher pump flows and placental flow with decreased systemic vascular resistance in the pulsatile pump group [44]. A role for shear stress in inducing the release of NO was postulated as the reason behind the beneficial effects of pulsatility in better preserving placental flow during bypass [45]. The group further demonstrated higher endothelin-1 levels and plasma renin concentration in fetuses on continuous flow bypass as opposed to the pulsatile flow in fetuses, suggesting a major role for endothelial dysfunction mediated by the renin-angiotensin system in placental insufficiency [46]. Reddy and associates provided further evidence for endothelial dysfunction as an etiological factor for placental insufficiency by documenting selective impairment of endothelial-dependent vasodilation post-bypass in the lamb fetus, linking it to a combination of decreased NO levels and elevated circulating endothelin-1 levels acting via vasoconstrictive endothelin-A receptors [47]. A recent study revisited this issue confirming altered placental NO pathway correlating with post-bypass placental dysfunction [48].

Understanding the Fetal Bypass Circuit

The conventional fetal bypass circuits had a volume of about 150 mL, which were primed with crystalloids and/or maternal blood. Large crystalloid volumes caused fetal hemodilution, and maternal blood in amounts sufficient to replace the fetal blood volume (especially in small fetuses),

may impair fetal tissue and placental oxygenation [49]. It is well known that the extracorporeal circuit triggered a systemic inflammatory reaction by the activation of complement and eicosanoids in adults and children [50,51]. This was also shown by Reddy and associates in the fetal setting in a study that revealed significantly elevated IL-6 levels post-bypass [52]. Along these lines, attempts were made to suppress the inflammatory reaction by maternal and fetal glucocorticoid administration and by introducing in-line hemofiltration during fetal bypass with modest results [53].

Reddy and colleagues also tested a novel in-line axial flow pump, the Hemopump, that minimized extracorporeal surface area and used no priming volume. This system demonstrated significantly higher placental flow and reduced placental resistance during and after bypass compared to a conventional circuit [54]. This pump was also used on long-term studies of fetal survival to term post-bypass and proved the technical feasibility of such an undertaking [55]. In further studies comparing the Hemopump with the conventional roller pump, they found significantly increased neutrophil degranulation accompanying placental dysfunction in the fetuses on roller pumps further underscoring the necessity to minimize extracorporeal surface area during fetal bypass [56]. The pump, however, was overly simplistic and lacked a mechanism to deal with inadvertent air embolism. Lombardi and associates used a similar miniaturized circuit with a centrifugal pump for placing immature fetal sheep on bypass [57].

Fetal Myocardial Protection

The fetal myocardial ultrastructure differs substantially from that of the mature myocardium, spawning significant differences in fetal cardiac function, as discussed earlier in this chapter. The fetal cardiac myocyte also has a reduced sarcoplasmic reticular content, with depreciated calcium storage and transport capacity [58]. These factors necessitate tailoring the myocardial protection strategies to the fetal context.

To this end Malhotra and associates compared the efficacy of cardioplegia solutions with varying calcium concentrations in preserving myocardial function on an isolated fetal sheep heart preparation [59]. They documented improved post-ischemia recovery and better preservation of myocardial function with solutions that had a reduced calcium concentration as opposed to normocalcemic or hypercalcemic cardioplegia preparations. In another study with a similar preparation, the group documented no difference in post-arrest cardiac function between normothermic fibrillation and hypothermic normocalcemic cardioplegia [60]. The latter study was performed to circumvent the theoretical difficulty of maintaining fetal hypothermia *in utero.*

Miscellaneous Factors

Eghtesady and colleagues report on maternal hemodynamic responses to fetal cardiac bypass in sheep [61]. They noted significant fluctuation in uterine arterial flow independent of the overall maternal hemodynamic status but associated with specific events during fetal bypass correlating with worsening fetal blood gases. In a recent study, the group quantified the fluid shifts occurring in a fetal lamb model emphasizing the possible role for extensive postoperative fetal fluid resuscitation [62]. These studies add a new dimension to the parameters that contribute to success in fetal cardiac surgery.

Future Directions

Most of the research in fetal cardiac bypass has been performed on lamb fetuses, and it is commonly believed by most researchers in the field that the sheep uterus is actually resilient to any manipulation. Hence, the principles gleaned in these years of research have to be prudently applied to primate models before their ultimate translation to human benefit. The first such primate model was reported by Ikai and associates, demonstrating the technical feasibility of placing baboon fetuses less than 1000 g on bypass [63]. Less invasive procedures (i.e., balloon angioplasty of the stenosed aortic valve, left atrial decompression for a restrictive atrial septum) have been reported as options for fetal hypoplastic left heart syndrome [64,65]. However, the case for open fetal cardiac surgery exists, if not for early correction of select severe lesions, at least to halt the progression of severe flow impairments, providing an enhanced probability for a postnatal biventricular repair. A deeper understanding of the placental microcirculation, the maternal, and fetal response to surgical stress, methods for myocardial protection, and advances in fetal extracorporeal support enriched by a molecular perspective would facilitate its translation from the laboratory to a clinical reality.

CHAPTER 4

Preoperative Diagnostic Evaluation

Introduction

Evaluation of the preoperative patient with congenital heart disease demands a thorough understanding of the anatomy and the physiology of each cardiac anomaly. Technical evolution of imaging modalities allows increasingly exact definition of anatomic detail, but such detail must be interpreted in the context of a clinical scenario that takes into account the patient's physiologic state. The art of interpreting and synthesizing information gathered from the history, physical examination, and adjunctive diagnostic tests remains the mainstay of clinical excellence. The exercise of this art is a crucial process that must be vigilantly undertaken for each patient in whom a cardiac surgical procedure is planned. This chapter will describe each of the components of a preoperative evaluation, from a detailed history to the delineation of complex anatomy and physiology by all the currently available tools.

History

A significant number of newborns are diagnosed with congenital heart disease before birth with the widespread use of fetal echocardiography [1]. The presence of a murmur, resting cyanosis, or exertional cyanosis account for most other referrals. Severe left-sided obstructive lesions can progress to shock as the presenting manifestation, with a history of rapid breathing, pallor, poor feeding, and lethargy typically preceding.

Infants with lesions that result in increased pulmonary blood flow begin to display symptoms after several days of life as the physiologic decrease in pulmonary resistance occurs. A history of rapid breathing, poor feeding, failure to thrive, and diaphoresis is typically elicited. Lack of symptoms in the first few months of life in an infant with unrestricted pulmonary blood flow should signal persistently elevated pulmonary resistance, and alert the clinician to the possibility of early onset pulmonary vascular disease. Duskiness around the lips or in the nail beds is usually observed in infants with cyanotic heart disease, and it is most pronounced with crying or feeding. Inconsolable crying and irritability in the first few weeks of life as pulmonary resistance decreases should raise the possibility of anomalous origin of the coronary artery from the pulmonary artery.

The onset of symptoms, such as exercise intolerance or chest pain, attributable to progression of obstructive lesions in a previously asymptomatic child, is almost always an indication to relieve the obstruction. Dizziness or syncope in a patient with congenital heart disease should call for a thorough investigation looking for the presence of atrial or ventricular arrhythmias. In the postsurgical patient, the presence of ventricular arrhythmias or refractory atrial arrhythmias may be an indication for surgical intervention, as in the patient with repaired tetralogy of Fallot (TOF) and chronic pulmonary regurgitation [2] or the Fontan patient who may benefit from Fontan revision and surgical cryoablation [3].

A family history of congenital or acquired heart disease should always be obtained [4]. Maternal illness or drug exposure during pregnancy, albeit infrequently, is associated with some forms of congenital heart disease [5]. Medications, previous surgical procedures, and any anes-

thetic complications should be reviewed in the preoperative interview.

Physical Examination

The presence of dysmorphic features can be associated with some forms of congenital heart disease and should be noted. General visual inspection of a patient can reveal the effects of chronic congestive heart failure: failure to thrive affecting preferentially weight but also height. In infants respiratory effort is increased, displayed by excessive use of abdominal and thoracic muscles. Pallor is seen in patients with low cardiac output, as in severe left-sided obstruction or ventricular dysfunction. Clubbing is a sign of long-standing cyanosis, and peripheral edema is seen in older patients with decompensated right or biventricular failure.

Vital signs, including oxygen saturation, and growth measurements should be part of every preoperative cardiac examination. The precordium should be examined in sequence: inspection, palpation, percussion, and auscultation. Cardiac impulse displacement is palpated with chamber enlargement. A hyperdynamic precordium is observed in large left-to-right shunt lesions or severe valvar insufficiency, while a sternal "tap" is felt with right ventricular hypertension. A thrill is caused by high velocity flow across a pressure drop, as in a stenotic valve or restrictive ventricular septal defect (VSD).

Palpation of the pulses in all extremities can be diagnostic of coarctation of the aorta (CoA), with diminished or absent lower extremity pulses, and a significant delay between the radial and femoral pulsations. In CoA with anomalous origin of the right subclavian artery from the descending aorta, the left arm pulses are normal and the rest diminished. Bounding pulses are felt with aortic insufficiency or aortic run-off lesions, such as patent ductus arteriosus (PDA).

Careful auscultation cannot only differentiate one lesion from another, but also assess severity. Each part of the cardiac cycle should be evaluated, listening for abnormal heart sounds, clicks or murmurs. A widely split second heart sound, along with a systolic ejection murmur in the pulmonary area, is diagnostic of an atrial septal defect (ASD). A pansystolic, high frequency murmur in the left mid to lower sternal border is typical of a VSD. Lower frequency systolic ejection murmurs at the base, sometimes accompanied by a click, are heard with valvar stenosis, and the duration and peak of the murmur vary with severity. A high frequency, early diastolic murmur of aortic insufficiency can be differentiated from the lower frequency apical diastolic rumble of severe mitral insufficiency or a large left-to-right shunt. A continuous murmur is characteristic of a patent ductus, but can also be because of an aortopulmonary shunt in the postsurgical patient, or to aortopulmonary collateral vessels in patients with TOF and pulmonary atresia. Relatively soft to and fro murmurs are typical of repaired TOF patients with severe pulmonary insufficiency. To and fro murmurs can also be heard in newborns with truncus arteriosus and truncal valve insufficiency, or TOF with absent pulmonary valve.

Palpation and percussion of the abdomen reveal hepatomegaly, and sometimes also splenomegaly, in patients with congestive heart failure or right heart dysfunction. Ascites or total body anasarca can be seen in patients with failed Fontan physiology, particularly in the presence of protein-losing enteropathy. Upper body edema is characteristic of patients with elevated superior vena cava pressure, as in superior systemic baffle obstruction following atrial switch for transposition of the great arteries (TGA), or cavo-pulmonary artery anastomosis with elevated pulmonary artery pressure.

Chest Radiography

The chest radiograph can demonstrate various cardiac and extracardiac abnormalities that can be helpful in the anatomic and physiologic evaluation of the patient with congenital heart disease [6]. Abdominal situs, position of the aortic arch, size and shape of the cardiac silhouette and pulmonary vascularity are all important clues in the preliminary evaluation of a patient suspected of having a congenital cardiac anomaly. Pulmonary parenchymal and skeletal abnormalities visible on a chest radiograph are associated with some forms of congenital heart disease. The chest radiograph is also a useful tool in the follow-up of a patient with a left-to-right shunt lesion, as changes in pulmonary vascular resistance will be reflected in changes in the degree of pulmonary vascularity.

Abdominal Situs

The position of the cardiac apex, stomach bubble, and liver is normal in the majority of patients with congenital heart disease, but frequently abnormal in patients with heterotaxy syndromes, asplenia, and polysplenia. Asplenia patients uniformly have complex congenital cardiac lesions, and about 75% of polysplenia patients have complex heart disease. Isolated dextrocardia is often associated with congenital heart disease, while situs inversus totalis has a low incidence of cardiac anomalies. Malposition of the heart can also result from lung hypoplasia, as in patients with Scimitar syndrome.

Cardiac Silhouette

The cardiac silhouette is enlarged with volume loading lesions, such as left-to-right shunts or valvar insufficiency. A boot-shaped heart is typically seen in patients with TOF, and results from up-turning of the cardiac apex resulting from right ventricular hypertrophy, and absence or decrease

in size of the pulmonary artery segment. A narrow mediastinum is characteristic of d-transposition of the great arteries (d-TGA) owing to the anterior-posterior orientation of the aorta and pulmonary artery. Severe Ebstein anomaly with severe tricuspid insufficiency gives the classic appearance of right atrial enlargement as a diffuse bulge of the right cardiac border and marked cardiomegaly. Total anomalous pulmonary venous return without obstruction is associated with the "snowman" or "figure of eight" sign attributable to enlargement of the right atrium and ventricle and a large left vertical vein.

Aortic Arch

The finding of a right-sided aortic arch should raise the suspicion of a conotruncal defect, such as TOF or truncus arteriosus, but can also be seen in the absence of congenital heart disease.

Lung Parenchyma

Pulmonary vascularity may be normal, increased, or decreased depending on the ratio of pulmonary to systemic blood flow. Lesions with a left-to-right shunt result in cardiomegaly and increased pulmonary vascular markings. Pulmonary edema with normal cardiac size is the classic finding in patients with obstructed total anomalous pulmonary venous return below the diaphragm (Figure 4.1). The lung fields have a ground-glass appearance as seen in newborns with respiratory distress syndrome. Pulmonary edema is also seen in patients with left heart failure.

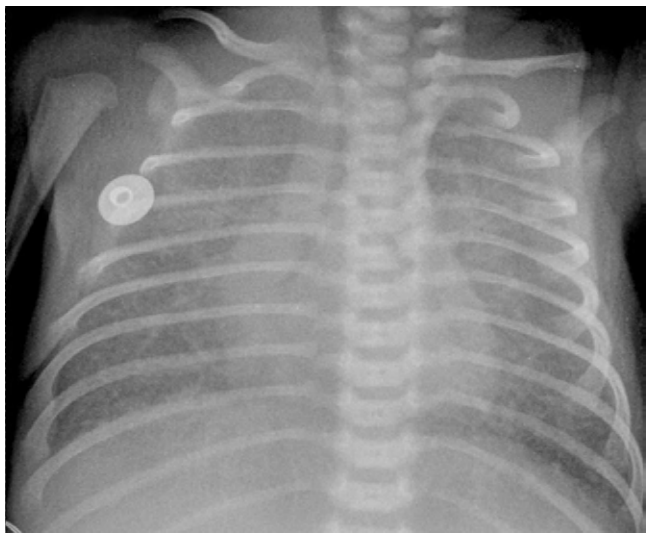

Figure 4.1 Chest radiograph of a newborn with obstructed total anomalous pulmonary venous return below the diaphragm. Note the presence of pulmonary edema with a ground-glass appearance, but normal cardiac silhouette.

Electrocardiography

The 12-lead EKG has always been considered an integral tool in evaluation of patients with suspected congenital heart disease. However, even in Helen Taussig's book *Congenital Malformations of the Heart*, she states that "although the electrocardiogram is a useful adjunct in the analysis of various malformations of the heart….it is of diagnostic value in only a few instances [7,8]." In the current era, the EKG is most helpful in: 1) identifying arrhythmias or potential conduction system disorders; 2) finding a previously unsuspected myocardial abnormality; or 3) its use as a reference point to identify changes that occur during the intracardiac repair or postoperative care.

Although few would argue that a cyanotic infant with left axis deviation would most likely have tricuspid atresia, none would omit further evaluation with echocardiography or some other imaging modality. Many structural congenital heart defects can have typical or classical findings on the EKG that may aid in making a correct diagnosis.

An EKG is the noninvasive tool to investigate the initiation and propagation of electrical wave fronts through cardiac tissue. Assuming the clinician knows the cardiac position, the P-wave axis and morphology can assess sinus node position and help assess its chronotropic adequacy. The lack of the expected normal P-wave axis can be seen in some congenital heart defects such as dextrocardia or sinus venosus ASDs. In some patients with sinus node bradycardia and dysfunction, a low atrial or junctional rhythm may be seen. These patients may need preoperative evaluation to assess the adequacy of sinus node function, so that if permanent pacing is needed and an epicardial pacing system required that system could be implanted at the reparative operation.

Patients with abnormal atrioventricular (AV) node conduction presenting either with second- or third-degree heart block will need careful preoperative evaluation. In our experience, patients with third-degree heart block and significant congenital heart disease will need a permanent pacemaker system. Patients with first- or second-degree heart block will benefit from either noninvasive monitoring with a 24-hour ambulatory monitor, stress test, or perhaps an invasive electrophysiologic study.

Patients whose electrocardiograms show a short PR interval and delta wave consistent with ventricular pre-excitation are not uncommonly seen when the underlying diagnosis is Ebstein anomaly of the tricuspid valve, or with AV and ventriculoarterial discordance. One should always remember that ventricular pre-excitation can be seen in almost any type of congenital heart disease patient. Many, perhaps most, will need ablation to avoid potentially hazardous arrhythmias such as supraventricular tachycardia or atrial fibrillation in the postoperative period [9]. It may be decided to perform an intraoperative ablation in selected cases.

EKG changes occur frequently after repair of congenital heart defects. The preoperative EKG provides a starting point from which we can evaluate new conduction system disturbances such as a change in AV conduction, or intraventricular conduction (i.e., right bundle branch block). Some new conduction system abnormalities seen postoperatively, such as second-degree heart block, may lead to further invasive investigation. Abnormalities in myocardial perfusion may be shown as new postoperative ischemia, perhaps in infants who have undergone an arterial switch to correct TGA.

Both 24-hour ambulatory monitoring (Holter) and stress testing are "EKG-based" studies that can be helpful to evaluate a patient preoperatively. When there is a question of sinus node adequacy, the clinician may use Holter tests to look for significant sinus bradycardia or long sinus pauses that can occur while the patient is in a restful state, and would be unaware of such occurrences. Likewise, a stress test would be able to assess the adequacy of the sinus node to increase appropriately when the patient is exercising.

We are including the topic of invasive electrophysiologic testing in this section, but we do not have the ability in this space to provide a complete review of its benefits [10]. Patients with ventricular pre-excitation or a pattern of Wolff-Parkinson-White on their EKG will benefit from at least an electrophysiologic evaluation to assess the conduction properties of the accessory connection. Many will need ablation. When easy access to the ablation site will be "lost" because of the type of surgical repair, ablation should be seriously considered if there is an inducible supraventricular arrhythmia, or if the accessory connection has the potential for rapid antegrade conduction. The electrophysiologic test also has value in patients returning for a repeat operation when there is a suspicion of intra-atrial re-entry tachycardia or ventricular arrhythmias. In this case the ablation can be performed either in the electrophysiologic laboratory or the electrophysiologic mapping study can help guide the surgeon to perform an intraoperative ablation.

Preoperative Echocardiography

Over the last few decades, advances in ultrasound technology have dramatically expanded the role of echocardiography. These advances not only include higher resolution two-dimensional imaging and M-mode, and improved Doppler interrogation (color, pulsed, high-frequency pulsed, and continuous wave), but also routine use of three-dimensional (3-D), pediatric transesophageal, and fetal echocardiography at many centers. Echocardiography is now the primary modality for diagnosing congenital heart disease. Multiple studies have validated the accuracy of echocardiography as the sole means of presurgical complete anatomic evaluation [11,12].

Full anatomic delineation should be undertaken before operative therapy, whenever possible, for appropriate surgical planning. We believe that incomplete or inaccurate information can be greatly minimized by performance of all echocardiograms for preoperative evaluation of congenital heart disease in a dedicated pediatric echocardiography laboratory. Preoperative evaluation is optimized by ensuring adequate patient cooperation with sedation and/or anesthesia when necessary. Care should be taken to acquire a thorough anatomic survey including pulmonary and systemic venous connections, aortic arch anatomy, and coronary artery origins and proximal courses to ensure discovery of any additional potentially surgical lesions or complicating anatomic abnormalities.

Three-dimensional echocardiography is helpful for better appreciation of complex cardiac geometry and spatial orientation of cardiac structures and lesions [13–15]. It provides unique imaging planes to allow clearer understanding of mechanisms of valvar disease and geometric configurations of septal defects. The reliability of quantitative assessment of ventricular function in complex single ventricular morphologies has been shown to be comparable to cardiac magnetic resonance when imaging windows are adequate [16].

Intraoperative transesophageal echocardiography (TEE) has become standard practice in centers performing repair of congenital heart disease. In one report, the majority of centers surveyed used intraoperative TEE in all open heart cases, while some centers employed TEE more selectively [17]. Intraoperative TEE is useful for obtaining further detail of anatomic lesions and for assessing immediate postoperative results. It is particularly valuable for high risk and complex congenital heart disease or cases involving valve repair, prompting return to cardiopulmonary bypass when residual lesions are found (Figure 4.2). It is also helpful for assessing ventricular function when separating from bypass [18]. Pediatric transesophageal 3-D probes are currently under development and live 3-D imaging holds promise for intraoperative assessment.

Atrial Septal Defects

Atrial septal defects are usually diagnosed in association with other congenital heart defects, but may be seen in isolation. The atrial septum should be examined as part of every complete initial echocardiogram since an ASD can be found incidentally or in the presence of a nonspecific flow murmur. A large atrial level left to right shunt leads to right ventricular volume overload. When right ventricular volume overload is seen on echocardiography, with right ventricular dilation and diastolic ventricular septal flattening (Figure 4.3A), full evaluation of the entire atrial septum and pulmonary venous connections with imaging and color Doppler is especially important.

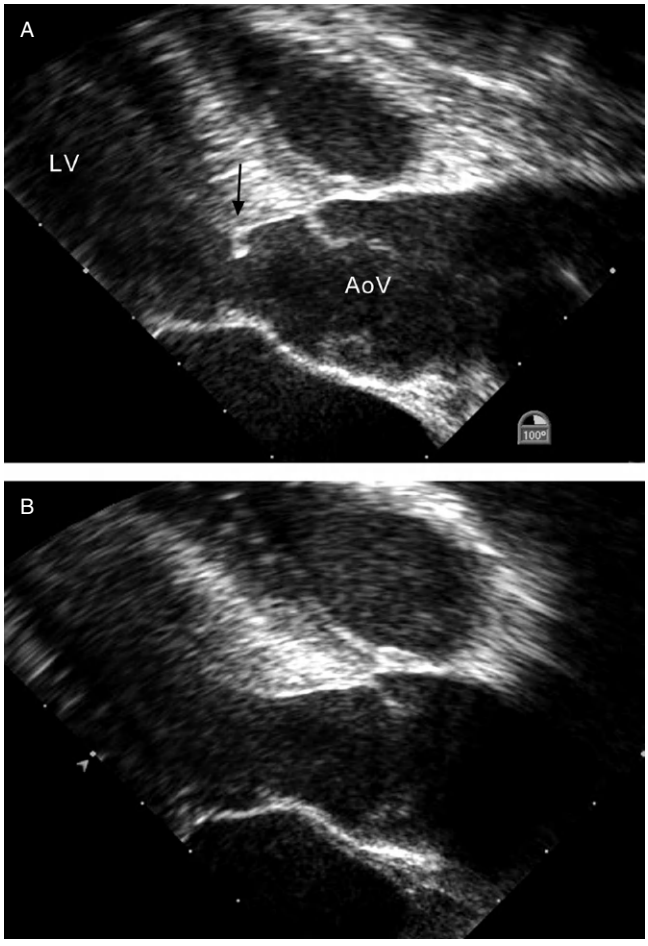

Figure 4.2 This intraoperative transesophageal echocardiogram shows **A,** a prominent subaortic membrane (arrow) before and **B,** following resection. (AoV, aortic valve; LV, left ventricle.)

When evaluating a patient with an ASD for surgery, it is important to understand the natural history of this lesion. Patent foramen ovale and ostium secundum ASDs <8 mm diagnosed in the first 3 months of life spontaneously close in 80% of cases [19], while spontaneous closure is rare after the age of 4 years [20]. The decision to close a secundum ASD by surgery versus catheter device closure depends on the size and anatomy of the defect. Surgery is generally the preferred option for repair of large defects when there are inadequate atrial rims for device closure. Sinus venosus defects and ostium primum ASDs do not close with time and require surgical repair when hemodynamically indicated.

In infants and young children, visualization of the atrial septum is best seen from subcostal views. Right sternal border view may be helpful in older patients. Secundum ASDs are seen in the central portion of the septum (Figure 4.3B). Sinus venosus defects are seen where there is an absence of the septum between the right upper pulmonary vein and the superior vena cava. This physiologically results in partial anomalous pulmonary venous return.

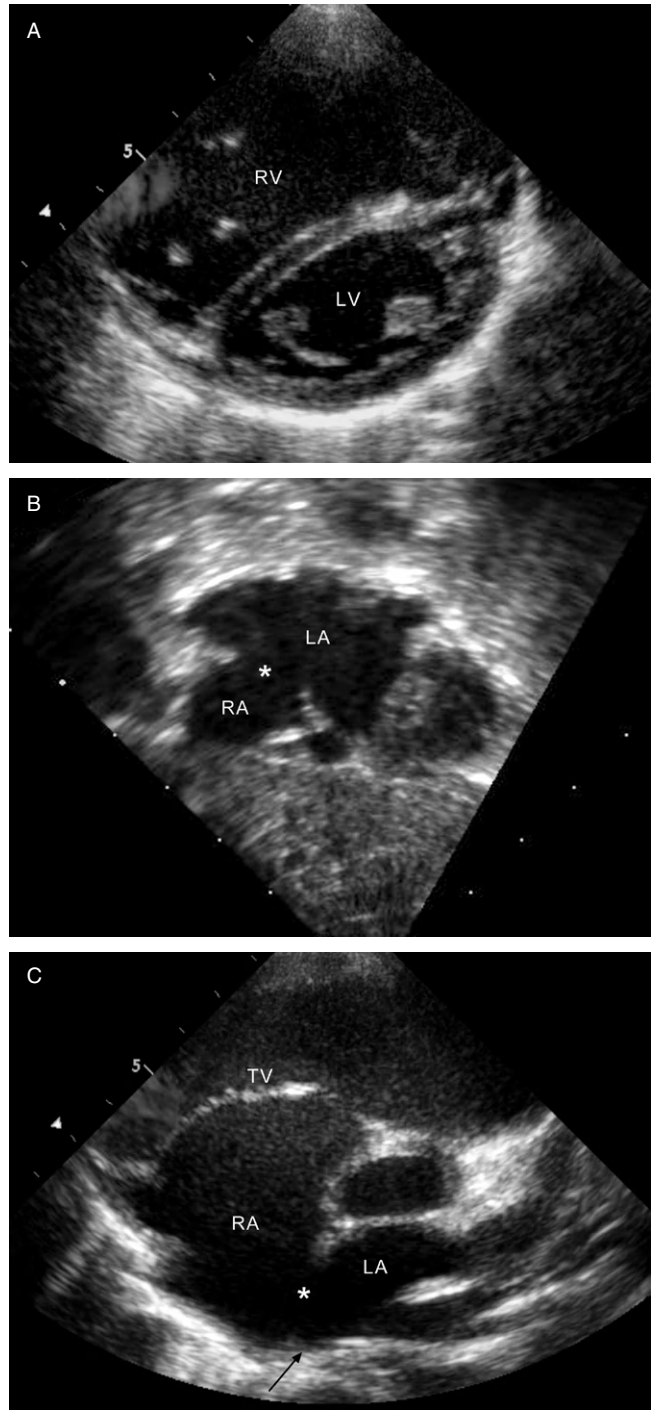

Figure 4.3 A, Parasternal short axis view shows right ventricular volume overload with right ventricular dilation and diastolic ventricular septal flattening. **B,** Subcostal long axis view shows a large secundum atrial septal defect (*).**C,** Parasternal short axis view shows an inferior-type sinus venosus defect (*). No posterior rim of septum is present. The arrow indicates the entrance of the right lower pulmonary vein. (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava.) See also Plate 4.1 (plate section opposite p. 594).

Additional or accessory right pulmonary veins may connect higher in the superior vena cava (SVC). This can often be demonstrated from right sternal border view. Sinus venosus defects are appreciated from subcostal and right sternal border views. As seen with color Doppler, flow is directed away from the orifice of the right upper pulmonary vein where it connects with the left atrium and across the defect into the proximal SVC (Plate 4.1A,B, see plate section opposite p. 594). Inferior type sinus venosus defects are found in the posterior-most portion of the atrial septum. Although the right lower pulmonary vein connection to the left atrium is normal, there is no atrial wall separating the right lower pulmonary vein flow from the right atrium. This is well seen from parasternal short view (Figure 4.3C). Primum ASDs are commonly seen with cleft mitral valve or as a component of common atrioventricular canal defect (CAVC). Primum ASDs are well imaged from apical four-chamber view.

Ventricular Septal Defects

Ventricular septal defects are described by their location (membranous, subpulmonary, conoventricular, or muscular) and their size. Like ASDs, VSDs may be seen in isolation, present with other lesions, or associated with complex congenital heart disease, such as TOF or CAVC. Echocardiographic evaluation is important for assessment of surgical necessity and associated heart defects. The natural history and associated cardiac lesions of each type of VSD may affect timing of surgical repair. Conoventricular malalignment VSDs occur as a result of anterior or posterior deviation of the conal septum and do not regress with time. Anterior malalignment VSDs may be seen alone or as part of TOF. Posterior malalignment VSDs are often seen in conjunction with aortic arch obstructions, such as CoA or interrupted aortic arch, particularly type B [21]. Some membranous VSDs may close spontaneously by growth of tricuspid valve tissue over the defect or be functionally restricted by aortic valve leaflet prolapsing into the defect. Membranous VSDs may occur with double-chambered right ventricular and/or subaortic membranes [22]. Subpulmonary (also called supracristal or intraconal) VSDs are found below the pulmonary valve and do not regress with time. These may be functionally restricted by unsupported aortic valve leaflet prolapsing into the defect. Early repair is usually recommended before aortic valve distortion and regurgitation occur or progress [23]. Many muscular defects become smaller or close with time. Large apical muscular defects can close functionally by hypertrophy of right ventricular muscle bundles or moderator band, such that the right ventricular infundibular apex remains open to the left ventricular apex and restricted from the right ventricular sinus (Figure 4.4A,B) [24].

Indications for surgery include congestive heart failure refractory to medical therapy or defects that do not appear to regress in the presence of pulmonary hypertension and/or left ventricular volume overload. Estimation of right ventricle pressure, using Doppler of the tricuspid regurgitation jet velocity, can be helpful in evaluating for pulmonary hypertension. In addition, systolic flattening of the ventricular septum may indicate elevated right ventricular pressure. Evidence of left ventricular volume overload owing to excessive left-to-right ventricular shunt includes measurement of left ventricular end-diastolic dimension and/or volume, which is compared with normative data relative to patient size (z-scores). Rarely, pulmonary artery banding may be preferable to allow time for potential closure or regression of some large defects or for defects that may be technically difficult for the surgeon to reach. Other indications for VSD repair include aortic valve prolapse resulting in aortic valve distortion with concomitant insufficiency.

VSDs should be imaged from all views to assess location, extent/size, and to find the optimal angle for Doppler interrogation of flow direction and transseptal gradient. Membranous, subpulmonary, and muscular VSDs (Figure 4.4C,D) are well seen from parasternal, subcostal, and apical views. Parasternal long and short axis views are particularly useful for assessing presence of aortic valve prolapse (Figure 4.4E,F). Subpulmonary VSDs should be distinguished from membranous VSDs since the surgical access is different. In parasternal short axis view, membranous VSDs are seen to the right of the aortic root just below the tricuspid valve (Figure 4.4F), while subpulmonary defects are anterior immediately below the pulmonary valve (Figure 4.4G).

Posterior malalignment defects are usually well defined from subcostal views, apical four-chamber view with anterior angulation to the left ventricular outflow tract (LVOT), and parasternal long axis view. Assessment of LVOT obstruction, which may be as surgically pertinent as the VSD, includes measurement of the LVOT diameter and Doppler estimation of the gradient. Anterior malalignment defects and inlet VSDs are discussed separately (TOF and CAVC sections, respectively).

Tetralogy of Fallot

Of the four basic components of TOF, anterior malalignment VSD, right ventricular volume outflow tract obstruction (RVOTO), overriding aortic valve, and right ventricular hypertrophy, the first two are surgically relevant. The VSD must be described with any posterior extension toward the inlet septum and/or the presence of additional VSDs. The severity and level of the RVOTO are variable. Usually subvalvar obstruction is found at the tip of the anteriorly deviated conal septum. There can be additional anterior muscle bundles at the os infundibulum (in the spectrum of double-chambered right ventricle). This is often well seen from subcostal and parasternal short axis views. The length and degree of conal septal thickening are well seen from parasternal views (Figure 4.5A,B). The pulmonary valve

(AoV, aortic valve; LA, left atrium; LV, left ventricle; PV, pulmonary valve; RA, right atrium; RV, right ventricle.)

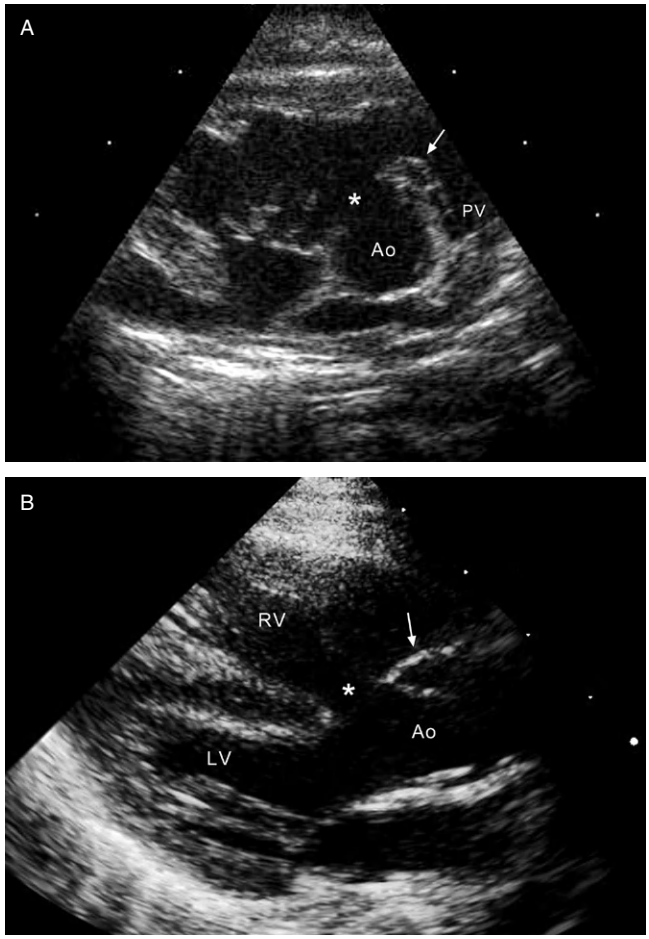

Figure 4.5 Parasternal short (**A**) and long (**B**) axis views of a patient with tetralogy of Fallot shows a thickened anteriorly deviated conal septum (arrow) with large conoventricular septal defect (*). (Ao, aorta; LV, left ventricle; PV, pulmonary valve; RV, right ventricle.)

annulus should be measured and leaflet motion assessed. If the pulmonary valve is adequate, a valve-sparing surgical technique may be possible [25]. An optimal angle for Doppler interrogation of the RVOT gradient can usually be obtained from subcostal short or parasternal views. In addition, the size and confluence of the branch pulmonary arteries need to be seen. In the most extreme form of TOF, or TOF with pulmonary atresia, branch pulmonary arteries may be diminutive with a majority of pulmonary blood flow provided by aortopulmonary collateral arteries. Angiography is often undertaken routinely to examine the extent and distribution of aortopulmonary collateral arteries; however, echocardiographic criteria of branch pulmonary artery size may be helpful in identifying patients who do not require additional diagnostic imaging [26].

The coronary anatomy in TOF should be identified. Echocardiography has been shown to reliably detect coronary abnormalities in TOF [27,28]. In TOF, there is often clockwise rotation of the aortic root such that the right coronary artery originates more leftward and the left coronary artery more posterior than in a normal heart. Of more importance, a significant conal branch or dual left anterior descending from the right coronary artery crossing anterior to the RVOT must be identified to prevent damage if an RVOT patch is required to relieve pulmonary outflow obstruction.

Associated lesions include ASD, PDA, and right aortic arch. TOF may be seen in combination with CAVC.

Truncus Arteriosus

In truncus arteriosus, one great artery is present giving rise to the coronary arteries, pulmonary arteries, and systemic arteries, usually with a conoventricular septal defect [29]. As with many forms of congenital heart disease, the diagnosis can be made by echocardiography from the initial subcostal sweep. A single common trunk with only one semilunar valve and outflow tract is seen (Figure 4.6A). The presence of a main pulmonary artery (type I) or position of the branch pulmonary arteries directly from the trunk (type 2 and 3) determines whether the pulmonary arteries can be excised from the trunk and anastomosed to the right ventricular–pulmonary artery conduit together or separately. Often the branch pulmonary arteries can be seen arising immediately adjacent to each other with minimal or no true main pulmonary artery (so called "type 1½"). The pulmonary artery arrangement from the trunk is usually seen best from parasternal short axis view (Figure 4.6B). The proximity of the main pulmonary artery or the branch pulmonary arteries to the left coronary ostium is well assessed from parasternal long axis view (Figure 4.6C).

The morphology and functional status of the truncal valve should be assessed for stenosis and/or insufficiency which could require valvuloplasty. The most common truncal valve morphologies are bicuspid, tricuspid, and quadricuspid (Figure 4.6D). It is important to evaluate the arch side and structure. Interruption of the aortic arch defines type 4 truncus arteriosus. As with all other diagnoses, other associated lesions such as ASD, additional VSDs, and PDA should be sought.

Common Atrioventricular Canal

Common atrioventricular canal, or atrioventricular septal defect, represents a spectrum of endocardial cushion defects with variations of the three main components. The complete CAVC includes a large primum ASD, large inlet VSD, and a common atrioventricular valve (AVV). A partial AVC includes presence of a primum ASD and cleft mitral valve only, while a transitional AVC includes also a functionally small VSD owing to AVV attachments to the crest of the ventricular septum restricting the ventricular shunt. Full preoperative evaluation, including definition of the size and extent of each component, can usually be accomplished with echocardiography alone [30].

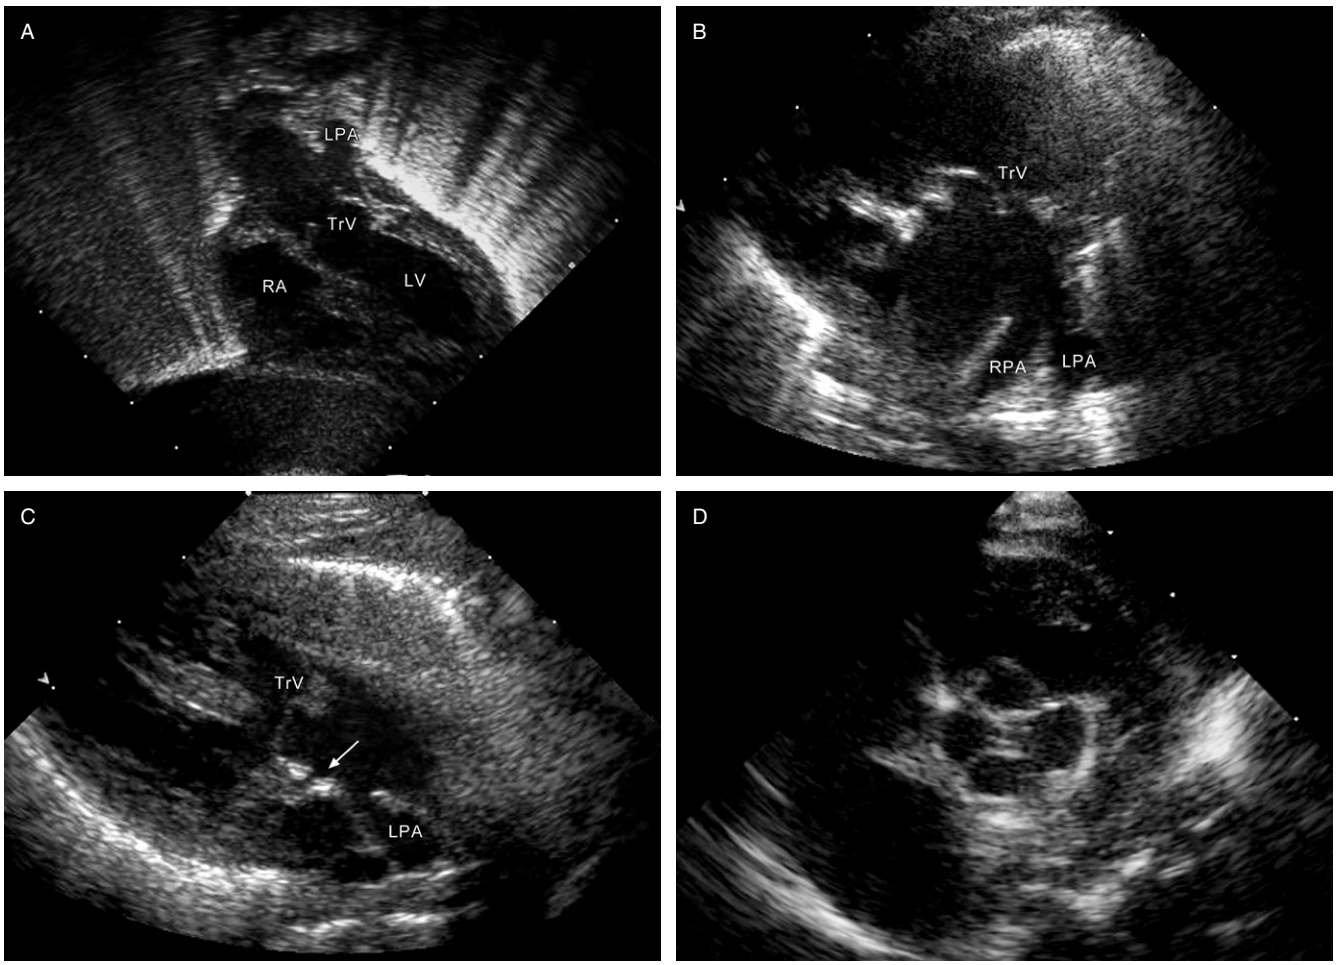

Figure 4.6 A, Subcostal long axis view of a patient with truncus arteriosus shows a single truncal outflow and the left pulmonary artery arising from it. **B,** Parasternal short axis view shows short segment main pulmonary artery arising from the left posterior side of the trunk. There is no evident conal septum seen. **C,** Parasternal long axis view shows the proximity of the left coronary artery ostium (arrow) to the left pulmonary artery takeoff. **D,** Parasternal short axis view shows a quadricuspid truncal valve. (LPA, left pulmonary arteryl; LV, left ventricle; RA, right atrium; RPA, right pulmonary artery; TrV, truncal valve.)

Assessment of ventricular balance of the CAVC defect is an essential part of the initial echocardiogram. CAVC can be well balanced with equal portions of the common AVV sitting over each ventricle or unbalanced with dominance of either right or left ventricle. This is well seen from a subcostal view slightly rotated counter-clockwise from short axis (in-between view) (Figure 4.7A). The number and spacing of the left ventricular papillary muscles should be seen. In cases of significant ventricular dominance (and concomitant hypoplasia of the other ventricle), a two-ventricle surgical approach may not be favorable.

Competency of the common AVV (or left and right AVVs in the case of partial AVC) is of obvious importance. Several views should be used to assess the degree and location of regurgitation jet(s) (Figure 4.7B). Apical four-chamber view also illustrates the apical displacement of the common AVV (Figure 4.7C). Separate AVV annuli are seen at the same level in partial AVC (normally the tricuspid valve is slightly apically offset from the mitral valve). AVV attachments, especially of the inferior bridging leaflet, to the crest of the ventricular septum should be noted. Straddling attachments may complicate the operation. Other hemodynamic preoperative considerations include LVOTO, from AVV attachments to the ventricular septum and/or a subaortic membrane, and pulmonary hypertension, both assessable by Doppler interrogation.

d-Transposition of the Great Arteries

In d-TGA, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. The pulmonary and systemic circulations in this disease are in parallel (rather than in series) and therefore completely inefficient. Survival depends on bidirectional shunting. An associated

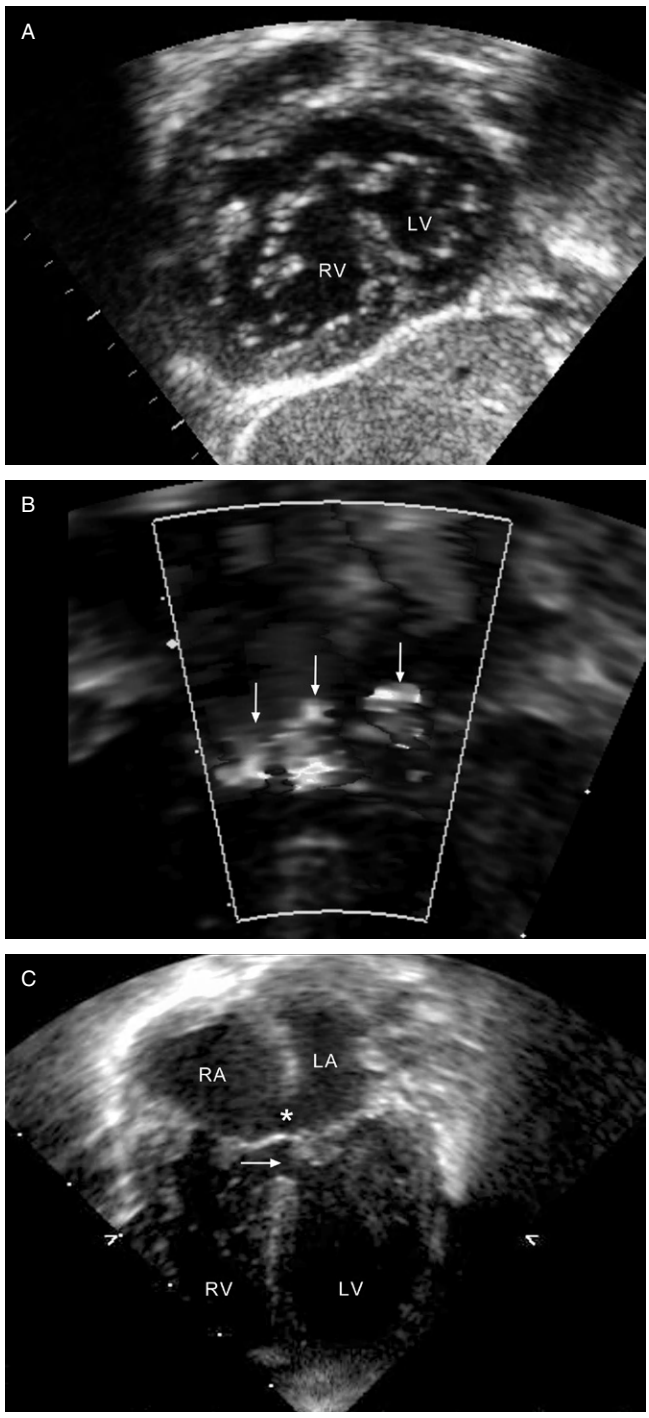

Figure 4.7 A, Subcostal "in-between" view shows a mild right ventricular dominant common atrioventricular canal defect. **B,** Color Doppler in apical four-chamber view shows common atrioventricular valve with multiple regurgitation jets (arrows). **C,** Apical four-chamber view shows a primum atrial septal defect (*) and an inlet VSD (arrow). (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.)

VSD, seen in 40–50% of cases, can be of any type or size. A VSD is not usually sufficient for adequate mixing of oxygenated pulmonary venous blood to the systemic circulation. Initially, maintenance of a PDA by administering prostaglandin E is necessary. Most often a balloon atrial septostomy (BAS) is performed for maximal atrial level mixing in order to allow for spontaneous ductal closure until definitive surgery is performed. BAS can now also be performed under echocardiographic guidance. Color and pulsed Doppler are used to ensure the ASD is unrestrictive following BAS.

From subcostal views, the pulmonary artery with its bifurcation is identified arising from the left ventricle. One can appreciate that the arteries arise parallel to each other instead of crossing outflow tracts. This parallel orientation of the great arteries is also well seen from parasternal long axis view (Figure 4.8A). Measurement of the diameters of the great arteries is possible from this view. The aorta is usually anterior and rightward of the PA, but the relationship can be side by side. This orientation is best seen from parasternal short axis view (Figure 4.8B).

Delineation of the coronary anatomy is of obvious preoperative importance before coronary transfer in the arterial switch operation. Echocardiography is now the primary mode of diagnosing coronary anatomy in d-TGA [31,32]. The most useful view for imaging the right and left coronary ostia and proximal segments is parasternal short axis. The bifurcation of the left coronary artery and proximal left anterior descending artery is often seen from leftward angled parasternal long axis [31]. Usually the coronary arteries arise from the right and left sinuses facing the pulmonary valve. The next most common variation is the left circumflex arising from the right coronary artery. Multiple other coronary patterns can be seen, including single coronary and inverted coronary anatomy. Uncommon coronary anatomy pattern, especially involving intramural segments passing between the arterial roots, had in the past been considered to be an operative risk factor for arterial switch operation [33], but more recently does not increase surgical risk at high volume centers [34]. Associated cardiac lesions should be identified. Complex d-TGA with VSD and aortic arch obstruction represents a higher operative risk group [35].

Coarctation of the Aorta

Coarctation of the aorta and other LVOT obstructions should be considered in any infant with clinical evidence of poor cardiac output. Patients beyond infancy with CoA may present with isolated systemic hypertension and decreased femoral pulses. Aortic arch imaging is best accomplished from suprasternal views. The classic finding is a posterior shelf or "3-sign" in the distal aortic arch (Figure 4.9A). In a high percentage of older patients, echocardiographic imaging of the CoA may not be ade-

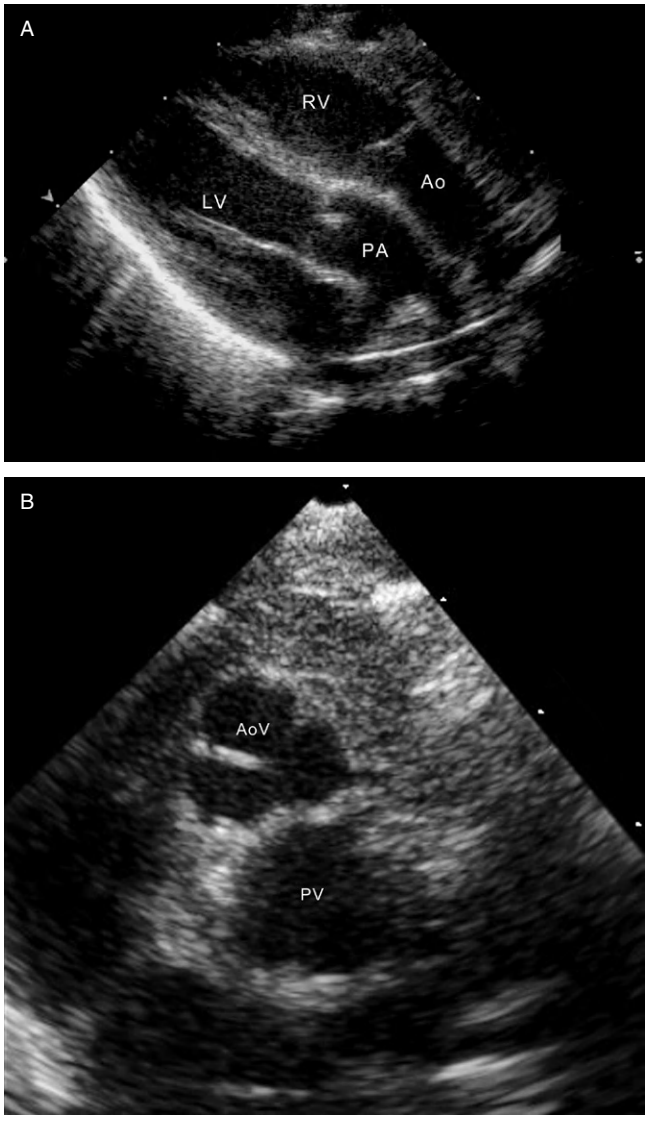

Figure 4.8 A, Parasternal long axis view in a patient with d-transposition of the great arteries shows the parallel orientation of the great arteries. **B,** Parasternal short axis view shows the anterior and rightward position of the aortic valve in relation to the pulmonary valve. Proximal coronary arteries are seen arising from the right and left facing sinuses. (Ao, aorta; AoV, aortic valve; LV, left ventricle; PA, pulmonary artery; PV, pulmonary valve; RV, right ventricle.)

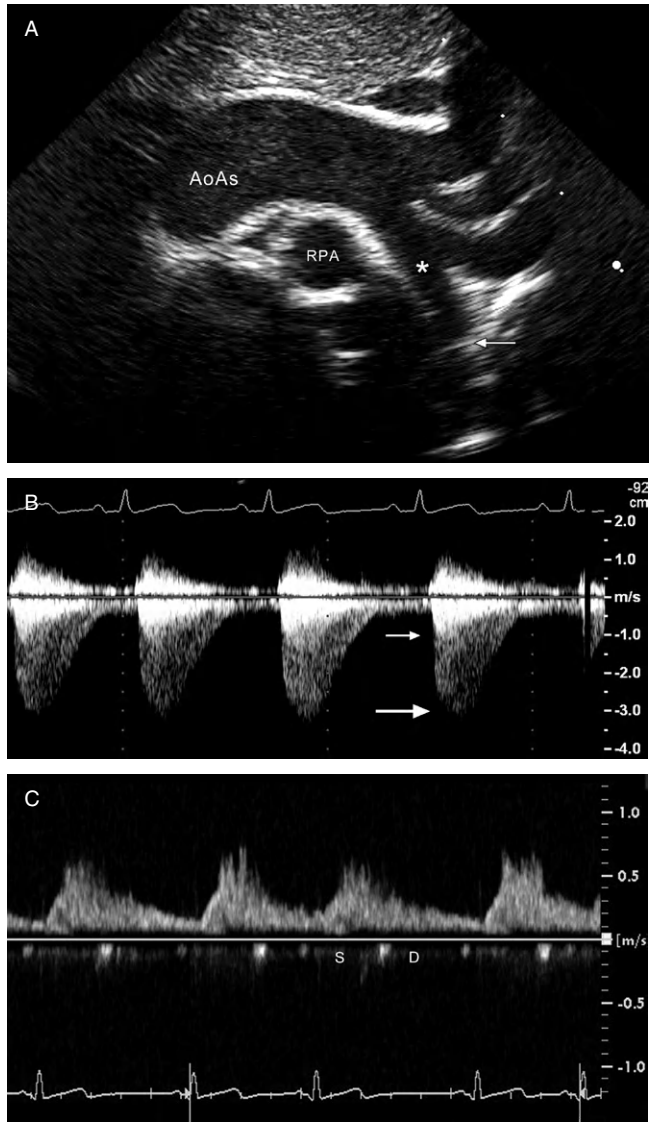

Figure 4.9 A, Suprasternal view of the long axis of the aortic arch shows an elongated hypoplastic transverse arch (*) and discrete posterior shelf at the coarctation site (arrow). **B,** Continuous-wave Doppler in the distal aortic arch shows a double envelope pattern. The small arrow indicates the low velocity proximal envelope and the large arrow indicates the accelerated flow across the coarctation site. **C,** Abdominal aortic Doppler interrogation shows blunted systolic upstroke (S) and continuous antegrade flow through diastole (D). (AoAs, ascending aorta; RPA, right pulmonary artery.)

quate; however, when this region is well seen, results are as reliable as those by magnetic resonance imaging (MRI) [36].

Continuous-wave Doppler across the distal arch reveals a double-envelope pattern, a low proximal velocity signal, and an accelerated flow signal across the coarctation site (Figure 4.9B). The characteristic abdominal aortic Doppler pattern has a blunted systolic upstroke and continuous antegrade flow through diastole (Figure 4.9C). These classic findings may not be readily evident in the newborn with a large PDA. However, an elongated hypoplastic transverse arch segment or other left-sided cardiac obstructive lesions should heighten suspicion and prompt repeated investigation of the aortic arch as the PDA closes.

Bicommissural aortic valve is associated with CoA in up to 85% of patients. Fusion of the right and left coronary leaflets is most common (70%), while aortic valve disease is more prevalent with fusion of the right and noncoronary leaflets [37].

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) represents a spectrum of congenital heart disease with hypoplastic obstructive left-sided cardiac lesions. It can range from aortic and mitral atresia with an underdeveloped left ventricle to milder forms of left heart obstruction [38,39]. Implied in this diagnosis is left-sided anatomy of insufficient size to sustain cardiac output and dependence on the right ventricle for pulmonary and systemic blood flow (Figure 4.10A,B).

The usual surgical approach to infants with HLHS is staged single ventricular palliation, culminating in the Fontan operation. Cardiac transplantation as a primary treatment for HLHS has lost favor because of donor availability and the long-term complications of chronic rejection. During staged palliation, blood is rerouted through the heart such that the right ventricle and tricuspid valve become the systemic ventricle and AVV, respectively, and the pulmonary artery becomes the neoaorta. Therefore, echocardiographic assessment must focus on the functional status of the pulmonary and tricuspid valves and the right ventricle. The sizes and gradients across the mitral and aortic valves are irrelevant because most of the pulmonary venous return is shunted to the right across the atrial septum. Echocardiographic evaluation of the atrial septum is important in the newborn with HLHS and includes imaging and color and pulsed Doppler interrogation of mean gradient. Mild restriction across the atrial septum is protective from pulmonary overcirculation. However, an intact atrial septum is associated with significant pulmonary hypertension and increased mortality [40]. Likewise, survival is dependent on right-to-left flow across the PDA for perfusion of the descending aorta and retrograde perfusion of the ascending aorta. Severe hypoplasia of the

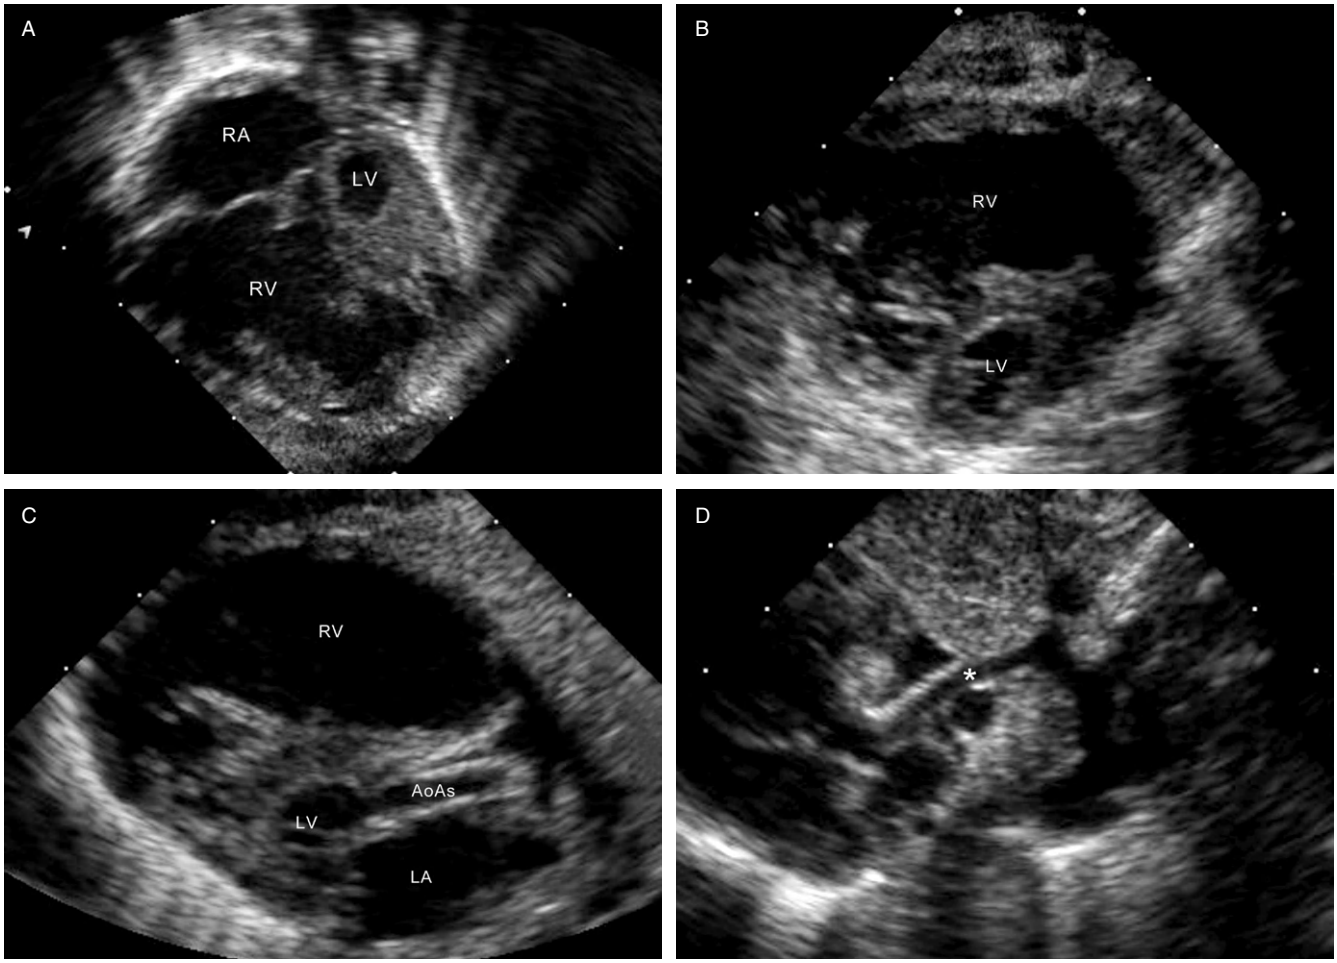

Figure 4.10 In a patient with hypoplastic left heart syndrome. **A,** Apical four-chamber view and **B,** parasternal short axis view show a hypoplastic left ventricle and large right ventricle. **C,** Parasternal long axis view shows a hypoplastic ascending aorta. **D,** Aortic arch image from suprasternal notch shows the size difference between the native ascending aorta (*) and the distal arch. (AoAs, ascending aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.)

ascending aorta has been associated with higher stage I mortality risk, likely because of dependence of the coronary perfusion on retrograde flow through the attenuated length of ascending aorta [41]. Measurement of the ascending aortic diameter is usually optimal from parasternal long axis view (Figure 4.10C). Assessment of coronary artery anatomy should be part of all preoperative echocardiographic examinations for HLHS since the surgical approach for HLHS involves the ascending aorta, and coronary injury may result if an anomaly is not identified [42]. Anomalous pulmonary venous connection and drainage has been reported in approximately 6% of patients with HLHS who underwent stage I Norwood procedure. Subcostal and suprasternal imaging and color Doppler flow mapping have been found most helpful for delineating pulmonary venous anatomy [43]. Imaging aortic arch anatomy is of obvious importance before reconstruction and Blalock–Taussig shunt placement (Figure 4.10D).

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (cMRI) has evolved into an excellent noninvasive imaging modality. It complements echocardiography in the diagnosis and preoperative and postoperative assessment of patients with a wide range of congenital heart disease. It is a tomographic technique where images are derived from protons, which are present in abundance in the human body.

Cardiac MRI provides detailed anatomic information with excellent spatial resolution, and it allows for 3-D reconstructions with no limitation of imaging plane. It can be particularly useful in children and adults with complex congenital heart disease, limited acoustic windows, limited vascular access, and in the assessment of extracardiac structures [44]. It has the additional advantage of not exposing patients to ionizing radiation or potentially nephrotoxic iodinated contrast agents, as in computerized tomography (CT) or heart catheterization. Limitations include the fact that it is not portable, it requires sedation in young children, the post-processing is long, and it is contraindicated in patients with certain metal implants. Although monitoring strategies for performing cMRI in patients with pacemakers and implantable cardiac defibrillators have been proposed, the presumed risks are not yet known sufficiently to justify routine cMRI in this group of patients [45].

Applications of Cardiac MRI

Cardiac MRI is considered the best imaging modality when anatomic and functional information are needed and its applications continue to expand. It includes the evaluation of patients with anomalies of the aorta, such as CoA, interrupted aortic arch, and vascular rings, systemic and pulmonary venous abnormalities, functional single ventricles, and arterial and venous collateral vessels. It can be reliably used to quantify shunts (Qp:Qs ratio), vessel-specific blood flow [46,47], regurgitant volumes, and ventricular volumes [48–50]. It has an advantage over echocardiography and CT in tissue characterization and the evaluation of myocardial and pericardial diseases [44].

The basics of MRI are beyond the scope of this chapter. However, some imaging features will be briefly addressed. Special software programs called pulse sequences are used to obtain the MR images. An individual pulse sequence is a combination of radiofrequency pulses, magnetic gradient field switches, and timed data acquisitions, all applied in a precise order. Before starting a study, protocols are predetermined and specific pulse sequences selected based on the question to be answered. Steady-state-free-precession (SSFP) and segmented K-Space gradient echo sequences are the two bright blood cine sequences widely used for cardiac anatomy. SSFP cines are highly reproducible in the measurement of ejection fraction, ventricular volumes and mass [49]. Cine MRI has become the gold standard for the measurements of these parameters [49].

Phase contrast velocity mapping or velocity encoded cine imaging (VENC) is used to measure blood flow velocities in arteries, veins, across cardiac valves, and to quantify cardiac shunts (Qp:Qs). It has been shown to correlate well with oximetry by catheterization [46,47]. VENC is the equivalent of Doppler in echocardiography. The measurement of the Qp:Qs ratio is often important. The ability to quantify Qp:Qs ratio by MRI can be very valuable in medical and surgical planning of selected patients with left-to-right shunt lesions such as ASDs and VSDs and partial anomalous pulmonary venous return.

Contrast-enhanced MR angiography (CE-MRA) is used to delineate arterial and venous structures [51]. Paramagnetic agents such as gadolinium (Gd) are given intravenously as Gd-diethylene-triamine pentaacetic acid (DTPA) and by altering the magnetic properties of tissues allow delineation of vascular structures with excellent spatial resolution [52]. Maximum intensity projection reconstructions allow 3-D visualization of arterial and venous structures. With the use of delayed contrast enhanced cMRI greater contrast can be achieved between normal and abnormal myocardium by a delay in the washout of contrast from the abnormal myocardium [52]. This technique has become the technique of choice to characterize tissues in myocardial and pericardial processes. Gadolinium DTPA has a safety profile superior to the iodinated contrast used in CT and heart catheterizations, but it has been linked to over 200 cases of nephrogenic systemic fibrosis in adults [53]. Thus far, this has not been reported in children.

Intracardiac Shunts

Atrial septal defects and VSDs are common, result in left-to-right shunts and the anatomy is well defined by echocardiography, the imaging modality of choice in young children. Cardiac MRI has been increasingly used in older patients and adults in whom echocardiographic images are often more limited. It can accurately provide anatomic and hemodynamic information by delineating the size, rims [54], direction of blood flow, number of defects in patients with ASD, and associated abnormalities most commonly seen in patients sinus venosus ASDs [55]. It is helpful in determining the suitability for percutaneous versus surgical closure of the defect. In patients with partial anomalous pulmonary venous return, cMRI is a valuable tool in precisely defining the anomalous drainage site and the relationship to adjacent structures, which are very important in the surgical approach to these patients. The Qp:Qs ratio can be determined by VENC by measuring flow in the ascending aorta and pulmonary artery. Gadolinium enhanced MRA is used to delineate the pulmonary and systemic venous anatomy (Figure 4.11).

Tetralogy of Fallot (TOF)

Tetralogy of Fallot is the most common form of cyanotic congenital heart disease and the anatomy can be well defined in infancy by echocardiography. Pulmonary artery branch stenosis is a common associated finding in these patients and SSFP cines and CE-MRA can be used to better delineate the pulmonary artery anatomy. It is important to identify the 5–6% of patients with a major coronary artery crossing the right ventricular outflow tract before surgical repair [28]. A free-breathing navigator gated and ECG triggered 3-D MRA sequence is a noninvasive alternative to define the proximal coronary anatomy [56] when echocardiography is suboptimal. Surgical repair during infancy, which includes a combination of infundibular resection, pulmonary valvotomy, and a transannular patch, often results in pulmonary insufficiency. Repaired TOF patients with a transannular patch often have significant pulmonary insufficiency. Chronic pulmonary insufficiency can lead to progressive right ventricular enlargement, right and left ventricular dysfunction, exercise intolerance, development of atrial and ventricular arrhythmia, and sudden death [57–60]. The long-term effects of restoring pulmonary valve competence by replacing the pulmonary valve are still unknown. Although improvement in ventricular dimensions and function and exercise capacity have been shown to directly correlate with the timing of pulmonary valve replacement (PVR) [61–65] recent data showed that PVR does not result in significant changes in QRS duration, incidence of ventricular tachycardia, or survival, supporting the need to continue to refine the appropriate timing

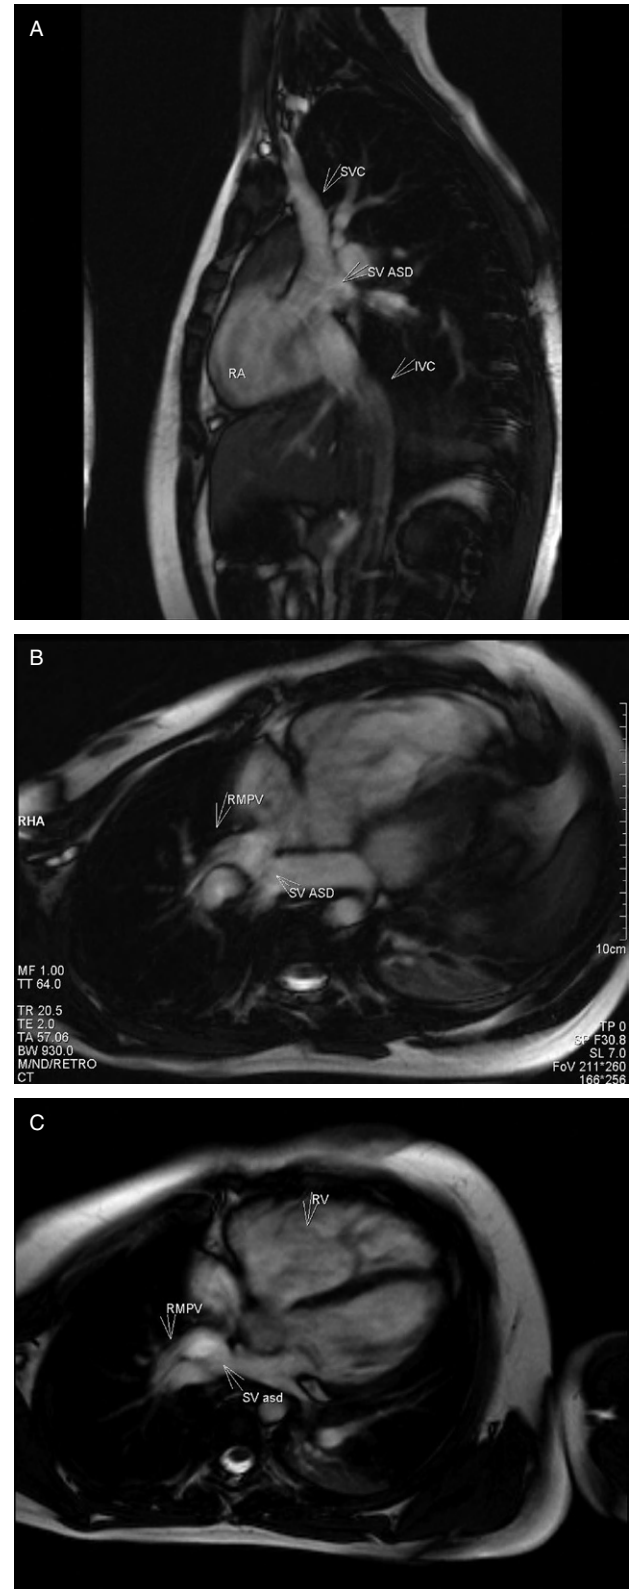

Figure 4.11 **A,** Cine – sinus venosus atrial septal defect (SV ASD). **B,** Partial anomalous venous return (PAPVR) of the right middle pulmonary vein (RMPV). **C,** Dilated right ventricle (RV). (IVC, inferior vena cava; RA, right atrium; SVC, superior vena cava.)

for PVR [66]. Cardiac MRI has become the gold standard in the evaluation of right ventricular volumes [61] and systolic function and the quantification of pulmonary regurgitation when trying to determine the appropriate timing for PVR. The use of Gd-delayed and enhanced MRI can detect areas of right ventricular and left ventricular fibrosis, which has been found to be a predictor of arrhythmia with potential prognostic implications in terms of morbidity and mortality in repaired TOF patients [67].

Pulmonary Blood Supply in Patients with Pulmonary Atresia

In patients with complex pulmonary valve stenosis or atresia, the pulmonary vascular bed may be supplied by stenotic, hypoplastic, or discontinuous pulmonary arteries. Pulmonary arteries may be absent and segments of the lung supplied by collateral vessels. Defining all sources of pulmonary blood flow, and the presence and distribution of aortopulmonary collateral vessels are very important for patient management [68]. Gadolinium-enhanced 3-D MRA has been shown to accurately define all sources of pulmonary blood flow with good agreement with X-ray angiography and it has been proposed as a noninvasive alternative to cardiac catheterization [69].

Congenital Vascular Abnormalities

Coarctation of the aorta consists of a discrete stenosis usually just distal to the left subclavian artery (Figure 4.12). It is frequently associated with hypoplasia of the aortic arch, anomalies of the brachiocephalic arteries, and mitral and aortic valve abnormalities. The diagnosis is usually made by echocardiography. However, in patients with complex aortic arch anomalies and suboptimal echocardiographic imaging, high resolution anatomic definition can be shown by cMRI using various MR techniques, including SSFP and CE-MRA. The severity of the obstruction can be determined by analyzing the descending aorta flow characteristics such as peak velocity and gradient, blood flow pattern, the presence of collateral vessels and their flow assessment by VENC imaging [70,71]. Cardiac MRI is also useful in the evaluation of left ventricular function, left ventricular mass, and associated lesions.

Vascular rings are rare malformations representing less than 2% of all forms of congenital heart disease. The presenting symptoms result from tracheoesophageal compression and include chronic cough, stridor, wheezing, recurrent pneumonia, cyanosis, and dysphagia. Double aortic arch with a dominant right aortic arch and hypoplasia or atresia of the left aortic arch is the most common form of vascular ring followed by a right aortic arch with anomalous origin of the left subclavian artery from a Kommerell's diverticulum (Figure 4.13). Although pulmonary artery sling and innominate artery compression are not complete anatomic rings, they are included in the

Figure 4.12 Severe coarctation of the aorta (COA) and a very prominent network of collateral arteries.

Figure 4.13 Three-dimensional reconstruction in a coronal view of a vascular ring (right aortic arch; RAA) with aberrant origin of the left subclavian artery (LSA) from a Kommerrel's diverticulum (KD). (LCC, left common carotid; RCC, right common carotid; RSA, right subclavian artery.)

description of these vascular abnormalities because of the similarities in presentation, diagnosis, and surgical management. Echocardiography is the initial choice of imaging and it is useful to exclude coexisting intracardiac abnormalities seen in up to 20% of cases [72]. However, cMRI is most useful in providing not only detailed anatomic information of the vascular anomaly but also the relationship to the airways and degree of obstruction, which along with the clinical symptoms will help determine the management choice in these patients. A combination of SSFP, conventional CE-MRA and the whole heart navigator gated 3-D MRA are used in the evaluation of vascular rings. The whole heart navigator gated 3-D MRA does not require the administration of contrast. It provides high spatial resolution images of the vascular anatomy with the ability to perform 3-D reconstructions with no limitation to the plane of imaging [71,73].

Single Ventricle

Patients with single ventricle physiology typically undergo a series of palliative operations. A heart catheterization is performed before the cavopulmonary anastomosis and before the Fontan completion as the standard of care to assess the anatomic and hemodynamic suitability for these procedures. It also provides the opportunity to perform catheter-based interventions such as embolization of arterial and venous collateral vessels and balloon angioplasty of CoA. In selected patients and after echocardiographic screening, cMRI has been shown to be safe, effective, and less costly in the preoperative evaluation of these patients, and it has been proposed as an alternative approach for single ventricle physiology patients [74] (Figure 4.14).

Multislice Computerized Tomography

The development of multidetector CT technology has allowed for extremely fast acquisition with very high spatial resolution. Computed tomography can be considered an alternative to cMRI for anatomic definition and 3-D reconstructions of cardiac and extracardiac structures. Limited functional information can be obtained [75]. Computed tomography has been more often considered an alternative in patients with pacemakers and also to conventional coronary angiography, as it provides valuable detailed anatomic information in patients with anomalous origin of the coronary arteries in terms of the site of origin and course in relationship to the surrounding structures. The short acquisition time and the obviation of the need for sedation are advantageous compared with cMRI, however, there are significant concerns with radiation exposure [76] and the use of potentially nephrotoxic iodinated contrast agents.

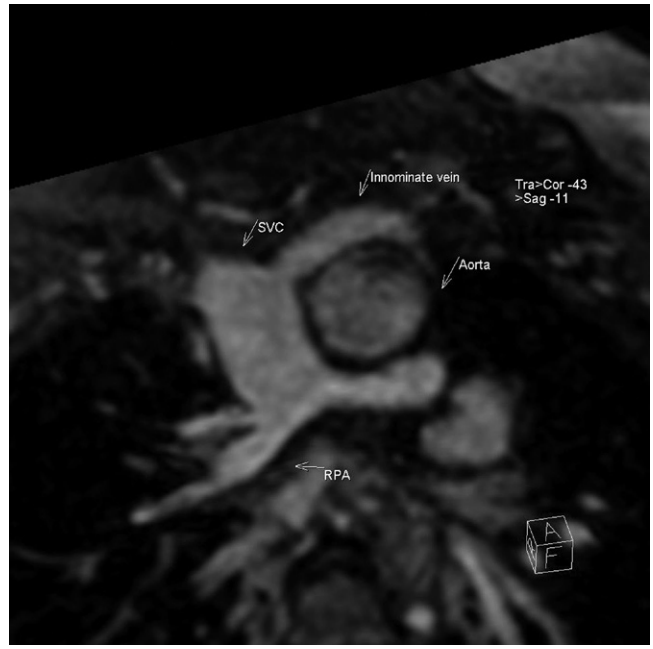

Figure 4.14 Whole heart three-dimensional MRA reconstruction of a widely patent cavopulmonary anastomosis (Glenn shunt) and pulmonary artery branches. (RPA, right pulmonary artery; SVC, superior vena cava.)

Cardiac Catheterization

The role of cardiac catheterization for congenital heart disease in infants, children, and adults has evolved tremendously over the past three decades. While initially utilized as a diagnostic tool to ensure precise definition of anatomy, its role has been transformed into a therapeutic tool and revolutionized the field, forming an even stronger association with the surgeon, be it via preoperative or postoperative intervention (ASD, VSD, aortopulmonary shunt, PDA, paravalvar leak closures, atrial septal angioplasty, valvar, branch pulmonary artery, conduit or aortic coarctation dilations, and/or stent implantations, as well as percutaneous valve implantation). These types of procedures will cause an even greater collaboration between surgeons and interventionalists in the future with the advent of more commonly performed hybrid procedures. Regardless of the type of catheterization, diagnostic or interventional, initial attainment of accurate hemodynamic data is essential.

A fundamental understanding of basic instrumentation and cardiovascular physiology is essential to properly assess hemodynamics in patients with congenital heart disease. While a complete assessment of techniques used to measure physiologic variables in congenital heart disease can be researched in more depth elsewhere, a basic overview to understand the methods follows.

Pressure Measurements

The pressure at the catheter tip is transmitted through the catheter and tubing to a transducer and then converted to an electrical signal, which is passed to a multichannel recorder and then by an optical beam to photographic paper. This entire system must meet certain requirements to accurately display intravascular pressures. Errors can occur in any of these components. These include accommodating for heart rate variations, damping, adjusting the height of the transducer and proper calibration, displaying pressures at different attenuations with display of the mean (time averaged pressure by electronic damping), and the type of catheter selected (stiff, large, and short catheters being ideal in this regard)

The normal right atrial pressure consists of the **a**, **c**, and **v** waves as well as the **x** and **y** descents. The **a** wave reflects atrial contraction at the end of diastole and is typically the prominent wave in the right atrium. The **c** wave represents displacement of the tricuspid valve toward the right atrium in early systole which is noted as the small note on the downslope of the **a** wave. The **v** wave peaks during late systole and reflects the continued atrial filling against the closed tricuspid valve. The **x** descent occurs owing to a decrease in pericardial pressure and movement of the tricuspid valve away from the right atrium during ventricular contraction and is the fall in pressure following the **a** and **c** waves. The **y** descent reflects the decrease in pressure after the **v** wave as the tricuspid valve opens at the start of diastole. Flow in the venae cavae is greatest during the **x** and **y** descents and have similar tracings to the right atrium except in cases of potential obstruction, which can be seen in patients who have undergone a Mustard or Senning procedure or repair of anomalous pulmonary venous connections involving the venae cavae. The normal mean right atrial pressure is 3 mmHg, with typical measurements made at the end of expiration when it is highest [77–79]. The **a** wave is typically larger but may be increased in cases of decreased compliance as a result of right ventricular dysfunction, tricuspid stenosis or atresia, particularly with a restrictive atrial communication. The **v** wave is higher in cases of tricuspid regurgitation.

The left atrial pressures have similar **a**, **c**, **v** waves and **x**, **y** descents but here the **v** wave is dominant. Normal mean left atrial pressure is 8 mmHg [77–79]. Left atrial hypertension occurs in patients with decreased compliance as with left ventricular dysfunction or with obstructive lesions such as mitral stenosis, especially with a restrictive ASD. The **v** wave is increased in mitral regurgitation as well as with large left-to-right shunts, and decreased in total anomalous venous return.

The pulmonary artery wedge pressure reflects the left atrial pressure and is obtained by advancing an end hole catheter with or without a balloon to occlude a pulmonary artery branch. This is often recorded simultaneously with the left ventricular end-diastolic pressure with which there should be no gradient. The capillaries and pulmonary veins cause a delay and relatively damped pressure as compared with direct measurement of the left atrial pressure, but the pulmonary artery wedge pressure is accurate below a mean of 20 mmHg. Normal values in children are a mean of 8 mmHg [77–79].

Pulmonary vein wedge pressure is useful in estimating the pulmonary artery pressure in cases when the pulmonary arteries cannot be entered. The technique is similar to that for the pulmonary artery wedge pressure and is dependent upon careful attention to proper wedging technique as well as transducer calibration. This measurement accurately estimates a pulmonary artery mean pressure of 20 mmHg or less when the mean is less than or equal to 15 mmHg but loses its predictability when elevated further [80].

Right ventricular pressure tracings are characterized by a rapid upstroke during isovolumic contraction, a systolic plateau, and a fall to near zero during isovolumic relaxation. The pressure varies with respiration as the right atrial pressure. The normal right ventricular systolic pressure is less than 30 mmHg and end-diastolic pressure 5 mmHg [77–79]. Right ventricular hypertension is seen in cases of outflow obstruction (valvar or subvalvar pulmonary stenosis, pulmonary artery stenoses, after placement of pulmonary artery bands, and in a double-chambered right ventricle), pulmonary hypertension (primary and secondary), as well as with nonrestrictive VSDs.

The left ventricular pressure wave form is similar to that of the right ventricle but has a more rapid upstroke and flatter systolic plateau. This pressure should be equal to the aortic systolic pressure. The end-diastolic pressure is typically less than 12 mmHg and is slightly higher than the left atrial mean pressure. Left ventricular hypertension associated with congenital heart disease is seen most commonly in valvar and/or subvalvar aortic stenosis or CoA.

The systolic pressure in the pulmonary artery should equal that of the right ventricle and also is subject to respiratory variation. The diastolic pressure is higher because of closure of the pulmonary valve. The normal mean pulmonary artery pressure is less than 20 mmHg.

The aortic pressure varies relative to where it is measured, with the systolic pressure increasing and diastolic pressure decreasing as the catheter is moved more distally toward the descending aorta or iliac arteries because of pulse amplification. In addition to obstructive lesions those with run-off, such as aortic regurgitation, PDA, systemic-to-pulmonary arterial shunts and/or collaterals, as well as arteriovenous malformations, cause an increased pulse pressure.

Pressure gradients are measured to quantify the degree of stenosis across cardiovascular structures and are expressed

as a peak systolic ejection gradient, an instantaneous gradient, or a mean gradient. However, as this is dependent on both the cross-sectional area and flow, if there is minimal flow (and/or a low cardiac output) across a severely stenotic area a falsely low gradient may be obtained. The accuracy of gradient data is also compromised when serial obstructions are present.

Saturations and Shunt Measurements

Shunting can occur because of both extracardiac and intracardiac lesions which allow mixing between the pulmonary and systemic circulations. Shunts may be left-to-right, right-to-left or bidirectional. While shunts can be localized by several means including angiography, echocardiography, and/or other indicators, in the catheterization laboratory shunting is quantified by the oxygen content (total amount of oxygen in the blood both as oxyhemoglobin and that dissolved in the plasma) and the saturation of the blood in the various sites. When this is combined with oxygen consumption one can calculate systemic and pulmonary blood flow.

O_2 content = (Hgb or hemoglobin concentration) (1.36) (fractional saturation of blood). The contribution of dissolved O_2 is small and ignored except when 100% oxygen is being administered.

$$\text{Pulmonary blood flow } (Qp) = VO_2\,(\text{mL/min}) = \frac{(\text{oxygen consumption})}{\text{PV O}_2\text{ con} - \text{PA O}_2\text{ con}}$$

$$\text{Systemic blood flow } (Qs) = \frac{VO_2\,(\text{mL/min})}{SAO_2\text{ con} - MVO_2\text{ con}}$$

$$Qp{:}Qs = \frac{SAO_2 - MVO_2}{PVO_2\% - PAO_2\%}$$

$$\text{Oxygen consumption} = \frac{PVO_2 - PAO_2}{SAO_2\% - MVO_2\%}$$

The variability in oxygen content is highest in the right atrium (67–87%) owing to variability from inferior vena caval, superior vena caval, and coronary sinus blood flow; therefore in the absence of shunting the pulmonary arterial saturation represents the mixed venous saturation. If a left-to-right shunt is present the mixed venous saturation is obtained from the site proximal to the shunt. As there is normal variation in saturations, an increase of more than 7%, 4%, and 4% is needed to detect a true left-to-right shunt between the superior vena cava and right atrium, right atrium and right ventricle, right ventricle, and pulmonary artery respectively [81]. With a right-to-left shunt pulmonary blood flow is calculated using the oxygen saturation measured proximal to the site of the shunt.

A right-to-left shunt is suspected if the aortic saturation is less than 95% or if there is a 2% or greater stepdown between the left atrial and aortic blood. More commonly, however, left-sided desaturation is secondary to pulmonary venous desaturation from a pulmonary cause and can be diagnosed and corrected with supplemental oxygen.

Cardiac Output Measurements

Cardiac output measures the amount of blood pumped by the heart into the systemic circulation measured in liters per minute, or more commonly in children is expressed as cardiac index where it is corrected for their body surface area ($L/min/m^2$) allowing for patients of different sizes to be compared (see formulas above). In the absence of left-to-right or right-to-left shunts, the pulmonary and systemic flows are equal. In the presence of shunts the pulmonary, systemic and effective blood flows are unequal and therefore their specific measurements important.

Left-to-right shunts can be quantified using the equation:

$$Q\,l-r = Qp - Qs$$

Right-to-left shunts are calculated using the equation:

$$Q\,r-l = Qs - Qp$$

The most common method for measuring cardiac output is via the indicator dilution method, using thermodilution technique where the indicator is cold saline, or the Fick method where the indicator is oxygen; the use of indocyanine green dye is not in current use. With thermodilution, the change in temperature from the iced saline injected into the port in the right atrium to its warming in the pulmonary artery is proportional to the blood flow; this is least accurate when the cardiac output is low. Thermodilution technique is useful when repeat cardiac outputs need to be performed during interventional procedures such as pre- and postdilation of aortic stenosis. The results are less reliable in patients with Fontan operations as a result of lack of thorough mixing of the iced saline bolus as well as in patients with significant tricuspid or pulmonary regurgitation. For the Fick method oxygen consumption can be measured directly or estimated from normograms based on gender, age, and heart rate.

Resistance and Valve Area Measurements

The calculation of vascular resistance, particularly the pulmonary vascular resistance, can be crucial to determining suitability for surgical palliation or repair. Vascular resistance is quantified by the mean pressure change relative to the flow across the vascular circuit with the pulmonary and vascular resistances calculated according to the following formulae:

$$\text{Pulmonary vascular resistance (PVR)} = \frac{\text{meanPA}_P - \text{meanLA}_P\ (\text{PCWp})}{\text{Qp}}$$

$$\text{Systemic vascular resistance (SVR)} = \frac{\text{mean Aop} - \text{mean SVC/RAp}}{\text{Qs}}$$

In children this is most often indexed for body surface area expressed as Woods units ($mmHg/L/min/m^2$).

When the pulmonary vascular resistance is over $4 WU/m^2$ pulmonary vasodilators are utilized including 100% oxygen and nitric oxide and repeat hemodynamics obtained in order to determine the reactivity of the pulmonary vascular bed; this is particularly important in cases determining suitability for cardiac transplantation versus need for heart–lung transplantation.

In cases where there is a significant discrepancy in the pulmonary blood flow the resistance in each lung bed should be calculated in addition to the total lung resistance.

Valve areas are calculated using a combination of two basic equations defined by Gorlin and Gorlin in 1951 [82]:

$$\text{Valve area} = \frac{\text{F (flow rate)}}{\text{C(constant)(44.3)h(square root of pressure gradient)}}$$

These equations relate the valve area directly to the flow across the valve and inversely to the square root of the pressure drop. The flow is measured while the valve is open either during diastole for the AVVs or during systole for the semilunar valves with the final formula accounting for this by including a diastolic filling time (DFP sec/beat) or the systolic ejection period (SEP, sec/beat) as well as the heart rate (beats/sec):

$$\text{A(area in cm}^2\text{)} = \frac{\text{CO cm}^3/\text{min}/(\text{DFP or SEP})\text{HR}}{44.3\,\text{C}(0.85\text{ for MV or }1\text{ for Aov, PV, TV})\sqrt{\text{mean gradient}}}$$

Calculating valve areas takes into account the gradient relative to the flow. A severe stenosis is present with a valve area of less than $0.5 cm^2/m^2$ for a semilunar valve and less than $1 cm^2/m^2$ for an AVV. In practice, however, the severity of valvar stenoses in young patients is defined by the transvalvar gradients, assuming that the majority of children have relatively normal cardiac outputs.

Angiography

The role of angiography in the anatomic evaluation of many congenital cardiac lesions has been largely supplanted by other less invasive imaging modalities. Intracardiac anatomy can be discerned in detail by echocardiography and also by cMRI and CT, while extracardiac structures can be well imaged by either MRI or CT [83,84]. Volumetric analysis, such as ventricular volumes and ejection fraction, can be obtained from MRI with high accuracy and reproducibility [85]. Studies have shown a good correlation between MRI and conventional angiography when evaluating larger aortopulmonary collaterals in patients with complex pulmonary anatomy such as TOF with pulmonary atresia [69]. However, because of limitations in spatial resolution in young infants and the inability to accurately define blood supply to lung segments in the presence of small collateral vessels, angiography remains the best imaging modality in this group of lesions, as well as in small patients with stenotic pulmonary veins and coronary artery abnormalities [86].

Another practical consideration in the choice of angiography over other imaging modalities is the need to obtain hemodynamic information or the potential need to perform an intervention, as in the pre-Fontan evaluation of patients with single ventricle complexes. Angiography of the pulmonary arteries is performed in these patients at the time of catheterization, and the site and angles chosen depend on the underlying anatomy and prior surgical procedures. The majority of these patients have had a cavopulmonary anastomosis, and a superior vena cava angiogram in anteroposterior and lateral projections will demonstrate the pulmonary artery anatomy. Visualization of the pulmonary veins is also important in these patients and is typically accomplished by following the contrast as it returns from the pulmonary arteries back to the heart, also known as levophase. If pulmonary vein stenosis is suspected, either a selective injection of contrast in the pulmonary vein, or a pulmonary artery wedge injection of contrast layered with saline will show the pulmonary vein anatomy in detail. To complete the angiographic evaluation of the pre-Fontan patient aortography should be performed to exclude the presence of significant aortopulmonary collaterals that may be occluded in the catheterization laboratory.

Definition of the pulmonary arterial anatomy is important in many patients with congenital heart disease. It is frequently possible to see them well by echocardiography in newborns and infants, but when peripheral stenosis must be excluded, angiography is the procedure of choice. Cranial angulation displays the bifurcation of the right and left branches as they course posteriorly towards the lungs, with the straight lateral projection as the orthogonal view.

Patients with TOF, pulmonary atresia, and major aortopulmonary collaterals need exact definition of the native pulmonary artery and collateral anatomy in order for the surgeon to plan reconstruction of a pulmonary arterial tree [87]. Scouting angiograms should be performed in the

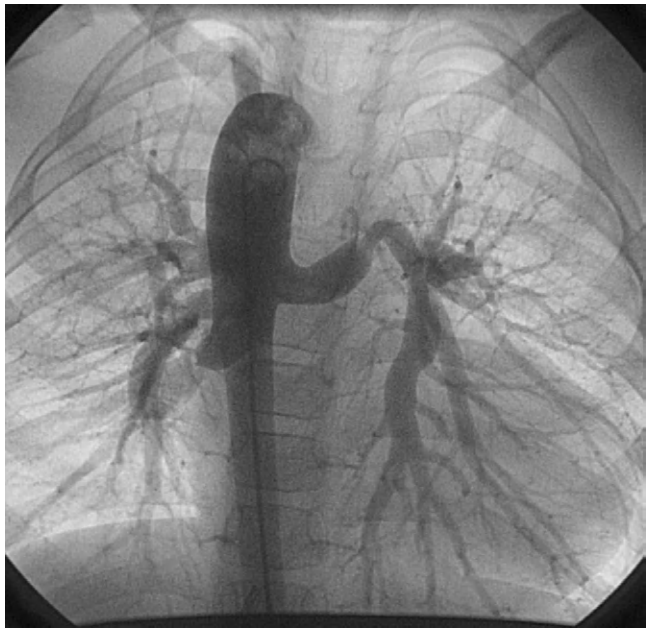

Figure 4.15 Descending aortogram in a patient with TOF and pulmonary atresia showing multiple aortopulmonary collateral vessels perfusing both lungs. The patient had tiny native pulmonary arteries that were opacified with selective injections in each collateral.

ascending and descending aorta, either with an angiographic catheter advanced from a venous approach into the right ventricle and aorta, or an arterial catheter advanced from the femoral artery (Figure 4.15). All the collaterals should be identified from these injections, including any that may arise from less common structures, such as the subclavian arteries or rarely even the coronary arteries. Often, the native pulmonary arteries are also visualized as they fill from one or several of the collaterals, ending blindly as a beak in the direction of the atretic pulmonary valve. Each collateral should then be injected selectively to delineate its origin, course and lung segment(s) perfused, and to evaluate the connections, if present, to the native pulmonary arteries.

In a minority of patients with TOF and pulmonary atresia the native pulmonaries are absent. To be sure, it is sometimes necessary to perform a pulmonary vein wedge injection of contrast layered with saline, which would fill the native pulmonary, if present, in a retrograde fashion.

Coronary Arteries

Patients with pulmonary atresia and intact ventricular septum require exact definition of the coronary artery anatomy to guide surgical management [88]. Echocardiography can be reassuring when the coronary arteries are seen arising normally from the aorta and there are not extensive sinusoids, but when in doubt aortography or selective coronary angiography must be performed. Right ventricular dependent coronary circulation, defined as right ventricle to coronary artery fistulas plus proximal coronary artery stenoses, is usually present in patients with smaller right ventricles and tricuspid valves, and is an indication for single ventricle palliation. Atresia of the proximal coronary arteries is an indication for cardiac transplantation [89]. Extensive sinusoids without right ventricular dependent coronary circulation calls for a conservative approach to RV decompression in newborns to avoid coronary steal into a low pressure right ventricle.

Preoperative evaluation of the coronary artery anatomy is important in patients with d-TGA in whom an arterial switch is planned. Echocardiography can almost always provide this information, and angiography is not typically performed. In the postoperative arterial switch patient, however, angiography may be necessary if there is any question about coronary insufficiency [90]. An aortic root angiogram should demonstrate the origin and distribution of the translocated coronary arteries. In the most common type D anatomy, both arise anteriorly from the neoaorta following translocation, with the left coronary artery leftward and typically more superior than the right. In these cases, it is preferable to then inject each coronary artery selectively in orthogonal views, to exclude any origin stenosis or kink in the vessel that may have resulted at the time of translocation.

Examination of the coronary arteries is also important in patients with TOF before undergoing complete repair, specifically ascertaining whether the left anterior descending branch originates normally from the left main coronary artery, or from the right coronary artery as in about 5% of patients. In the latter case it would course across the right ventricular outflow tract, and extreme care must be taken by the surgeon to avoid injury. In some cases there is a "dual" left anterior descending system, with a branch arising normally and the other from the right coronary artery, which must also be preserved at the time of surgery. These details can usually be ascertained by echocardiography, but, in TOF patients undergoing preoperative catheterization for other reasons, selective coronary angiography should be considered.

Coronary angiography is mandatory in patients with a history of Kawasaki disease and clinical evidence of myocardial ischemia, and in Kawasaki patients with no symptoms but giant aneurysms by echocardiography (Figure 4.16) [91]. These patients have a significant incidence of coronary artery stenosis that may require bypass grafting [92]. Patients with anomalous origin of the left coronary artery from the pulmonary artery are often diagnosed by echocardiography, but may require angiographic confirmation.

Figure 4.16 Giant right coronary aneurysm in a patient several years after Kawasaki disease.

Introduction

It is the nature of medical disciplines and therapies to evolve through cycles of association and separation for further refinement or specialization. Over the past decades there have been noteworthy improvements within the specialties of congenital cardiothoracic surgery and interventional cardiology. These advancements have been manifest by falling mortality rates for congenital heart therapies. However, within each discipline there remain certain procedures and patient populations that have suboptimal outcomes. Moreover, with the overall increased survival for congenital heart disease, the importance of morbidity and its impact on the quality of life for our patients has become paramount. At the same time technologic developments seem to be introduced into our surgical/interventional armamentarium at an ever increasing rate. These combined forces have resulted in a closer association between the congenital cardiothoracic surgeon and the interventional cardiologist, along with the teams that support them, in a mutual quest to improve the quantity and quality of life for our patients. This spirit of collaboration is at the core of what we call a "hybrid approach" to congenital heart disease.

A hybrid is often defined as the offspring of two different species. Although this can happen randomly, the purposeful development of a hybrid can optimize the strengths of each species while minimizing the weaknesses of each. One could certainly think of a cardiothoracic surgeon and an interventional cardiologist as different species by the nature of their training, skill sets, expectations, and mannerisms. But more importantly the crafts of surgery and catheterization have areas of strengths and weaknesses that can be optimized by cooperation as a hybrid therapy. These hybrid therapies then develop further with careful planning into a management strategy involving the other services within a heart center, namely the other cardiologists, anesthesiologists, intensive care team, nurses, perfusionists, and even outside services such as neonatology and radiology. This team approach encourages the sharing of ideas, expertise, equipment, and techniques, allowing one to think "outside the box" and to develop novel treatment strategies.

Throughout this chapter we will explore some of the ways that this spirit of collaboration has led to new hybrid therapies for the management of congenital heart disease.

Elements of a Hybrid Program for Congenital Heart Disease

The goals of hybrid therapy are many: 1) to reduce both morbidity and mortality; 2) to reduce the cumulative impact of multiple interventions over a lifetime that are often required to treat those with complex congenital heart disease; 3) to improve the patient's quality of life; 4) to deliver more efficient and cost-effective care; 5) to develop novel treatment strategies; and 6) to encourage teamwork. There are a few key requirements for initiating a successful hybrid program. These requirements are not expensive, do not take up a lot of space, and are within the grasp of all programs; however, without them the likelihood of success is small. Simply put – attitude, respect, and the removal of obstacles to collaboration are the key ingredients to a successful hybrid program. First and foremost, there can be no competition between the surgeon and the interventionalist. There must be mutual respect for each other and the talents

and limitations that each possess. It is important that no individual's opinion is weighted more than the other…it is a partnership. We have coined the term "Two Perspectives – Single Focus" to represent this respectful partnership. But this respect needs to be supported by an operational structure that does not put the surgeon and interventionalist in competition with each other for administrative voice, academic advancement, infrastructure and equipment support, or the economics surrounding case volume. Moreover an operational structure for all members of a heart center team (surgery, cardiology, anesthesia, intensive care, perfusion, and nursing) that aligns expectations, outcomes, and awards together, such as a unified service line rather than a collection of separate entities, fosters collaboration. This type of operational structure reflects strong hospital administrative support, another key element for a hybrid program to exist and flourish [1]. Once the obstacles to collaboration are removed, a cultural shift can foster a collective attitude that values and supports innovation through hybrid therapies. Once these key elements are in place, secondary considerations reflecting space, equipment, staff, and training can augment a hybrid program. Nevertheless, a successful hybrid program is clearly more about attitude and collaboration than about a piece of equipment.

Design of a Hybrid Suite

As the collaboration between the cardiothoracic surgeon and interventional cardiologist has increased, and as the lines between surgical and transcatheter treatment have blurred, the need for a therapeutic suite compatible to both disciplines has become apparent. The design of a hybrid suite is a long process that involves many individuals, meetings, and constant monitoring to see the project through to completion.

The initial step in the development of a hybrid suite requires the support and endorsement of hospital administration. The vision, or concept, of the hybrid suite must be presented by the cardiothoracic surgical and interventional cardiology teams, with commitment of the entire heart center team. Once administrative support has been attained and a planning budget established, the design phase can begin.

A design team derived from a variety of clinical and nonclinical areas must be established. Team members should include hospital engineers, architects, building contractors, electrical engineers, administration, and a representative cardiothoracic surgeon, interventional cardiologist, cardiac anesthesiologist, electrophysiologist, echocardiologist, perfusionist, operating room (OR) and catheterization lab nurses and specialists (respiratory therapist [RT], registered cardiovascular invasive specialist [RCIS]), nurse practitioner, and physician assistant). It is important that each member from each group represented takes ownership of the vision and understands that his or her contribution is essential to the end-product of the suite design. The cardiothoracic surgeon and interventional cardiologist must make the time commitment to this process to guarantee that the entire design team understands the vision and purpose of the hybrid suite. It may be necessary to spend time re-selling the vision and maintaining the motivation of the team over the design–implementation phase. It is also extremely important for the design team to be open-minded and creative in finding solutions to problems that will most certainly arise.

The cost associated with the design and construction of a hybrid suite can be significantly greater than a conventional operating or interventional catheterization theater. Consideration must be given to how the suite will be used on a day-to-day basis. Will the suite be used primarily as a cardiothoracic operating theater with cardiopulmonary bypass procedures (Plate 5.1, see plate section opposite p. 594) [2] or principally for interventional catheterization procedures (Plate 5.2, see plate section opposite p. 594)? There are different design considerations, and costs, associated with an interventional catheterization suite compared with an operative suite. While the suite will be used by combined services, it still should have a primary user around whom the designed work-flow and patient-flow should occur. The greatest difference between the two types of rooms, both in design and cost, will be in the selection of the digital radiographic imaging equipment, specifically the need for bi-plane versus single-plane imaging.

As the design phase progresses and equipment is being considered, it is extremely helpful for the entire design team to participate in as many site visits as possible. These in-person site visits reveal both positive and negative aspects to different designs and can be invaluable to the design team. As many members of the design team as possible should attend these visits as the best room design will incorporate input and feedback from all members. These site visits should include as many different centers and equipment variations as possible. Particular attention should be paid to the room layout, imaging equipment and procedure table design and function, boom vendor selection, and audiovisual integration and information management. Pointed questions need to be asked regarding the successes and failures of each site to help understand the issues that will be faced.

Ideally, selection of the vendors for the radiographic imaging equipment, booms, and audiovisual integration would occur early on as these vendors should become part of the design team to assist with additional room design items such as adequate space, heating, ventilation, air conditioning, air exchange, electrical supply (adequate to support the high energy demands of these systems), and even flooring design outlining movement of the C-arms (which can assist staff with equipment placement when

the room becomes operational). Additionally, it would be optimal to design a hybrid suite, interventional suite, and cardiothoracic suite all in direct proximity of each other to better optimize the necessary equipment and staff resources.

The types of equipment used, both available today and anticipated for the future, must be considered; space must be allocated for use during the procedure as well as for storage when not in use. The minimum square footage for the procedure area should be 900 ft^2 (84 m^2). Additional space will be necessary for control room (minimum 200 ft^2 [19 m^2]), induction room, pump room, supplies, cold room for radiographic imaging equipment, audiovisual image management router, and equipment storage. The preferred room design is square more than rectangular to allow for ample access on all sides of the patient for all team members.

The choice to design the suite around either the interventional cardiology team or the cardiac surgical team should be determined early. There are two key components to this decision: the digital imaging system (bi-plane versus single-plane) and the procedure table type (traditional interventional versus surgical).

Interventional catheterization procedures are based around the bi-plane imaging system and the ability to see from multiple and complex angulations, with as much as 90% of the procedure time requiring imaging. These bi-plane systems require more floor space and make patient access more difficult depending on the manufacturer and design. Conversely, the cardiothoracic surgical team typically prefers single-plane, ceiling-mounted imaging systems because most of their procedures may involve cardiopulmonary bypass where imaging time may be less than 10% of the total procedure time.

There is not currently a universal hybrid procedure table that performs to all of the specifications of the interventional cardiologist and cardiothoracic surgeon. Interventionalists tend to prefer free-floating, carbon fiber table tops with plenty of width and length for wires and catheters with little concern for table height. Cardiothoracic surgeons, on the other hand, do not typically care about table length but prefer a wide range of table height options, prefer the table top to be as narrow as possible to prevent unnecessary back strain, require Trendelenburg and reverse Trendelenburg, need the table to roll laterally right and left, and frequently have stainless steel rails for attaching auxiliary devices. To meet the need of both operators, table flexibility will need to be taken into consideration. A procedural table with a small, fixed-base footprint and with close to 360-degree rotation is the optimal solution.

One of the most common design features is to get as much off the floor as possible without causing other obstruction and traffic flow problems within the room. One must also consider that while objects on the floor may be obstructions, so too may the items hanging from the ceiling. So caution in design must be employed when moving objects to the ceiling. Moreover, the ceiling is already challenging considering the rail system for a ceiling mounted C-arm as well as other equipment such as surgical lights, numerous monitors [2–6], injector, gases, and video feeds.

There are a number of different boom designs and manufacturers. Ceiling-mounted telescoping columns are frequently promoted by architects as functional and cost effective, yet tend to create a traffic flow problem in many room designs. If the columns are not located directly over the sources that require the services there will be many cables (electrical, gas, vacuum, video, etc.) running across the floor to where the column is located creating a hazard. Having to pick the exact location of a column leaves little flexibility for adaptation or change of procedures within the suite.

All booms are not created equal, and what may work for one service may not work for the combined needs of the hybrid suite. Slim-line designs with flexibility to raise and lower and the number of joints available for maneuvering into optimal position must all be considered. All boom ceiling mounts need to be located outside the ceiling tracks of the C-arm with adequate length to be able to reach into the area of need. Boom design for anesthesia and perfusion need to be of adequate height and arm length to remain above the equipment they will serve and must allow maneuverability to permit adaptability to change. Figure 5.1 is a typical boom design that shows maneuverability of boom arms within a hybrid OR suite. Reliance on the boom and radiographic imaging vendors to assist in design and placement of the equipment is absolutely necessary. Most vendors have the ability to create three-dimensional graphical displays of the hybrid suite with boom placement, rotation, and movement.

Service to the booms must be sufficient to supply all the equipment. Adequate electrical circuits are needed to supply adequate amperage to the equipment that will be fed by the boom. Appropriate quantity and types of gases (air, CO_2, O_2, N_2, N_2O, anesthetic gas waste, vacuum), composite video, variable-gain amplifier (VGA), electrocardiogram (EKG) synchronization between booms (for synchronized cardioversion, pulsatile perfusion, or echocardiogram [ECHO]), network jacks, etc., all need to be considered. Inadequate planning could result in a very expensive correction.

If an equipment boom is used, special consideration to the number of shelves and the stored equipment is necessary. Electrocautery, defibrillators, video recording equipment, endoscopic equipment, and surgical head lights may all be mounted on this boom if appropriate. Redundant composite video and VGA jacks, network jacks, power, vacuum and additional air, CO_2, O_2, and vacuum should be added. The equipment boom will occupy floor space

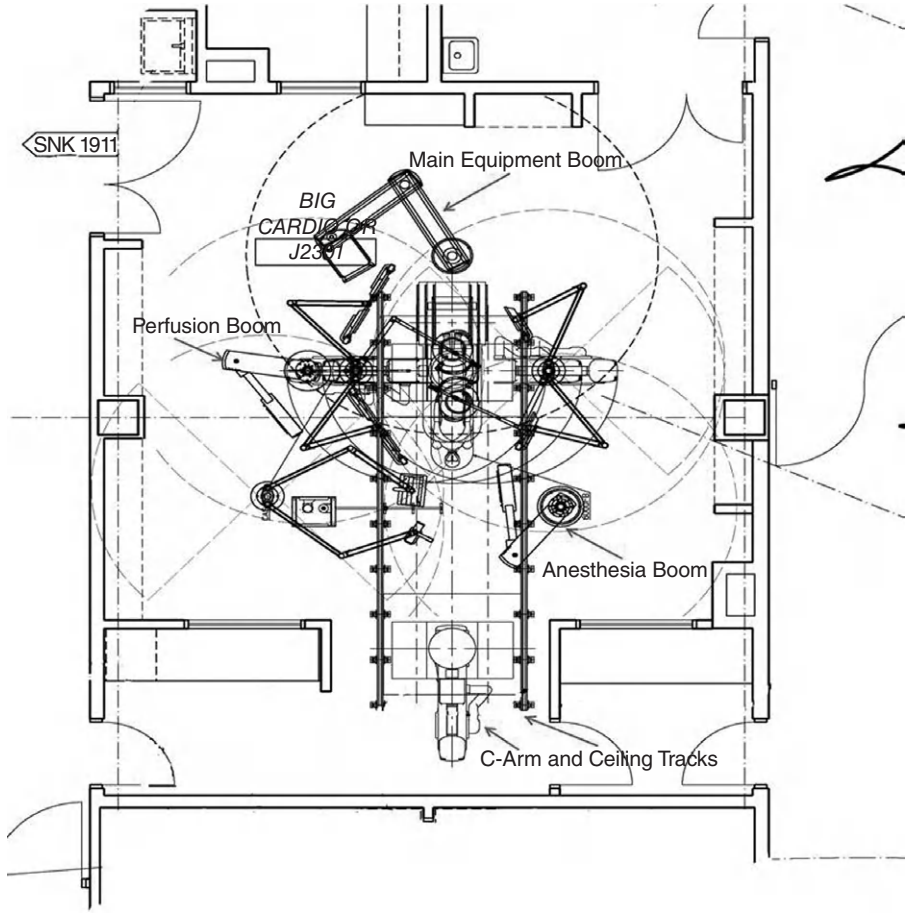

Figure 5.1 Overhead schematic of boom location and movement.

and as such may best be designed to optimize maximal shelves to support future needs.

It is desirable to have monitors of adequate size and number placed about the hybrid suite to allow any personnel within the room to visualize what is occurring during a procedure. A substantial amount of data and images may need to be routed, including angiograms, ECHO imaging, picture archiving and communication system (PACS), physiologic monitor data, live video imaging, etc. Once the decision is made to route and manage the images, the ability to expand in any number of directions is practically endless: images can be routed to or from remote sites on campus, to surgeons' or interventionalists' offices, to the ECHO reading room, or to the conference center, or images and voices can be routed simultaneously between theaters to allow the interventional cardiologist and cardiothoracic surgeon to consult with each other while both are in procedures. Because video integration, routing, and visualization are optimized throughout the room adding additional composite video and VGA jacks on all booms and all walls is a minimal up-front expense that allows any ancillary or future equipment to be easily and quickly added to the system for routing and image capture.

Once design is completed the construction and installation phase begin. It is imperative that one stay involved at this critical point in the project. It is advisable for at least one clinical team member and physician walk through the room at least weekly to stay informed, to ensure that no unanticipated issues arise, and to make critical decisions on design issues early, while design changes are still relatively easy to implement. If there is not active participation by all team members, the finished product will reflect the design of nonclinical individuals who will not need to function within the finished suite on a daily basis, possibly resulting in suboptimal conditions.

Hybrid Therapy for Vascular Stenoses

The role of Hybrid Vascular Therapy

The treatment of vascular stenoses poses significant challenges to the cardiothoracic surgeon as well as the interventional

cardiologist [7]. While surgical patch augmentation has been considered the gold standard for many years, the introduction of endovascular stents into the interventional armamentarium, pioneered by Chuck Mullins, has documented benefits [8–10]. Following the introduction of transcatheter stent therapy, the role of hybrid strategies in the therapy of vascular obstructions has evolved considerably over the last 10 years from a "surgical bailout procedure," to being considered an important alternative treatment strategy for patients with congenital heart disease [2–6,11,12]. As such, current therapeutic options available include surgical patch augmentation, transcatheter balloon angioplasty and stent therapy, or intraoperative hybrid therapy. Each available treatment strategy has advantages and disadvantages (Table 5.1) and an approach that is suitable for one patient may not necessarily be appropriate for another with a similar lesion. Only an understanding of the strengths and limitations of each individual approach will enable the physician to choose the most appropriate treatment strategy for each individual patient.

Selecting the Appropriate Therapy

A variety of factors must be taken into consideration before selecting an individual approach.

Need for Cardiopulmonary Bypass

Intraoperative hybrid therapy under direct vision with or without endoscopic guidance invariably requires the use of cardiopulmonary bypass. Thus, this approach is usually only considered if bypass is required to treat another cardiovascular lesion. Even if cardiopulmonary bypass is used, intraoperative stent placement may in selected cases avoid the need for aortic cross-clamping and reduce the complexity and risk of a surgical procedure [13,14]. However, if a patient does not need cardiac surgical therapy, then vascular lesions are usually better treated in the cardiac catheterization laboratory under angiographic guidance.

Location and Type of the Vascular Stenosis

Very calcified vascular obstructions may benefit from surgical, rather than hybrid therapy [15]. This applies specifically to the proximal branch pulmonary arteries (PAs) where a long-standing, distorted, calcified lesion may require resection and augmentation at the time of conduit or pulmonary valve replacement, rather than transcatheter or hybrid stent delivery. In contrast, stenotic lesions created by vascular folds or external compression are notoriously difficult to address surgically, even with a "perfect" patch repair. In these situations, stent implantation is frequently the most

Table 5.1 Advantages and disadvantages of individual approaches to treat vascular lesions (transcatheter approach, hybrid approach, surgical approach). (CPB, cardiopulmonary bypass).

Approach	Advantages	Disadvantages
Catheter	More accurate measurements and stent positioning Better roadmaps No need for sternotomy or other surgical access No need for cardiopulmonary bypass	Need for stiff wires and large sheaths Use of adult-size stents in small infants often prohibitive Stents have to be used "as is" (cannot be modified) Vascular/technical complications may require surgical bailout Increased hemodynamic instability especially in small children Longer fluoroscopy and procedure times Procedures often technically demanding
Hybrid	No need to minimize delivery system No need to track "curves and bends" No need for stiff wires and long sheaths Use of adult-size stents in small children Potential for stent modification Often hemodynamically better tolerated Better control of vascular and technical complications Shorter fluoroscopy and procedure times Technically less demanding Vascular lesions can be inspected before deciding therapy	Distal wire and stent position more difficult to assess Less suitable to obtain roadmaps Need for sternotomy or other surgical exposure Need for CPB if using direct vision/endoscopy Use of contrast may impact kidney function after CPB
Surgical	Vascular lesions can be inspected before deciding therapy Can often easily be integrated with concomitant surgery Calcified lesions can be resected Surgical patch augmentation adds extra tissue to a vessel No need for fluoroscopy or contrast Hemodynamic stability on CPB Very good control of vascular and technical complications	Some vascular lesions difficult to reach surgically Less suitable to treat kinks and external compressions Need for sternotomy or other surgical exposure Often need for CPB Surgical angioplasty may create focus for recurrent stenosis

appropriate option. Sometimes a combination of surgical resection with patch augmentation followed by stent implantation is required, in which case hybrid stent delivery under direct vision is clearly the treatment of choice.

Not infrequently, though, it is difficult to exactly predict the morphology and type of vascular lesion based solely on angiographic imaging in the cardiac catheterization laboratory. Therefore, in a patient who will require a surgical procedure in the near future (e.g., conduit replacement), final decisions on the extent of surgical resection and the most suitable form of vascular rehabilitation may only be made intraoperatively. In those situations it can be advantageous to defer transcatheter stent placement, especially for proximal PA lesions.

In contrast to the proximal branch PAs or aorta, some vasculature, such as distal branch PAs, cannot easily be reached using surgical techniques and therefore naturally lend themselves to transcatheter therapy. Even though hybrid therapy may occasionally be suitable for isolated distal branch PA lesions, in general the rehabilitation of peripheral branch PA stenoses requires detailed angiographic guidance. As such, treating these lesions in the cardiac catheterization laboratory before any surgical intervention is usually recommended.

The location of a vascular obstruction is very important when planning the most suitable therapeutic approach. The proximal branch PAs are the most common location for intraoperative stent placement [16–23], but are equally amenable to transcatheter or surgical therapy. Pulmonary venous obstructions have a uniformly poor long-term prognosis, whether treated surgically or in the cardiac catheterization laboratory [24–27] but are theoretically amenable to all therapeutic strategies, including a hybrid approach [27–29]. With the exception of infants with associated anomalies, native obstructions of the aortic arch in patients under 10 kg are often better addressed surgically rather than using a transcatheter approach [30,31], whereas transcatheter therapy for recoarctation is usually the primary treatment of choice [32–36]. Patients with more complex arch obstructions can be treated in the catheterization laboratory [37] or may benefit from a hybrid approach to avoid the use of cardiopulmonary bypass [38]. Vascular lesions in superior vena cava (SVC) or inferior vena cava (IVC) are usually easily amenable to all therapeutic strategies.

Other morphologic reasons that may favor a hybrid approach in the OR include extremely hypoplastic vessels or complete vascular obstructions, which are associated with an increased risk of vascular injury or rupture during balloon angioplasty or stent deployment. In these situations, surgical exposure in the OR may allow direct access to the vessel without the use of cardiopulmonary bypass, but with bypass on standby should any complications occur.

Some vascular lesions may be impossible to reach in the cardiac catheterization laboratory due to very steep angulations, protruding stents, or other reasons. In these situations, one approach short of using cardiopulmonary bypass to treat the lesion surgically would be a hybrid approach with surgical exposure through, for example, median sternotomy, with subsequent direct vascular puncture, which may facilitate stent placement or angioplasty in a more direct fashion than using a percutaneous transcatheter route.

Age of the Patient

The younger the patient and the smaller the stenotic vessel, the greater the challenge for transcatheter therapy. Implantation of stents that can be expanded to adult size frequently requires the use of large delivery sheaths and stiff guide wires, which may be poorly tolerated even in otherwise healthy infants. The use of large sheaths may also be prohibitive with standard femoral arterial access in infants with a weight below 10 kg owing to the risk of significant femoral arterial injury. While low-profile, balloon-mounted stents are relatively easy to implant in the cardiac catheterization laboratory and more suitable for small vessels, they cannot be expanded to adult size of the vessel and will therefore create considerable difficulties in the future, especially if a stent has to be removed surgically in a patient that otherwise would not have required a surgical intervention.

Stented vascular obstructions are at risk of developing neointimal proliferation or in-stent stenosis [39–41], the risk of which is further enhanced if stents are implanted into vessels with a very small diameter, an experience learned extensively when placing coronary stents [42]. Balloon angioplasty avoids some of the limitations of stent implantation and has been used intraoperatively in patients undergoing palliative surgery for hypoplastic left heart syndrome (HLHS) [43,44]. However, balloon angioplasty in general, whether in the cardiac catheterization lab or intraoperatively, is associated with a higher recurrence rate and is usually considered only a temporizing measure [33,34,43]. Hybrid stent delivery has considerable advantages in small infants, as it allows implantation of adult-sized stents while avoiding access-related problems and the use of large delivery sheaths and stiff guide wires. Furthermore, stents can be manually shortened in the OR to accommodate shorter vascular lesions [17].

At the other end of the age spectrum, PA rehabilitation in adults can be technically challenging in the cardiac catheterization laboratory. Stents are often required to be expanded to diameters in excess of 20 mm, requiring delivery sheaths that exceed the size of the presently available braided and reinforced sheaths. While transcatheter stent delivery in proximal branch PAs is certainly feasible, the same can frequently be accomplished in a small fraction of the time using hybrid stent delivery under direct vision with endoscopic guidance during concomitant cardiac surgery.

Clinical Status

Sick patients in the early postoperative period are at higher risk of significant hemodynamic instability during transcatheter interventions [45,46]. These procedures are often poorly tolerated because of the use of stiff guide wires and larger delivery sheaths required for stent delivery, which may create hemodynamic instability by holding open the atrioventricular valve and/or arterial valves. However, residual structural pathology after cardiac surgery in itself is poorly tolerated; therefore, these patients require a therapeutic intervention [47]. In these situations, hybrid therapy can offer direct surgical exposure without the use of cardiopulmonary bypass. This allows direct access to a vascular lesion, with balloon angioplasty or stent implantation being performed through a sheath inserted directly into the relevant vascular structure that offers the most appropriate direct exposure. Cardiopulmonary bypass can be readily available if needed, offering an extra safety margin for these procedures.

Previous and Expected Further Surgical and Transcatheter Procedures

Repeated failure to address a vascular lesion using a specific therapeutic strategy should be considered when deciding on a new approach. It is equally important to consider the need for further surgical interventions before implanting endovascular stents in the cardiac catheterization laboratory, as implanted stents subsequently may need to be removed completely or partially, which can be technically challenging or even impossible and may sometimes require patch augmentation [18,48]. As an example, it is advisable to avoid stent implantation to the proximal right PA in a patient who is still expected to undergo Fontan completion. Similarly, stent implantation for an anastomotic SVC stenosis after heart transplantation may interfere with a potential need for retransplantation.

These considerations often vary from patient to patient and between surgical operators. As is the case for all aspects of hybrid therapy, communication between the cardiothoracic surgeon and the interventional cardiologist is essential when considering percutaneous stent implantation in a patient who is expected to require further cardiac surgery. For some lesions, temporizing balloon angioplasty may be preferable to defer stent implantation until the time of surgery, using a hybrid approach.

Setup, Equipment, Stents, and Balloons

While a dedicated hybrid operating and/or cardiac catheterization suite certainly helps in performing complex hybrid therapy [2], it is not an essential requirement for these procedures. The main ingredient to facilitate successful hybrid therapy to treat vascular obstructions is a cooperative environment between cardiac surgical and interventional teams, combined with a high degree of flexibility and the ability to improvise. It is a good practice to discuss with the cardiothoracic surgeon at the time of cardiac catheterization any intended vascular rehabilitation in a patient who is anticipated to undergo open-heart surgery in the near future. Thus, the most appropriate treatment strategy can be defined at a time when all treatment options are available to the patient.

To enable intraoperative hybrid stent delivery, adequate preoperative imaging data are required that allow selection of the appropriate stent and balloon size. In small infants, for example, the distance to vascular side branches is much easier to determine angiographically or by computed axial tomography (CAT) scan than by using direct intraoperative visualization and assessment. The operator should have a very good idea about stent/balloon type and size before stepping into the OR.

It is essential to have a wide variety of stents and balloon catheters available. Table 5.2 lists a variety of stents that can be expanded to adult size and their individual characteristics [49]. Not all of the listed stents have achieved US Food and Drug Administration (FDA) premarket approval, and it is important to note that none of these stents has been approved for use in pediatric patients with congenital vascular lesions, such as branch PA stenosis or coarctation. As such, all these stents are being used on an "off-label" basis [50].

Intraoperative imaging has evolved as an essential component of cardiac surgical procedures [51–53]. While angiography is not always necessary, especially if stent delivery is performed under direct vision with endoscopic guidance, the use of fluoroscopy has a variety of advantages during most stent implantations [54]. Documenting stent expansion on cine-recording or fluoroscopy, allows the operator to detect unequal expansion, maladjustment of the stent from the balloon, or balloon rupture, much more readily than would be noted with direct vision alone. In

Table 5.2 Selected characteristics of some of the most commonly used endovascular stents in congenital heart disease.

Name (Manufacturer)	Material	Max diameter (mm)	Available length (mm)	Flexibility	Shortening	Cells –design
Genesis XD (Cordis)	Stainless steel	18	19, 25, 29, 39, 59	–	–	Closed
Mega LD (EV3)	Stainless steel	18	16, 26, 36	++	++	Open
Max LD (EV3)	Stainless steel	25	16, 26, 36	+	++	Open
CP Stent 8zig (NuMed)	Platinum/iridium, gold	25	22–45	0	–	Closed

addition, if previous "baseline" angiographies are available, these can be used as roadmaps during stent positioning, specifically using fixed objects such as clips or residual wires for orientation. Furthermore, angiographic evaluation of the result in the OR (exit angiography) allows detection of any potential problem or malposition at a time when corrections can still be made relatively easily [53]. A fixed, ceiling-mounted C-arm is a beneficial luxury, but a portable C-arm will work just as well provided the procedure is carefully planned. Patients may have to be positioned in a more unconventional manner so as not to interfere with the operating table itself. Angiographies in larger pediatric patients usually require a power injection; therefore, a portable power injector should be readily available. This alone does not always guarantee optimal image quality, and flow reduction on the cardiopulmonary bypass circuit as well as temporary occlusion of, for example, opposite branch PAs may further enhance image quality.

Techniques available to perform intraoperative stent placement have expanded considerably [17,19,20,55]. In general, two fundamental hybrid techniques, as well as a potential mixture of both techniques, are available for intraoperative stent delivery:

1. stent delivery under direct vision, using endoscopic guidance;

2. perivascular stent delivery through a sheath, using angiographic guidance.

The decision on whether to deploy the stents using direct vision (which invariably requires the use of cardiopulmonary bypass) or using angiographic/fluoroscopic guidance through direct vascular puncture on the beating heart depends on the type of surgical procedure performed, the need for cardiopulmonary bypass, and whether preexisting landmarks are available from previous angiographic imaging.

The majority of patients will have hybrid stent delivery performed under direct vision with the patient on cardiopulmonary bypass (Plate 5.3, see plate section opposite p. 594) [2]. A prerequisite for this technique is the availability of imaging data and measurements of the lesion to be treated. This is usually obtained during prior cardiac catheterization or a CAT scan, but may be obtained through intraoperative angiography before stopping the heart and exposing/opening the vessel. Branch PA stenoses are the most common lesions requiring hybrid therapy [45].

Endoscopy is a very valuable tool to facilitate stent positioning and deployment, as it allows a much more detailed inspection of the relevant lesion, including the distance to any of the side branches (Plate 5.3, see plate section opposite p. 594). For this purpose, the endoscope is advanced across the stenosis until the origin of a side branch can be visualized, which allows one to measure the distance the endoscope has been advanced into the branch PA (Plate 5.3, see plate section opposite p. 594). This provides a good estimate of the maximum stent length that should be used to avoid jailing of a PA side branch and complements the data available from previous imaging. The endoscope further aides in confirming accurate placement of the guide wire. Wire placement in a small PA side branch may lead to stent malposition, jailing of adjacent pulmonary vasculature, and possibly even vascular injury of the side branch during balloon expansion. For the same reason, operators should avoid the temptation to "quickly" deploy a stent without using a guide wire, as the position of the distal balloon tip cannot be reliably assessed during balloon inflation. In contrast to percutaneous stent placement though, hybrid stent delivery does not require stiff guide wires as a rail, and standard soft j-tipped wires are perfectly appropriate. Once the stent is delivered, the result is examined by endoscopy. Stent meshwork that is slightly protruding into the main PA can easily be crimped and folded, as to create a smoother surface and aid subsequent transcatheter interventions (Plate 5.3, see plate section opposite p. 594). Similarly, the OR offers the possibility to even shorten a stent if necessary [17]. Further, hybrid stent delivery is much more forgiving to balloon rupture or stent migration during stent deployment than transcatheter therapy, and a suboptimally deployed or not fully expanded stent can easily be removed under direct vision.

Deploying stents using angiographic guidance is reserved for very specific lesions and circumstances (Plate 5.4, see plate section opposite p. 594) [2]. This approach usually entails performing the procedure without cardiopulmonary bypass and with the surgical team providing access to the vascular lesions [56], be it via sternotomy, thoracotomy, or vascular cut-down. This approach is helpful in hemodynamically unstable patients where the percutaneous use of stiff wires and long sheaths may be poorly tolerated. Similarly, it offers advantages when vascular lesions are very difficult to access using a transcatheter approach because of protruding stents or steep angles. With cardiopulmonary bypass being readily available, this approach may also add an extra safety margin to the therapy of extremely tight or hypoplastic vascular lesions that carry a higher risk of vascular trauma or rupture (Figure 5.2) [2]. With angiographic guidance being the most important part of this procedure, it is important to plan the position of patient as well as the C-arm at the outset of the procedure. To maximize the potential benefit of this approach, the vascular entry point should be directly opposite in a straight line to the lesion that requires treatment. However, care must be taken that the entry side is sufficiently distant from the lesion to allow stent and/or balloon expansion, without the shoulders of the balloon interfering with the entry site. Wire positions and angiographic guidance are very similar to the approach that would be used in the cardiac catheterization laboratory, with the exception that softer materials can be used and that larger, adult-sized stents may be much

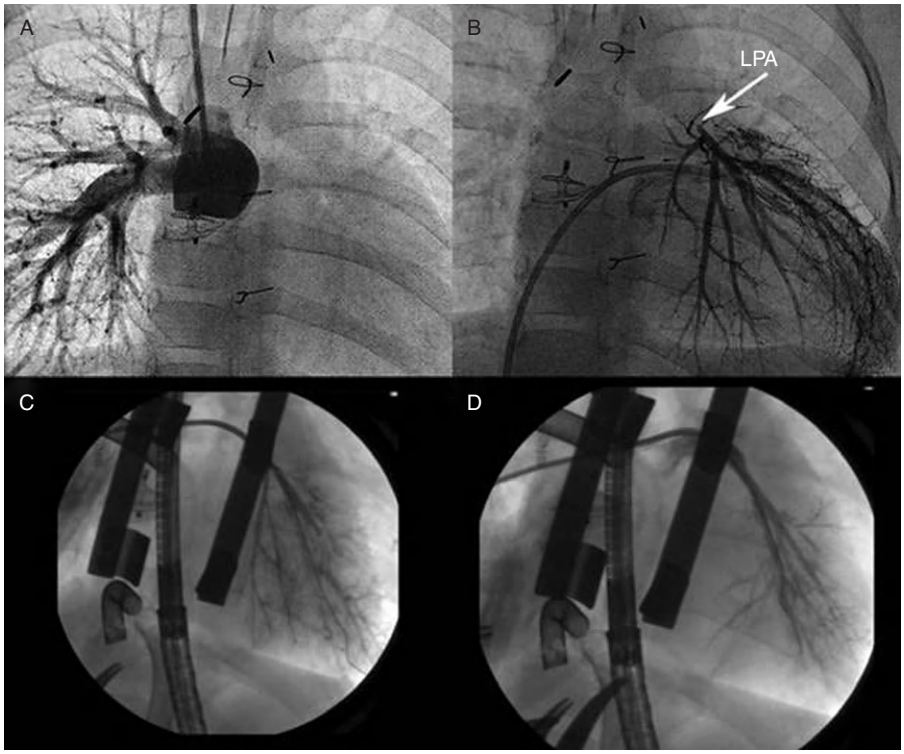

Figure 5.2 3-year-old girl with hypoplastic left heart syndrome and a history of modified Norwood procedure as well as subsequent bidirectional Glenn. Pre-Fontan catheter evaluation documented a disconnected LPA. **A,** Pre-Fontan SVC angiography documenting no filling of an LPA. **B,** Reverse left pulmonary venous angiography documenting a small and hypoplastic LPA. **C,** Intraoperative angiography after advancing a catheter directly into a structure felt to be the LPA, documenting extreme hypoplasia of this vessel. **D,** After deployment of a premounted Genesis stent, this angiography documents improved flow to the distally still severely hypoplastic LPA [2]. (LPA, left pulmonary artery; SVC, superior vena cava.)

better tolerated. With this approach requiring more catheter and wire manipulation when compared to an approach under direct vision, the length of the OR table (if the procedure is performed in the OR) may add an additional challenge, as there will remain less space to hold all wires and equipment in an orderly fashion than an interventional cardiologist is usually accustomed to. Therefore, OR staff and the interventional cardiologist must work closely together and communicate well to avoid wires and other equipment accidentally "dropping" on the floor.

As a summary, hybrid therapy of vascular obstructions neither replaces transcatheter rehabilitation nor surgical angioplasty. However, it adds additional treatment modalities that include aspects of both approaches, which may in combination offer the most beneficial treatment strategy for a selected group of patients. An individualized approach is essential and should be founded on detailed planning and communication between surgical and interventional teams.

Hybrid Closure of Atrial Septal Defects and Ventricular Septal Defects

Hybrid Closure of Atrial Septal Defects

Anatomy

Hybrid closure of an atrial septal defect (ASD) usually entails closure of either patent foramen ovale or secundum ASDs.

Indications

In general most ASDs are able to be closed via percutaneous technique; however, periatrial ASD closure can be safe and effective in small children less than 1 year of age [57]. The approach can also be beneficial during other procedures such as patients with a ventricular septal defect (VSD) being closed via a periventricular approach.

Technique

As with the hybrid closure of VSD, described later, the hybrid closure of ASDs requires a team approach between the interventional cardiologist, the cardiothoracic surgeon, and the echocardiographer. This approach requires placing a purse string in the right atrial appendage and placing a needle across the defect, followed by wire and the delivery of the sheath [58]. Once the sheath is across, the ASD device can be positioned and deployed. This technique is very similar to the periventricular closure of VSD described in greater detail later [58].

A periatrial approach for closure of ASDs can be performed safely with limited morbidity in children. This approach can be useful in patients undergoing other procedures or for children who are smaller and cannot undergo closure via a percutaneous approach [14,57].

Hybrid Closure of Ventricular Septal Defects

Anatomy

The most frequent location is muscular VSDs, with certain apical VSDs being the most challenging to close. The apical

VSD can have inadequate room from the right ventricular (RV) free wall to deploy the RV disc appropriately. There have been reports of closing perimembranous VSDs with the periventricular closure technique.

Indications

The hybrid approach to closure of muscular VSDs was coined "periventricular closure" by Zahid Amin *et al.* [59,60]. Periventricular VSD closure can be beneficial in patients less than 5 kg [61] and either where surgical closure can be difficult to visualize or where cardiopulmonary bypass is not indicated. As with any other hybrid technique, the skills of both the interventional cardiologist and the cardiothoracic surgeon are employed. In addition, however, the guidance of an experienced echocardiographer is crucial with periventricular VSD closure.

Technique

The technique for periventricular closure of muscular VSDs has been detailed in several reports [62–64]. Usually a limited lower midline sternotomy (Plate 5.5, see plate section opposite p. 594) is performed, but a limited anterior thoracotomy can also be used. During the procedure a transesophageal ECHO is performed, but an epicardial ECHO is another option. An appropriate entry point at the RV free wall across from the VSD is selected under echocardiographic guidance, and a purse string is placed. The location should be directly across from the VSD to facilitate placing an 18-gauge, 2-inch needle through the purse string and directed toward the VSD, as depicted in Figure 5.3. Placing a slight bend in the needle facilitates directing the needle more directly toward the VSD. The echocardiographer must find the needle tip, which can be made more echogenic by scratching the tip with a bovie pad, to help align the tip with the VSD [65]. Subsequently, a 0.035-inch angled guide wire is advanced through the needle across the VSD. The wire position is confirmed by echocardiography. Then a short 7-Fr delivery sheath is advanced over the wire across the VSD. Care must be taken to visualize the tip of the sheath to prevent inadvertent penetration of the left ventricular (LV) free wall. A technique to help avoid this complication is to tie a suture around the sheath before insertion to mark the maximum length to be advanced through the VSD. The VSD device is placed into the loader, attached to the delivery cable, and is de-aired. The loader is placed into the delivery sheath and delivered into the LV. The left-sided disc is deployed in the LV, avoiding pushing against the LV free wall. The sheath and device are pulled back into the VSD (Figure 5.4). Further pulling the sheath into the RV allows the RV disc to deploy. Before releasing the delivery cable, the ECHO is used to ensure that the VSD has no leaks around the device and there is no entrapment of the mitral or tricuspid valve. The delivery cable is released (Figure 5.5).

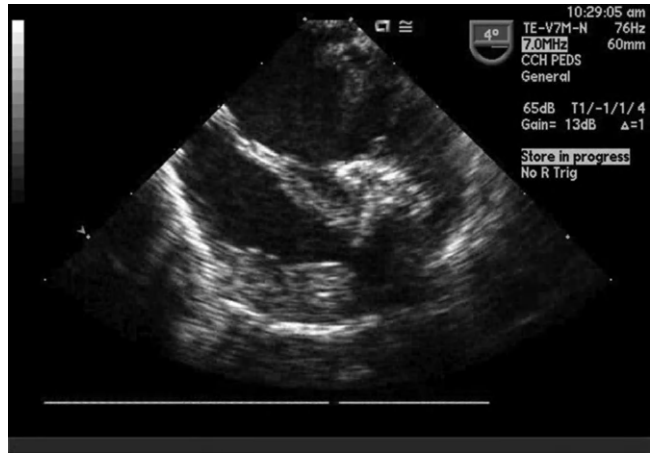

Figure 5.4 Left ventricular disc deployed.

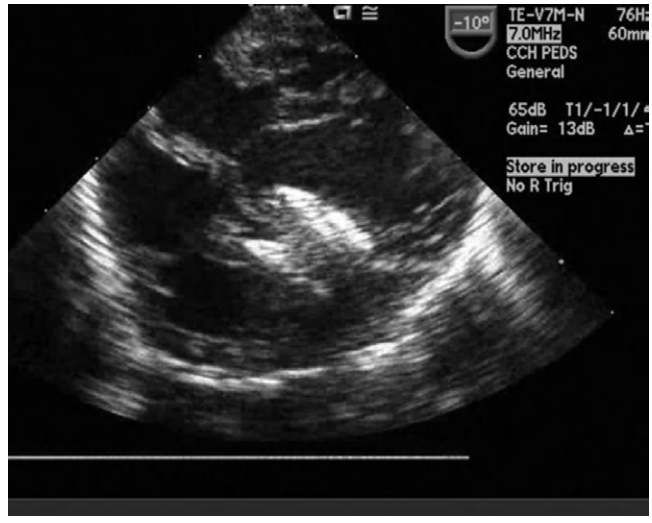

Figure 5.5 Ventricular septal defect closed with the device.

With further development of the techniques, these hybrid procedures will be able to be executed successfully using robotic assistance [66]. Hybrid periventricular approaches are most suited to patients who weigh less than 5 kg and without associated extracardiac anomalies that may increase the risks associated with surgical or transcatheter closure of these defects [65]. Percutaneous closure of mid-muscular VSDs is highly effective; however, reports have documented an increased risk associated with this procedure used for small patients [61]. These smaller patients do not tolerate the valve incompetence created by the wire loop and delivery sheath. Successful device implantation using the Amplatzer muscular VSD device as reported in a multicenter trial was achieved by 86.7% of the procedures, with a closure rate of 92.3% at the 12-month follow-up visit [61]. Patients weighing less than 5 kg had a greater number of major complications than larger patients. Both the periventricular and periatrial approach can be done safely with few complications [57,62,66].

Hybrid Approach for Hypoplastic Left Heart Syndrome

Introduction

The results of staged surgical palliation for HLHS have improved significantly over the years. Nonetheless, the overall morbidity and mortality of the initial Norwood procedure and its impact on the long-term success of the resulting Fontan circulation remain suboptimal [67]. Recent enthusiasm for the use of an RV-PA conduit instead of a modified Blalock-Taussig (BT) shunt during the Norwood procedure has not significantly changed the overall survival [68–70]. Important information about these two options will be forthcoming from the National Heart, Lung, and Blood Institute-sponsored, multicenter, prospective, randomized, clinical trial that is currently underway.

An alternative to the traditional Norwood approach is the hybrid approach for the management of HLHS. The primary goal of the hybrid approach is to create a stable, balanced circulation without the use of open-heart surgery (bypass, cross-clamp, circulatory arrest) with its associated risks in a neonate. The major open-heart surgical procedure is thereby shifted to later in life at an age when a circulation in series can be established with a cavopulmonary anastomosis.

Technique

To date we have experience with more than 100 hybrid stage 1 procedures, 60 comprehensive stage 2 procedures, and 25 Fontan completions in patients treated with this hybrid approach. Now, having developed a reliable, reproducible technique, we may impart some insights that may help lessen the learning curve for other groups adopting this strategy.

Hybrid Stage 1

The goals of initial palliation include: 1) unobstructed systemic output through the patent ductus arteriosus (PDA); 2) balanced pulmonary and systemic blood flows; and 3) an unobstructed ASD. This is currently accomplished by placing bilateral PA bands and a PDA stent via a median sternotomy as one hybrid procedure, followed by a balloon atrial septostomy several days later before discharge (Plate 5.6, see plate section opposite p. 594) [71]. Several lessons learned during this experience have led to our current approach.

Banding. Placing the bands before the stent is important. The PDA stent does not change the patient's hemodynamics or add any stability over an open PDA secondary to prostaglandin. However, adequately placed branch PA bands will improve the hemodynamics by balancing the circulation and improving systemic perfusion, which helps stabilize the patient for any subsequent procedures. Moreover, with the PDA stent in place the left PA is harder to isolate for banding and the stent is at greater risk for distortion while trying to encircle the left PA.

By fashioning the bands from Gore-Tex® (W.L. Gore & Associates, Flagstaff, AZ), some of the historical problems of dense scarring with potential loss of pulmonary segments on band removal have been eliminated. From a standard 3.5-mm tube graft (3 mm for weights <2 kg) an approximately 1 mm wide ring is cut to serve as the PA band. The ring is opened and passed around the right and left PAs. On the right, exposure is straightforward and the band is positioned on the right PA between the ascending aorta and SVC proximal to the right upper PA take-off. Exposure on the left is much more difficult. It is easier to visualize and maneuver a clamp around the left PA with the surgeon standing on the patient's left side, facilitating band placement right at the origin of the left PA. The bands are then tightened by reclosing the band with a 5-0 horizontal mattress suture. An additional stitch is placed through the band and tacked to the local adventitia to resist band migration.

The tightness of the band is an intraoperative decision based on the child's size, PA size, systemic blood pressure, and saturation response to tightening. However, experience has shown that bands closed to approximately 3.3 mm (slightly smaller than the original diameter of the shunt) will adequately balance the circulations and protect the pulmonary bed, while not becoming too tight with resultant cyanosis as the child grows to around 5.5 kg at 6 months of age, when the comprehensive stage 2 procedure is performed.

Stenting. Any transcatheter wire course through the HLHS heart can lead to hemodynamic compromise sec-

ondary to acute tricuspid and pulmonary valve insufficiency from wire distortion. This can lead to end-organ damage or, rarely, valve damage. Therefore, we now avoid any wire course through the heart by placing a sheath directly into the main PA above the pulmonary valve, through which the PDA stent can be deployed without crossing any valves. Moreover, by placing the sheath directly into the large main PA, vascular complications from groin access are eliminated, especially in the lower-weight neonates.

After the bands are placed, a 6-Fr sheath is placed in the main PA as proximally as possible just above the sinotubular junction. A silk suture is placed around the distal sheath approximately 2 mm from the tip to serve as an external marker for the surgeon as to how far to insert the sheath. This is important to avoid the sheath being inserted too far into the PA, thereby hindering deployment of the stent to cover the entire length of the PDA. A small hand injection of contrast through the sidearm of the sheath nicely defines the PDA, left PA, descending aorta, and retrograde aortic flow. The PDA length and diameter are measured at the distal, middle, and proximal ends, and the appropriate stent is chosen. Balloon-expandable or self-expandable stents can be used. The key is to be sure the entire length of ductal tissue is covered, which typically spans from the origin of the left PA to past the transverse aortic arch.

Atrial septostomy. Finally, creating an unrestrictive, durable, atrial septal communication in the HLHS heart is more difficult than using a standard balloon septostomy for other anomalies. This has to do with the size and location of the defect, the size of the left atrium, and the stability of the patient. We have varied the timing of the procedure, used other techniques (including static balloon dilatation with and without cutting balloons), and have even placed atrial septal stents. No technique yielded a reliable, reproducible result until our current approach. Now we simply delay the balloon septostomy by nearly a week, which allows some growth of the left atrium, thereby accommodating a 2-cc balloon and yielding a more substantial and durable opening in the atrial septum.

Interstage Monitoring

Close interstage monitoring has been the key to minimizing interstage mortality, as well as perioperative complications at the comprehensive stage 2 procedure. A home monitoring program coupled with a minimum of every-other-week cardiology assessment has been essential to the early detection of treatable problems. Echocardiography is used liberally to monitor for obstruction to flow across the ASD or through the PDA stent, antegrade or retrograde into the transverse aortic arch. Decreased RV function or increased tricuspid regurgitation can serve as another indicator of obstruction. Any evidence of obstruction or decreased ventricular function leads to a catheterization to diagnose and treat the level of obstruction.

Comprehensive Stage 2

This is a formidable operation. Despite the magnitude, the resultant circulation in series rather than in parallel outside of the neonatal period has been well tolerated. Unexpected benefits of the new initial hybrid palliation have been the growth of the native PAs and the transverse aortic arch. Because the transverse arch/innominate artery junction has grown, the aortic cannula can be positioned into the innominate artery during arch reconstruction, thereby removing the need for circulatory arrest with its associated risks. Moreover, much of the procedure can be done with the heart beating on bypass without aortic cross-clamping, thereby minimizing the period of cardiac ischemia.

The open-heart surgery consists of removal of the PDA stent and PA bands, repair of the aortic arch and PAs (if necessary), division of the diminutive ascending aorta with reimplantation into the pulmonary root, main PA to reconstructed aorta anastomosis, atrial septectomy with removal of the atrial stent (if present), and a modified cavopulmonary anastomosis (Plate 5.7, see plate section opposite p. 594) [71].

All of these steps are familiar to a pediatric cardiothoracic surgeon with single-ventricle experience, except for the removal of the PDA stent. This is the most intimidating aspect of the procedure because of the delicate nature of removing the distal part of the stent that continues into the descending thoracic aorta. However, aided by removing the time element of circulatory arrest, a reproducible technique of opening the stent longitudinally with a heavy scissors followed by gently peeling the stent out of the aorta has allowed the stent to be removed every time without injury to the aorta or local nerves. Hopefully, with future stent development specifically designed for this procedure, easier stent removal or, better yet, absorbable stents will make this significant technical hurdle obsolete for surgeons.

Results

Early reports on the initial outcomes of the hybrid approach [72–74] were limited by the impact of the learning curve of this new therapy, small cohorts of patients with mixed diagnoses and risk stratification, as well as short follow-up. Subsequent reports have focused on the use of the hybrid approach in high-risk HLHS patients [75–77]. Importantly, to truly assess the risks of the hybrid approach as compared to the Norwood approach, both stage 1 and 2 results as well as the interstage period must be considered. Recent reports from the groups in Columbus, Ohio and Geissen, Germany, show promising results with this emerging technique [71,78,79].

The goal of our report [71] was to evaluate the benefits and risks of the hybrid approach in a uniform cohort of patients with HLHS, including stage 1 and 2, so that a reasonable comparison can be made to patients treated with the Norwood approach. This is the largest single-institution experience with this hybrid approach, which is offered to all patients with HLHS. The only exclusion criterion is ECHO evidence of restricted flow into the retrograde transverse aorta from the ductus arteriosus. In this report patients with weights >1.5 kg were included even though 2.5 kg is commonly used as the cut-off for high risk.

Our results of the hybrid stage 1 procedure indicate a low-impact, low-risk procedure where 80% of patients are extubated and on enteral feeds within 24 hours, blood usage and inotropic support are rare, delayed sternal closure or extracorporeal membrane oxygenation (ECMO) are not necessary, the intensive care unit (ICU) stay is short, and hospital survival is 97.5%.

Interstage mortality (5%) and reintervention rates (36%) are similar to those reported for the Norwood procedure. Our reintervention rate may be high because we use close interstage monitoring with ECHO and take an aggressive approach to maintaining unrestricted flow through the PDA stent, both antegrade and retrograde, as well as maintaining an unrestricted atrial septal opening.

Only 10% of patients (4 of 40) developed significant retrograde stenosis into the transverse aorta. All were effectively treated by placing an additional retrograde stent and went on to a successful comprehensive stage 2. Given this low incidence we do not recommend a prophylactic reverse central shunt [80]. Moreover, given our experience in three patients with this type of shunt, the unknown physiology it creates with the potential of a coronary steal, and the more complicated postoperative course in patients with this shunt reported in the literature [81] we no longer use a reverse central shunt.

Although the comprehensive stage 2 procedure is a long operation involving essentially all the steps of a traditional Norwood stage 1 and 2 procedure, plus removal of the PDA stent and PA bands, the results show that the postoperative course is more similar to that of a Norwood stage 2 (Glenn) only. Our results indicate that the majority (85%) are extubated within 24 hours, inotropic support greater than the empiric use of milrinone (a cyclic adenosine monophosphate [AMP]-specific phosphodiesterase [PDE] inhibitor) is rare, RV function is preserved, and indicators of overall perfusion are normal by lactate, renal function, lack of seizures, and no ECMO requirements. This is presumably because the patients have a low-risk preoperative profile (normal ventricular function, no end-organ dysfunction, protected pulmonary bed). Then the conduct of the operation minimizes end-organ ischemia with the majority of the procedure performed on bypass with a beating heart and no circulatory arrest time, while the resultant circulation in series with a cavopulmonary shunt is more stable than a circulation in parallel, such as is the case with a Norwood stage 1. In conclusion, our study supports the use of the hybrid approach for the management of HLHS patients with the usual risk profile.

In the 25 patients who have undergone their Fontan completion after starting with a hybrid stage 1 palliation, there have been no deaths, no end-organ dysfunction, and only one patient was fenestrated. These results support the adequacy of branch PA banding in protecting the pulmonary vascular bed for a successful Fontan circulation.

Future

It is clear that this hybrid approach for palliating complex neonatal patients is an additional technique that will only improve over time as experience is accrued. Long-term follow-up and multicenter trials will be important to more clearly define which cohorts of patients gain the most at the lowest risk from this technique. Another area of research and potential benefit of the hybrid stage 1 procedure is the benefit of delaying the necessity of bypass until the brain is more developed. There is a growing body of knowledge that suggests that the developing brain, especially in those with complex congenital heart disease, may be more vulnerable to injury in the neonatal period [82–85]. Hence, a delay in exposure to cardiopulmonary bypass, the associated inflammatory response, and some of the hemodynamic consequences, may have the benefit of better long-term neurologic outcomes.

Completion Angiography in the Cardiac Operating Suite

Postoperative significant residual structural pathology after cardiopulmonary bypass surgery is associated with increased morbidity and poor outcome [45,47]. Intraoperative ECHO imaging has evolved as an essential tool to assess immediate intracardiac and, to some extent, extracardiac surgical repairs [86]. It provides not only important physiologic parameters that may aid in the postoperative management of these patients, but more importantly allows identification of important residual defects at a time when intraoperative surgical or hybrid therapy can still easily be delivered. However, while ECHO is very helpful in assessing ventricular and valvar function and identifying residual septal defects, its use is limited when assessing for residual vascular stenoses within the aorta, coronary, or branch PAs [87,88].

Delayed recognition of residual structural pathology that is not easily identifiable by ECHO, may lead to a compromised and complicated postoperative course. Once a patient deteriorates and has to be taken to the cardiac catheterization laboratory in the postoperative period the prog-

nosis is usually poor [46]. Asoh and colleagues recently reported on 49 children who underwent 62 cardiac catheterization procedures before discharge from ICU and found an overall mortality of 43%, as compared with 5% in patients who did not require cardiac catheterization. Delay to cardiac catheterization of >2–3 weeks was found to be a significant risk factor for death [46].

Angiography may complement the available intraoperative imaging modalities. While completion angiography can be readily performed using a standard C-arm, it is more difficult to obtain when compared with a specifically designed hybrid OR and requires some "planning ahead," with a longer setup and preparation time. A portable C-arm usually needs to be requested in advance, and provisions must be made for adequate archiving of the obtained images. Sufficient space has to be made available when moving in the C-arm. It is much easier to adjust for those requirements at the beginning of a procedure, rather than having to adjust intravenous (IV) poles and drapes in the middle of a case. While most staff can easily step back during image acquisition, the surgeon usually has to remain at the operating table; therefore, some radiation protection must be provided. A lightweight and practical solution is the provision of radiation protection pads that can be attached to the surgical gown using vascular clamps [89]. Obtaining the necessary angiographic projections can be a challenge, especially if using very steep projections where the X-ray tube may impinge on the surgical OR table. To overcome this limitation, one has to tilt the OR table in a way to provide more angulations, without further moving the C-arm.

Once adequately planned, the angiographic evaluation itself is usually fairly straightforward and does not require significant time. In most circumstances, a traditional Berman angiographic catheter is introduced directly through a purse-string suture and positioned by the cardiothoracic surgeon. Alternatively, a hemostatic sheath can be inserted, which facilitates the additional use of guide wires and other catheters, which can be particularly helpful when having to advance a catheter around the aortic arch. The insertion site depends on the vascular structure that requires evaluation. As an example, after a bidirectional Glenn procedure or comprehensive stage 2 palliation for complex single-ventricle physiology, the catheter is placed in the SVC, whereas after repair of tetralogy of Fallot or pulmonary atresia with VSD, the catheter is usually placed in the main PA or RV. Most angiograms are usually performed with low flow, or briefly off cardiopulmonary bypass.

Limited data are available on intraoperative angiography [17,53]. Holzer *et al*. retrospectively reviewed completion angiography in 15 patients after cardiac surgical procedures performed in a specially designed hybrid operating suite [2]. The underlying surgical repairs included a variety of procedures such as comprehensive stage 2 palliation for HLHS, aortic arch reconstruction, conduit or pulmonary valve replacement, and others. Completion angiograms confirmed expected results in 47% of patients, while 53% identified unexpected abnormalities or residual lesions, and 40% of these underwent hybrid therapy at the same procedure [53]. Figure 5.6 is an example.

It is clear that significant residual structural pathology should be treated as soon as identified, and Zahn *et al*. have shown interventional therapy can be safely delivered to very fresh suture lines [45]. However, doing so in the OR with cardiopulmonary bypass readily available adds an

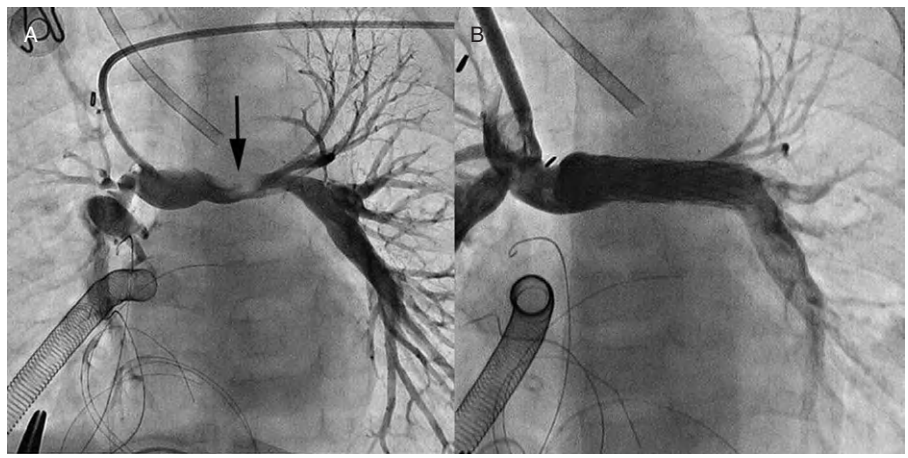

Figure 5.6 6-month-old male infant with HLHS and a past history of hybrid stage 1 palliation. **A,** Comprehensive stage 2 palliation was performed and an intraoperative completion angiogram documented a significant stenosis from a fold in the mid-portion of the LPA (arrow) with some swirling of contrast. **B,** A 25-mm Genesis XD stent was implanted and expanded to 7 mm with excellent angiographic result. (HLHS, hypoplastic left heart syndrome; LPA, left pulmonary artery.)

extra safety margin when compared to a procedure performed in a hemodynamically unstable patient 1 week postoperatively in the cardiac catheterization laboratory. However, despite very strong reasons to avoid residual structural pathology, at this point it is still unclear which lesions require immediate action, which ones can be monitored closely with delayed intervention, and which ones do not require any form of treatment. Angiographic imaging, especially after comprehensive stage 2 palliation, may be misleading, and the combination of an open chest and cardiopulmonary bypass can make interpretation of the images difficult. Equally, it is unclear which surgical repairs may benefit from routine postoperative evaluation. Whether ultimately angiography is routinely performed only in a small group of procedures, such as bidirectional Glenn or PA rehabilitation, or may include a wider spectrum of vascular procedures remains to be defined. Importantly, though, the decision on whether any identified lesion is significant and warrants surgical or hybrid palliation is a collaborative one made by the surgeon and the interventional cardiologist.

In summary, completion angiography complements the available intraoperative imaging modalities and may aid in early identification of significant residual structural pathology. Cooperation between surgical and interventional teams is essential during planning, set-up, and performance of the procedure, as well as during interpretation of the angiographic data. Prospective studies are ongoing to better identify the group of patients that benefit from completion angiography and how to identify pathology that should be treated in the OR.

Hybrid Approach to Valve Replacement

Philip Bonhoeffer's landmark report of the first successful percutaneous implant of a transcatheter pulmonary valve using the NuMED CP stent (NuMED, Inc, Hopkinton, NY) and the Contegra bovine jugular vein graft (Medtronic, Inc, Minneapolis, MN) started a new era in the nonsurgical treatment of congenital heart disease [90]. Within 2 years, Alain Cribier followed with the first successful percutaneous implant of the Cribier–Edwards Transcatheter Heart Valve (later Edwards-SAPIEN THV, Edwards LifeSciences, Irving, CA) in the aortic position [91]. Over the past decade, there have been numerous companies attempting to design and manufacture the "perfect" valve replacement that can be delivered percutaneously through a standard transfemoral vein or artery approach. The delivery systems have steadily decreased in size from 25 Fr to 18 Fr. Currently, the Edwards-SAPIEN THV (Edwards LifeSciences, Irving, CA) and the CoreValve ReValve System (CoreValve, Irving, CA) have gained CE Mark approval in Europe for percutaneous aortic valve replacement, while the Medtronic Melody Transcatheter Pulmonary Valve (TPV) (Medtronic, Inc, Minneapolis, MN) also has CE Mark approval for percutaneous pulmonary valve replacement in RV-PA conduits. There are currently as many as 17 percutaneous aortic valve replacement prosthesis clinical trials worldwide, with at least seven more with First in Man implant results, and others at different stages of development at this time. There are currently two clinical trials evaluating percutaneous pulmonary valve replacement and two trials evaluating percutaneous aortic valve replacement in the United States as of this writing.

However, what happens when the usual transfemoral artery or vein are not suitable for delivery? In fact, because of the large delivery system required for transfemoral arterial implant of an aortic valve, the cardiac surgeon has been involved in the procedure to provide access via cut down, arteriotomy, and vascular closure. In addition, the surgeon places the patient on cardiopulmonary bypass as needed. However, up until recently, the cardiac surgeon had not participated in the transfemoral venous approach to percutaneous pulmonary valve replacement, although was integrally involved in the clinical trials and valve design.

A hybrid approach using transapical transcatheter aortic valve implantation techniques has been developed recently, especially in those patients with increased age, and many comorbidities such as cerebral vascular disease, low ejection fraction, pulmonary hypertension, respiratory insufficiency, chronic renal failure, and peripheral arterial occlusive disease. The first approved multicenter clinical trial for transapical minimally invasive aortic valve implantation was reported recently [92]. The team consisted of cardiac surgeons and interventional cardiologists using the Bovine Pericardial Xenograft mounted on a balloon expandable low profile stainless steel stent (Edwards-SAPIEN THV, Edwards LifeSciences). Access to the LV apex was gained through a left anterolateral mini thoracotomy in the fifth intercostal space with horizontal opening of the pericardium. Teflon-reinforced purse-string sutures were placed in the LV apex with temporary pacing wires and femoral cannulation for possible cardiopulmonary bypass. A 14-Fr soft sheath was inserted in guide wire position to cross the stenotic aortic valve. Balloon aortic valvuloplasty was performed initially with a 20 mm balloon and rapid RV pacing. Afterwards, the sheath was exchanged for a 33-Fr transapical valve delivery system. Either a 23 mm or 26 mm Edwards-SAPIEN THV was implanted (Plate 5.8, see plate section opposite p. 594). The average EuroScore predicted risk mortality was 27 ± 14% for the 59 patients in the study. In-hospital mortality was actually only 13.6% without any valve dysfunction. Actuarial survival was 75.7 ± 5.9% at 110 ± 77 days follow-up.

One of the most important aspects of this multicenter trial was the transnational team approach used by the cardiac surgeons, as well as the excellent collaboration with

the interventional cardiologists, anesthesiologists, and perfusionists. Future refinements in sutureless devices are being made, as well as improvement in image guided assistance using three-dimensional computed tomography and transesophageal echocardiography data sets. Miniaturization of the delivery system will continue to evolve and may someday preclude mini thoracotomy. There has also been a recent report of deploying a CoreValve ReValving System through an 18-Fr introducer through the ascending aorta in a hybrid setting [93].

While hybrid delivery has been advocated and useful in the delivery of transcatheter aortic valve implants for all of the previously mentioned reasons, the same cannot be said of transcatheter pulmonary valve implantation. With the venous system able to accommodate a large diameter delivery sheath and the readily accessible femoral, jugular, and subclavian veins, there was no real "urgency" in developing a hybrid approach in the typical patient with a degenerating RV to PA valved conduit. One could even use a transhepatic venous approach if necessary. However, significant pulmonary regurgitation (PR) remains a long-term problem after surgical or percutaneous treatment of numerous congenital cardiac defects. The current Medtronic Melody TPV (18, 20, and 22 mm expanded diameters) delivered percutaneously in degenerating RV-PA conduits, while very effective and safe, only addresses approximately 13% of all affected patients with PR. In addition, delivering in small children may prove problematic. In 2006, 4 years after Dr Bonhoeffer's landmark report, the Shelhigh Injectable Stented Pulmonic Valve (Shelhigh, Inc, Union, NJ) was implanted off-pump by cardiac surgery [94]. In 2008, a multicenter study reported 12 patients ranging from 5.8–53.5 years with severe PR and dilated RV who underwent successful off-pump implant of the above Shelhigh Pulmonic Valve [95]. The prosthesis consists of a porcine pulmonic valve inside a tube of bovine pericardium mounted on a self-expandable Nitinol stent with sizes ranging from 17–31 mm. The valve was delivered through a purse-string suture in the distal RV outflow tract and transmural sutures are used to avoid migration. Also in 2008, a hybrid pulmonary valve implant was reported using the Shelhigh Injectable Stented Pulmonic Valve through the main PA, rather than the RV outflow tract [96].

Two reports in 2009 emphasized the continued interest in developing a hybrid approach to pulmonary valve replacement [97,98]. Feasibility studies using a transapical approach and an RV outflow tract approach in pigs and sheep, respectively, highlighted two new device designs. Both were a modification of the original Bonhoeffer–Medtronic concept using a bovine jugular vein graft (Contegra Pulmonary Valved Conduit, Medtronic, Inc) that was modified with a second endoprosthesis that was based on a self-expandable Nitinol graft. Both studies give promise for further clinical trials in the future. As a matter of fact, Professor Bonhoeffer has recently successfully implanted a (First in Man) modified Melody Transcatheter TPV in the native RV outflow tract using a self-expandable Nitinol graft in a young man in Milan, Italy with severe PR (personal communication with Dr Bonhoeffer).

Summary

Hybrid strategies for complex congenital and structural heart disease are here to stay and will only grow as the collaborative spirit between cardiac surgeons, interventional cardiologists, and other members of the heart center becomes "one voice, one team."

CHAPTER 6

Anesthesia for the Patient with Congenital Heart Disease

H. Jay Przybylo

Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

The contemporary era of surgical intervention to correct congenital heart defects began when Robert Gross performed the first successful ligation of a patent ductus arteriosus in 1938 [1]. At that time medications for pediatric anesthesia consisted of volatile general anesthetic agents and narcotic analgesics. Today, more than 70 years after Gross' landmark operation, some of these medications are still an integral part of the anesthetic regimen for pediatric patients undergoing cardiac surgical procedures. Nevertheless, this is an era of great change, in that modern pediatric anesthesiologists continually strive to provide safer operating conditions for the patient. These include monitoring techniques and therapies that limit or prevent complications from the underlying cardiac disease or the techniques used for correction. Currently, we are working on strategies to prevent complications resulting from the inflammatory response to cardiopulmonary bypass and to provide better brain protection during artificial or altered circulation [2]. Also, there has been an expansion of pediatric cardiac anesthesia care outside of the conventional operating room including the cardiac catheterization suite, interventional radiology, computed tomography scanner, and magnetic resonance imaging center [3]. Perhaps the greatest changes we are experiencing are the collection, analysis, and distribution of data. Improvements in speed and storage capability of information technology allow studies of large samples to be easily collected and transmitted worldwide.

Demographics

In recent years a trend has emerged in that there has been an increase in the number of hospital admissions for older patients with a primary diagnosis of congenital heart disease, and at the same time, a decrease in overall mortality in this patient population [4]. As more children with congenital heart disease survive to adulthood many of them will require revision of previous surgical interventions or further diagnostic and therapeutic procedures. The American Heart Association estimates that there are approximately 800 000 people alive in the United States who have had a procedure for a cardiac malformation [5]. We are now anesthetizing patients with congenital heart disease who are in their fifth and sixth decades of life and have the health concerns of adulthood complicating the normal pediatric cardiac anesthesia care [6]. In order to provide care for this growing patient population, anesthesiologists must be knowledgeable in all aspects of congenital heart disease and repair.

The development of ultrasound technology made it possible to not only diagnose congenital heart disease *in utero*; it also provides greater insight into fetal pathophysiology and neonatal cardiac anatomy. This has aided congenital heart surgeons in the selection of patients and timing for early surgical intervention. As heart malformations are the most common congenital defect requiring anesthesia care today, it is expected that members of the cardiac anesthesia team will anesthetize more neonates than any other group of patients who require cardiac procedures. The cardiac anesthesia team therefore will be responsible for the care of patients from extreme prematurity to 50 plus years of age [7].

Our experience has demonstrated approximately one-third of patients who require congenital cardiac anesthesia are less than 1 year of age, one-third are 1–15 years of age, and one-third are adults (some of them in the sixth decade of life). Neonates and infants tend to have malformations that result in abnormal blood flow while older patients are more likely to suffer from heart rhythm disturbances and valve problems. This knowledge is important in developing cardiac anesthesia teams, educational programs, and designing anesthetic protocols [8]. In addition to young

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

age, other variables related to increased morbidity and mortality in anesthesia include increased severity of the illness as measured by physical status and emergency procedures [9,10].

There has been a decrease in overall mortality to less than 5% for all patients with congenital heart disease who underwent an anesthesia-related procedure [11]. Vigilance is ever important for the anesthetist. Anesthesia care provided to children with congenital heart disease entails even greater risk over other children [12]. The demographic considerations clearly demonstrate the wide scope of patient care required by the cardiac anesthetist and the American Academy of Pediatrics has recommended that a pediatric cardiovascular center use the team approach for all aspects of care and intervention for these patients [13]. The quality of life in children after the repair of congenital heart disease is regarded as lower than in other children, the more severe the lesion, the lower the quality of life [14]. The anesthesia team will be charged with developing new modalities of care that will improve on this finding.

Anesthetic Assessment

These complex patients require a thorough evaluation by the anesthesiologist before the procedure. The evaluation will include the present and past history including previous anesthetic experience, family history including prenatal evaluation where necessary, a physical examination, and a review of all studies performed leading to the intended procedure. Our task in anesthesia has become much easier with the electronic medical record. Before the patient visit, it is now possible to review all previous encounters and interventions, be aware of the diagnosis and medical history to date, have a list of all medications, obtain all test results, and review previous anesthetic exposures. In addition, information regarding the specifics of the congenital heart lesion and therapy can be quickly researched via internet access, searching both surgery and anesthesia databases [8,15]. A note of caution that this should be done before actually examining the patient as motivated parents will have this information in hand and issues and questions can be handled in a timely fashion, preventing unnecessary delays searching for pertinent information and building the confidence of parents.

The history should include information specific to the malformation present and the age of the patient, including gestational age for newborns. The prenatal and maternal history should be obtained to balance confounding issues such as prematurity and maternal diabetes. The presence of one congenital defect should always initiate the search for others and the possible presence of a syndrome that could alter the anesthetic management. Cardiac lesions are in the midline groups of congenital defects and are associated with neurological, renal, and intestinal defects in addition to other organ systems. Altered neurological outcome in children with congenital heart disease is now well recognized, and the history should include specifics of the birth and other indicators of preexisting neurologic impairment [16].

Children can be uncooperative with diagnostic testing and exercise tolerance might not be easily quantitated. The level of physical activity by history can give an indication of cardiac function. Other more subtle indicators include the feeding history and the frequency of respiratory infections. A child with low cardiac reserve may not be able to eat well and be smaller than anticipated while frequent respiratory infections are associated with congestive heart failure. A question of continuing debate regards the child with an upper respiratory tract infection. If multiple symptoms are present the airway might be reactive provoking hypoxemic episodes surrounding the time of anesthesia. The patient's temperature might fluctuate during the anesthesia and airway secretions are increased leading to the possibility of mechanical obstruction of the endotracheal tube. If it is possible the case should be delayed until resolution of the infection [17].

Adult patients, in addition to a complete history of the cardiac malformation and previous interventions, are questioned regarding disease processes related to age. The patient's internist and all other adult specialists caring for the patient should be consulted. The history may help determine cardiac function, but this can also be measured by exercise testing. Some patients with prior repairs develop heart rhythm disturbances over time and this should be investigated.

The patient with functional single ventricle physiology requires special attention. These patients live with passive pulmonary blood flow. Worsening cyanosis can be an indicator of collateral vessel formation or intracardiac shunting. Previous Fontan procedures are associated with protein-losing enteropathy, thromboembolic events, hepatic dysfunction, and thyroid dysfunction as a result of amiodarone therapy for rhythm disturbance [18]. The presence of a single left ventricle (versus right) is beneficial information.

The physical exam by the anesthesiologist is a tool to confirm information obtained by the history and the review of previous records. The physical exam also concentrates on the anatomy of the airway, the ability to gain intravenous access, and an examination of pulses to determine the feasibility of arterial line placement.

Preanesthetic blood testing includes electrolyte levels with special attention to potassium levels potentially altered by or associated with diuretic therapy. Patients with cyanotic heart disease compensate for hypoxemia with polycythemia. There is no agreement at present regarding the upper limit of acceptable hematocrit and the decision to decrease the red cell mass by phlebotomy is generally

guided by the presence of associated complications such as thrombosis. Platelet count and coagulation studies should be obtained in patients undergoing cardiopulmonary bypass.

The American Society of Anesthesiologists has developed guidelines for recommended fasting before the induction of anesthesia [19]. These guidelines are intended to provide safe conditions for the induction of anesthesia with the minimum risk of aspiration of gastric contents as the airway reflexes are ablated. The recommendations for fasting balance the concern for preventing dehydration and hypoglycemia while limiting the amount of gastric volume and acid content. Special considerations regarding fasting include the administration of routine medications as prescribed with a small amount of clear, nonfat-containing fluid. Patients with single ventricle physiology are encouraged to maintain normovolemia through oral intake of clear fluids, optimizing pulmonary blood flow at the time of the induction of anesthesia. It is generally safe to allow clear liquids up to 2 hours before the scheduled start of anesthesia.

Anesthetic Management

Most outpatient elective cardiac patients benefit from premedication before being taken to the operating room. Several studies have demonstrated that midazolam and dexmetotomidine decrease anxiety and improve the process of parental separation [20]. Parental presence in the operating room at induction has also been used. Individual preferences, parental cooperation, and the ability to administer and monitor the effects of these medications are determinants as to best practice for the anesthesiologist. In the child with poor or indeterminate cardiac function the use of ketamine may be considered. Concerns of increased pulmonary artery pressures and worsening cyanosis have not been proven [21]. Ketamine can be administered by virtually all routes.

Aside from the standard equipment for the administration of anesthesia special considerations for congenital cardiac anesthesia include the availability of intravenous fluids and various fluid and blood administration sets. Our standard practice for the majority of open heart cases is two peripheral intravenous lines, a double-lumen central line, and a peripheral arterial line. If excessive or brisk blood loss is a potential problem as in reoperations or patients with coagulopathies, rapid infusing devices and infusion pumps should be prepared and determined to be operating appropriately. Distal infusion and low volume injection ports are used to allow prompt administration of medications to the child's circulation. This will also avoid fluid overload in extremely small infants and speed the effects of changes in dosing of medications by continuous infusions. Equipment for airway management should be prepared and checked for function with all necessary devices (especially fiberoptic capability) to ensure safe securing of the airway is readily available for patients with potentially difficult airways.

Resuscitation medications should be prepared based on the patient's weight, accurately labeled, and placed in locations easily available and located in areas that will not cause confusion with other anesthetic medications. For example, heparin for anticoagulation before cardiopulmonary bypass is prepared on a weight basis and placed in a position unique for this drug and away from other medications. Methods for heart rhythm control including the defibrillator should be prepared. Medications used in the process of anesthesia such as antifibrinolytic, inotrope, and vasodilator infusions should be prepared and checked for accuracy. The complexity of caring for these patients is nowhere more obvious than in the number of drugs administered and the different routes by which this is accomplished. The continuous infusion of medications is particularly prone to error. Great care must be taken to assure the concentrations are correct, the infusion pump is programmed appropriately, and the delivery system is connected without error. This is even more critical when caring for extremely small infants. The availability of blood and blood products should be confirmed during the patient "time-out."

The responsibilities for all members of the team should be delineated before starting the induction of anesthesia. Airway management, monitor placement, and venous and arterial access are designated to individual members to ensure expedient preparation of the patient for the procedure. The operation of the defibrillator is also clarified before the beginning of the case.

The induction of anesthesia is primarily directed by the cardiac function. In patients with normal ventricular function, any of the standard anesthetic agents can be safely used for induction. In patients with decreased ventricular contractility ketamine remains a popular choice and can be used by either the intramuscular or intravenous routes. Etomidate administered by intravenous route is useful in older patients potentially avoiding the psychic phenomenon associated with ketamine.

Anesthesiologists often face challenges in establishing vascular access in patients with congenital heart defects. The high number of newborn infants and patients with multiple previous procedures limits available sites for both venous and arterial access. Consideration of these issues before inducing anesthesia allows alternate plans to be developed, adds efficiency to the process, and minimizes anesthesia time. Experience in ultrasound-guided access should be part of the cardiac anesthesiologist's skill set. The use of ultrasound-guided placement has been demonstrated in accessing the central venous compartment via

the internal jugular vein. However, in our experience we find children do not tolerate catheters in the neck well and object to the tethering effect of intravenous tubing at this site. Hence, our preference has been for subclavian vein central venous access. Ultrasound-guided access has been shown to decrease the time to successful placement of catheters for venous access [22]. Variable results have been yielded with arterial access [23]. The rate of complications is decreased using guided technology [24]. Another paradigm shift in approaching the patient with difficult vascular access involves a change in technique. In anesthesia we learn to gain venous access using catheter over needle devices. Micropuncture technique and equipment utilizes a guide wire through a narrow guage needle, dilators used as necessary, and the catheter then placed over the guide wire.

Halothane, previously associated with a high incidence of cardiac complications, is no longer available for use. The remaining volatile agents provide essentially equal cardiac stability and all can be used successfully. Of the volatile anesthetic agents currently used in pediatric anesthesia sevoflurane is more easily accepted by children. During induction care must be taken to carefully observe vital signs. There is evidence that all the volatile agents are cardioprotective and decrease mortality in patients anesthetized for heart surgery [25,26].

An anesthetic technique of high-dose narcotics was previously shown as the best technique to prevent the stress response during and after anesthesia for the repair of congenital heart defects in infants [27]. Halothane was the volatile agent used in comparison. More recently, 50 μg/kg total fentanyl dose has been demonstrated to be a sufficient amount for anesthesia, higher doses of 100 μg/kg were noted to increase the frequency of hypotension without noticeable improvement in the state of anesthesia [28]. In more recent studies the focus has been on the benefits of brain protection and preconditioning of the heart. These studies have demonstrated the benefits of using volatile anesthetic agents during and after bypass maintaining cardiac function after intervention [26,29]. Sevoflurane might depress cardiac function to a greater extent than isoflurane after bypass and the use of all volatile agents in this period should be carefully monitored [30].

Presently a combination of moderate dose fentanyl up to 50 μg/kg with sevoflurane before initiating bypass and either desflurane or isoflurane during and after bypass achieve successful results. Patient recall is possible with narcotic technique, and amnestic agents either benzodiazepines or volatile agents at a concentration of one-half minimum alveolar concentration should be administered. Rapid cooling and rewarming is associated with impaired neurologic outcome and weaning from bypass at lower core temperatures utilizing prolonged hypothermic neuroprotection may be warranted [31,32].

It is well recognized that cardiopulmonary bypass results in an inflammatory response. The impact of all facets of anesthesia care on the inflammatory response remains unclear. This includes the use of steroids and volatile agents and the use of ultrafiltration after bypass [33,34].

A method for intraoperative monitoring and clinical correlation after repair entails the use of transesophageal echocardiography (TEE). Care should be exercised after the probe is placed in infants as the immature airway lacks cartilage support and is prone to collapse. Carbon dioxide retention may occur without a concomitant increase in end-tidal levels [35]. In patients with a retroesophageal subclavian artery, passage of the TEE probe may affect the waveform of the arterial line if it is placed in the affected arm.

Three specific cardiac lesions deserve special attention. First, the newborn with hypoplastic left heart syndrome remains a particular clinical challenge. Risk is entailed when these babies are transported from the neonatal intensive care unit to the operating room. These newborns require a high pulmonary vascular resistance to promote systemic perfusion. Extreme caution must be exercised in transporting and caring for these patients before the initiation of bypass. Hypoxic gas mixtures, added low-dose carbon dioxide, and aggressive systemic afterload reduction are necessary to maintain the delicate balance of pulmonary to systemic blood flow [36–38]. Oxygen saturation should be kept at 70–80%; excessive oxygen saturations result in a decrease in pulmonary vascular resistance and excessive pulmonary blood flow at the expense of systemic perfusion. The second condition, the patient with Fontan physiology also requires careful attention to ventilation parameters. Passive pulmonary blood flow is optimized with ventilation that allows negative intrathoracic pressures [39]. Positive-pressure ventilation decreases pulmonary blood flow, and continuous positive airway pressure can have deleterious effects on perfusion, both pulmonary and systemic. Early extubation of these patients is a consideration [40]. A third condition that requires particular attention is the patients having a bidirectional superior cavopulmonary anastomosis. These patients rely on sufficient cerebral blood flow to provide venous return to the pulmonary arteries for optimal arterial oxygen saturation. In these patients hyperventilation is actually detrimental and hypoventilation (pCO_2 = 50–55 mmHg) improves oxygenation. Because this is counterintuitive, the anesthesiologist must be aware of this curious physiology [41,42].

Neurologic issues can occur in infants and young children with congenital cardiac defects. A sign of neurologic involvement is evidenced by periventricular leukomalacia (PVL) which has been found to be present in 20% of infants presenting for surgery. The presence of PVL increases to 50% after surgery requiring cardiopulmonary bypass [43]. Signs and symptoms in the child may not be evident early

in life but become more apparent on entrance to school. Neuroprotection during cardiopulmonary bypass is a consideration for the anesthesiologist. Variables noted to possibly affect neurologic outcome include the use and length of time of deep hypothermic circulatory arrest (DHCA), the level of hemodilution, acid–base management at deep hypothermia, cerebral blood blow optimization, and the speed of rewarming [31]. Near infrared spectroscopy (NIRS) has recently been used to measure cerebral and somatic regional oxygen saturation. The NIRS probe uses a light source that directs light through bone and tissue which is then sensed by a shallow and deep detector. The absorption data returned to the detectors reflects deoxygenated hemoglobin and total hemoglobin from which regional (cerebral or somatic) oxygenation is calculated. Kussman and colleagues recently reported that perioperative periods of diminished cerebral oxygen delivery, as indicated by rSO(2) <45%, are associated with 1-year Psychomotor Development Index and brain magnetic resonance imaging abnormalities among infants undergoing reparative heart surgery [44,45]. At present methods thought to prevent brain injury include limited use of DHCA, monitoring and responding to regional cerebral perfusion (NIRS), achieving uniform cooling, utilizing pH stat arterial blood gas strategy, and recognizing that hyperglycemia is preferred over hypoglycemia. Raising the hematocrit to 30% during cardiopulmonary bypass appears to result in less neurologic injury [46]. Pharmacologic intervention includes using volatile agents to increase cerebral blood flow and achieve more uniform cooling and rewarming. Medications that have been studied in an effort to reduce neurologic injury include free radical scavengers, antiepileptics, erythropoietin, and anti-inflammatory agents [47]. None have proven unequivocally beneficial to date.

Blood loss after cardiopulmonary bypass continues to be a challenge and subject of debate. Before induction of anesthesia a clear understanding of the desired hematocrit at the end of the procedure will allow adequate preparation of blood and blood products. In general terms for the patient having a two ventricle repair a hematocrit of 30% is adequate. For the functional single ventricle that is still mixing (e.g., Norwood, bidirectional Glenn) a hematocrit of 45% is optimal. After the Fontan procedure a hematocrit of 30–35% is acceptable. In younger patients it is more likely that blood loss will be greater and therefore a higher end hematocrit will be desired [48]. Consideration must be paid to the number of donor exposures each patient will experience. The use of blood products is associated with the potential transfer of pathogens and alloimmunization, both of which may affect the long-term health of the patient [49]. Platelet count and function decreases are frequently encountered [50]. A rational plan for post-cardiopulmonary bypass includes the use of an antifibrinolytic, followed by platelet infusion, cryoprecipitate to increase fibrinogen, and factor VII in increasing order of problematic bleeding [51].

Regional Anesthesia

The use of regional anesthesia techniques for cardiac surgery remains controversial despite its routine use at many pediatric cardiac centers across the country with little if any reports of serious complications. The main objection to the technique (although not supported in the literature) is the theoretical increased risk of epidural hematoma formation with a neuraxial technique followed by systemic anticoagulation. The incidence of spontaneous epidural hematoma has been estimated at 1:150 000 [52]. The estimates of the incidence of epidural hematoma formation after neuraxial anesthesia in cardiac surgery remains speculative and currently very little data exists on which to base a risk–benefit analysis.

Evidence-based data on the use of regional anesthesia in pediatric cardiac surgery is limited. The most common type of regional technique used is a single shot caudal block with morphine, however the duration is usually short and the need for systemic opioids remains [53]. Several reports have been published on the use of neuraxial techniques in congenital cardiac surgery without any adverse events. These studies have all failed to demonstrate a significant objective increased benefit in terms of postoperative recovery [54,55]. Therefore, based on current evidence a neuraxial technique can be used safely, however outcome studies are lacking in terms of the true benefit of the technique. It is recommended that anticoagulation does not occur until 1 hour after the regional block is placed [56].

Fast Tracking and Early Extubation

Many children undergoing cardiopulmonary bypass and congenital cardiac surgery can be rapidly weaned and extubated safely in the operating room or shortly thereafter. In order to fast track patients a multidisciplinary team must be assembled to expedite the patients through the perioperative process. The best way to achieve these common multidisciplinary goals is through clinical pathway algorithms [57,58]. The main goal of the fast track process is early extubation which leads to shorter ICU and hospital stays, with cost savings for both the patient and health care facility. Several studies have proven the effectiveness of employing this strategy in congenital cardiac surgery [59,60]. Many variables need to be considered when one decides on the fast track process that include the following: size of the patient, length of procedure, hemodynamic stability, bleeding, hypothermia, pulmonary dysfunction, and the need for ongoing inotropic support. In the largest series to date of early extubation in children

undergoing cardiac surgery with CBP, early extubation was accomplished in 72%, which included 50% of patients less than 1 week of age [61]. Whether it is more advantageous to facilitate endotracheal extubation before the patient leaves the operating room or upon arrival in the ICU has not been determined.

The cardiac anesthesiologist must be vigilant in the preplanning aspect of the anesthetic approach as the traditional high-dose narcotic, neuromuscular blocker, and inhalational agent technique will prevent a patient from being fast tracked. The narcotic dose and choice of narcotic should be tailored with this goal in mind. Both fentanyl and remifentail can be effective in achieving early extubation in pediatric cardiac fast track patients [62]. Finally, the child must have excellent postoperative analgesia for the fast track process to proceed without incident. Many centers have advocated the use of a combined general anesthesia plus regional anesthesia technique for pediatric cardiac surgery patients with no evidence of epidural hematoma [63]. However, the use of neuraxial analgesia in light of complete anticoagulation remains controversial.

Anesthesia and Cardiac Imaging

Anesthesia for cardiac imaging places responsibility on the anesthesiologist to provide optimum conditions for the acquisition of the best images. The cardiac catheterization laboratory continues to require anesthesia care as interventional transcatheter techniques continue to grow and improve. Anesthesia care is required for procedures ranging from closure of septal defects, to dilation of stenotic valves, to transcatheter valve insertion. The location of the cardiac catheterization laboratory is frequently distant from the traditional operating rooms and requires the development of process and protocols for managing the anesthesia of these patients in remote locations. Malignant hyperthermia is one example that requires prompt therapy to limit morbidity and mortality. Dantrolene must be available so that it can be administered immediately after the diagnosis is made. The logistics of communication with support staff and the attainment of additional assistance, equipment, and therapy before induction of anesthesia in these locations is advised.

Computed tomography (CT) scans of the heart in addition to occurring in a remote location requires anesthesia for procedures of short duration, a brief period of apnea to acquire images without respiratory motion, and slow heart rates to eliminate cardiac motion [64]. Short-acting neuromuscular blockers are utilized and the pharmacologic methods of slowing the heart rate for a brief period of time may be needed. Heart rates near 80 beats per minute yield the best results [65]. Deepening the depth of anesthesia or the use of beta blockers may be requested. A contrast injection is necessary and this places the added burden of a large bore intravenous catheter being placed in the right arm to provide rapid and direct access to the heart. Magnetic resonance imaging (MRI) of the heart requires multiple lengthy episodes of apnea. Endotracheal intubation is normally required to accomplish this in children. Consideration on methods to secure a difficult airway in remote locations is advised.

Pulmonary Hypertension

The use of inhaled nitric oxide (iNO) in the setting of congenital cardiac surgery has become quite routine. Patients with increased pulmonary blood flow or pulmonary venous obstruction coupled with endothelial injury caused by cardiopulmonary bypass benefit from iNO which is a selective pulmonary vasodilator [66]. Inhaled nitric oxide therapy is an easily administered pulmonary vasodilator added to the anesthesia circuit with no clinically evident systemic vasodilation which can be safely used even in the setting of hemodynamic instability.

When delivered to the respiratory tract, nitric oxide diffuses rapidly across the alveolar–capillary membrane into the smooth muscle layer of the pulmonary vessel. Inhaled nitric oxide catalyzes the formation of cyclic guanosine monophosphate (cGMP) resulting in smooth muscle relaxation. This smooth muscle relaxation is inhibited by the cyclic nucleotide phosphodiesterases (PDE). Of note, PDE5 is inhibited by the phosphodiesterase inhibitor sildenafil, an oral treatment for pulmonary hypertension. Inhaled nitric oxide therapy gains its role as a selective pulmonary vasodilator from nitric oxide's rapid bloodstream deactivation as it combines with hemoglobin to form methemoglobin and nitrate [67]. Methemoglobinemia is measured to determine toxicity. Nitrogen dioxide, another toxic metabolite leads to increased airway reactivity and, later, pulmonary edema [68].

Congenital cardiac anomalies associated with a high risk of elevated pulmonary resistance include atrioventricular septal defect, common arterial trunk, transposition of the great arteries, ventricular septal defects, and total anomalous pulmonary venous connection [69]. Current evidence supports the use of iNO therapy in congenital heart disease both in treatment of pulmonary hypertension and in a prophylactic fashion during surgeries for lesions associated with a high risk of pulmonary hypertension. The effective iNO dose in congenital cardiac surgery rarely exceeds 20 ppm, and this has remained the manufacturer's recommendation for initial administration [70,71]. The prophylactic role of iNO in preventing postoperative pulmonary hypertensive crises and speeding time to extubation has also been established [72]. Nitric oxide therapy needs to be continued during all transports. Future directions will address the role of iNO in combination with intravenous

vasodilators, and of the causes of interpatient response variability and its relationship to endothelial biology.

Cardiac Pharmacology

Several drugs used in the conduct of congenital heart procedures warrant mention. Prostaglandin E1 has been infused in newborns for the past 30 years to maintain the patency of the ductus arteriosus in lesions that require continuous flow through this structure to maintain life [73]. Experience continues to demonstrate that this drug is associated with a significant rate of complications divided almost equally between the respiratory system and the heart. Apnea and hypotension are possible and demand careful attention during the transport of these infants [74].

Arginine vasopressin is an antidiuretic hormone (ADH) that is a potent vasoconstrictor. The therapeutic use of this drug includes any form of vasodilatory shock from sepsis to anaphylaxis [75]. Although this drug will likely be used infrequently, it should be considered in conditions of hypotension unresponsive to other mechanisms of support [76].

Pulmonary hypertension is commonly associated with various cardiac malformations. Knowledge of the various pharmacologic approaches to this disease process is needed to provide optimal care. In addition to nitric oxide which must be administered by a metered continuous flow apparatus, oral medications include sildinefil, a phosphdiesterase type 5 inhibitor, the endothelin antagonist bosentan, and the prostenoids, iloprost, a metered inhaled medication, and epoprostenol administered by the intravenous route [77,78]. Patients who require cardiac anesthesia may be taking these agents alone or in combination.

Postanesthesia Process

The transition of patients to the intensive care unit after cardiac surgery involves the physical movement of the patient and equipment, exchange of patient data, and the transfer of responsibility of care. Critical information about the patient is conveyed to the critical care team during a time of significant hemodynamic vulnerability [79]. Elements found critical to the successful transition of a patient include the efficient transition of monitors and equipment, limiting discussions to those related only to the patient, a face-to-face handoff of patient information, and discussion of a plan between all care providers involved, and limited interruptions during the information handover [80–82]. Several studies to date have investigated the standardization of the handover process in pediatric patients after transition from the operating room to the cardiac intensive care unit following cardiac surgery [83,84].

A multidisciplinary team of key stakeholders should be assembled to develop a protocol for the transition of cardiac patients to the intensive care unit following cardiac surgery. The goal of any transition protocol is to improve patient safety by reducing the number of latent and realized errors that occur during the transition process [85]. Root cause analyses are performed by the team appraising key steps in the process where concerns from performance evaluation have arisen. Actual errors identified are also subject to additional root cause analysis. Ultimately a transition protocol should be developed and tools created to facilitate protocol compliance. After a structured educational period, protocol implementation can begin.

The goal of the transition protocol is that a "sterile team environment" must be maintained throughout the transition process while the anesthesiologist acts as transition team leader until responsibility of care has been transferred. Other highlights of the transition protocol include:

- a critical care team member enters the operating room near the end of the case to receive handoff instructions from the cardiovascular surgeon;
- a focus on the efficient transition of all patient monitors before anesthesia handoff;
- the implementation of a written tool to guide the anesthesiologist's verbal handoff.

Conclusion

The congenital cardiac anesthesiologist must be prepared to care for a wide-ranging group of congenital heart patients from extremely premature infants to patients in the sixth decade of life. The underlying cardiac defects range from cyanotic to acyanotic cardiac malformations as well as disturbances of heart rate and rhythm. The patient with functional single ventricle physiology presents special challenges. This very complex system of disease management entails the potential for numerous errors and the team approach appears to offer the best outcome [86]. This team consists of dedicated anesthesiologists as well as dedicated members from each specialty to develop protocols including standardized methods for transfer of care of these patients.

There is no single regimen of anesthesia that has been demonstrated to be superior, but a balanced technique of narcotics and volatile anesthetic agents appears to provide safety while affording protection for the brain and limiting the inflammatory response for patients undergoing cardiac surgery. Further challenges include providing anesthesia care in remote and isolated locations for nonsurgical procedures including cardiac catheterization and imaging. Transporting these patients before and after anesthetics necessitates specialized equipment such as portable nitric oxide and the ability to deliver hypoxic gas mixtures.

Finally, the anesthesiologist should develop a method of providing pain relief from the end of the procedure until it is no longer an issue. Regional anesthetic techniques may play an important role in the early period after a procedure

while patient-controlled analgesia and parent-controlled analgesia for children who are too young to understand will play a pivotal role in the recovery process and improvement of care in these patients.

CHAPTER 7

Perioperative Care

Carl L. Backer,[1] John M. Costello,[1] Jason M. Kane,[1] and Constantine Mavroudis[2]

[1]Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Chicago, IL, USA
[2]Florida Hospital for Children, Orlando, FL, USA

The improved results after surgical treatment of congenital heart defects in recent years can in part be attributed to the attention now focused on perioperative care. Specific techniques used to accomplish a smooth postoperative course are determined by the patient's age, the nature of the cardiac defect, the child's preoperative clinical condition, and the type of repair performed. Postoperative care of the infant or child following cardiac surgery differs considerably from that of adults. For example, the circulatory response to cardiopulmonary bypass and the anatomy and physiology of the respiratory system vary greatly by age. Postoperative monitoring of infants and children emphasizes noninvasive techniques (especially physical examination) as compared to the routine invasive monitoring of adult cardiac surgery patients. Comorbidities encountered in children also differ vastly from those encountered in adults.

Many different multidisciplinary models are currently used to provide cardiac critical care. Optimal perioperative care requires a multidisciplinary team that includes cardiovascular surgeons, cardiac intensivists, cardiologists, cardiac intensive care unit (ICU) nurses, and respiratory therapists [1,2]. Consultation should be available from all other pediatric subspecialties. The anatomic, physiologic, and electrophysiologic manifestations of many types of congenital and acquired heart disease are complex and often esoteric. A thorough understanding of the subtleties of each cardiac lesion, along with the growing number of diagnostic tools and treatment options used in their management are central to the provision of critical care for this patient population. The cumulative experience and critical mass of the entire team likely contributes to the improved outcomes achieved by centers performing a higher volume of pediatric cardiac surgical procedures [3–6]. To consolidate this experience, many programs now provide care for all critically ill children with cardiac disease in dedicated cardiac ICUs [7]. Regardless of the care model, the cardiac surgeon will have the most intimate knowledge of the intraoperative findings and the adequacy of the repair and thus assumes final responsibility for the patient.

Although many children will have a smooth postoperative course, it is important to maintain a high level of vigilance for early warning signs of possible complications so that the initiation of appropriate therapy is preemptive in nature and not simply a reaction to problems as they arise. Constant attention to detail is essential and prevention of complications (anticipatory rather than reactive care) is the key to optimal postoperative outcomes.

Preoperative Preparation

A smooth operative and postoperative course begins with preparation of the child for surgery. Children undergoing elective surgery should have a careful history and physical examination 1 or 2 days before the procedure. The cardiologist and surgeon should review relevant cardiac diagnostic information to ensure that the evaluation is complete and the surgical plan is clear. Any chronic medical problems that require special attention (e.g., diabetes, seizure disorder, asthma, anticoagulation), or any acute medical illnesses (e.g., pneumonia, upper respiratory infection, otitis media) that would mandate cancellation of elective surgery should be identified [8]. For closed-heart operations (performed without cardiopulmonary bypass [CPB]), routine laboratory evaluations include a chest radiograph, complete blood cell and platelet count, and urinalysis. For open-heart operations we also obtain a prothrombin time, partial thromboplastin time, and serum electrolyte measurement. Blood should be obtained for drug-level assays if

the patient is being treated with drugs such as digoxin and phenobarbital. These laboratory tests screen for abnormalities that may have to be corrected before surgery or require special attention during surgery, such as anemia, hypokalemia, and bleeding disorders.

In contrast to older children, the vast majority of neonates who are awaiting cardiac surgery require hospitalization in an ICU. Neonates with critical congenital heart disease may be broadly categorized as having ductal-dependent systemic blood flow, ductal-dependent pulmonary blood flow, transposition physiology, or obstructed pulmonary venous return. Historically, many neonates with critical congenital heart defects who present with shock or severe cyanosis require emergent surgical intervention. However the introduction of prostaglandin E1 (PGE_1) infusions to reopen and maintain patency of the ductus arteriosus in the 1970s has largely eliminated the need for emergency surgery [9]. With the exception of severely obstructed pulmonary venous return, the administration of PGE_1 along with other supportive measures (e.g., judicious use of mechanical ventilation or inotropic support) will allow surgery to be deferred for a few days while awaiting recovery of myocardial and end-organ function. Side effects of PGE_1 include apnea, hypotension, fever, and rash. In patients receiving PGE_1 who develop apnea or those who require interhospital transport of PGE_1, mechanical ventilation has traditionally been initiated. However, the elective initiation of mechanical ventilation in this patient population is associated with a number of side effects and may not be warranted in many cases [10]. A PGE_1 dose of 0.01 μg/kg/minute is effective for maintaining ductal patency, and higher doses are likely associated with more side effects. Aminophylline or caffeine may be safely used to minimize the occurrence of apnea in neonates receiving PGE_1 [11].

Lesions with ductus-dependent systemic blood flow include hypoplastic left heart syndrome and interrupted aortic arch (Table 7.1) [12]. Neonates with these lesions will develop myocardial dysfunction, metabolic acidosis, and hepatic and renal dysfunction as the ductus arteriosus constricts. Systemic perfusion is further compromised as pulmonary vascular resistance falls, leading to preferential shunting to the pulmonary circulation, and volume overload of the systemic ventricle. Preoperative management in these cases is aimed at restoring systemic perfusion and supporting myocardial function. In addition to a PGE_1 infusion, the judicious use of inotropes and afterload reduction may be beneficial to support the volume-overloaded systemic ventricle and augment systemic perfusion. Therapies that further lower pulmonary vascular resistance, such as excessive supplemental oxygen or hyperventilation should be avoided. Additional strategies to improve the balance between systemic and pulmonary blood flow include the use of subambient inspired oxygen and hypoventilation, both of which may increase pulmonary vascular resistance. Hypoventilation improves systemic oxygen delivery and thus is the favored approach, but concurrent pharmacological paralysis is required to suppress the patient's respiratory drive [13]. Neonates with ductal-dependent systemic blood flow are at risk for developing necrotizing enterocolitis [14] and many clinicians are reluctant to provide enteral nutrition before surgery.

Table 7.1 Ductus-dependent lesions.

For pulmonary blood flow
Pulmonary atresia with intact ventricular septum
Tetralogy of Fallot with severe pulmonary stenosis or pulmonary atresia
Critical pulmonary stenosis
Tricuspid atresia with severe pulmonary stenosis
For mixing
Transposition of the great arteries
For systemic blood flow
Hypoplastic left heart syndrome
Interrupted aortic arch
Severe coarctation of the aorta
Critical aortic stenosis

Ductal-dependent pulmonary blood flow is present in neonates with severe or complete right ventricular outflow tract obstruction (Table 7.1) [12]. These patients present with progressive cyanosis as the ductus arteriosus constricts. A PGE_1 infusion will reliably reopen the ductus arteriosus and improve systemic oxygen saturation levels [15]. In contrast to patients with hypoplastic left heart syndrome or interrupted aortic arch, the ductus in neonates with right ventricular outflow tract obstruction is typically long and tortuous, providing resistance that usually limits pulmonary overcirculation. Such patients generally do not require interventions to balance the circulation, and can tolerate enteral nutrition while awaiting intervention.

In patients with d-transposition of the great vessels, the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. Neonates with transposition physiology are dependent on mixing of oxygenated and deoxygenated blood at the ductus arteriosus and through any atrial or ventricular septal defects. In patients with restrictive septal communications, marked cyanosis will be present at birth or will develop with constriction of the ductus arteriosus. PGE_1 is initiated when this diagnosis

is suspected followed by an emergent balloon atrial septostomy (BAS), which will facilitate mixing at the atrial level and thus improve systemic oxygenation [16]. Additional benefits of a BAS include a reduction in left atrial pressure, which may facilitate a drop in pulmonary vascular resistance. For these reasons, many centers perform an elective BAS in all patients with d-transposition of the great vessels, unless a sizable secundum atrial septal defect is present.

Patients with obstruction of pulmonary venous return or left atrial egress may present with profound cyanosis within minutes to hours of birth. Neonates with severely obstructed total anomalous pulmonary venous return will not have sustained improvement with medical therapies and require emergent surgical repair. Neonates with hypoplastic left heart syndrome and a severely restrictive or intact atrial septum are at high risk for mortality due to the severity of the heart defect, abnormalities in pulmonary lymphatic development, and late development of pulmonary vein stenosis. Acute stabilization is best achieved by emergent creation of an atrial septal defect in the catheterization laboratory, followed by stage 1 Norwood palliation once pulmonary congestion has improved [17].

Neonates with critical congenital heart defects require preoperative evaluation for noncardiac comorbidities. Major noncardiac structural anomalies (e.g., omphalocele, tracheoesophageal fistula, renal anomalies) are found in approximately 15% of neonates with congenital heart disease [18,19]. An ultrasound scan of the brain should be obtained to rule out intraventricular hemorrhage or other intracranial abnormalities, particularly in neonates who were premature, had a difficult delivery, or presented in shock or with severe cyanosis. Recent literature indicates that the prevalence of central nervous system abnormalities before surgery in newborns with congenital heart defects has been under-appreciated [20]. Preoperative brain magnetic resonance imaging (MRI) examinations obtained in research protocols in term newborns with transposition or single ventricular physiology reveal anatomical and functional characteristics comparable to premature neonates, suggesting abnormal brain development in utero [21,22]. Licht and colleagues have shown that preoperative cerebral blood flow is diminished in neonates with severe congenital heart defects [23]. Microcephaly, periventricular leukomalacia, or stroke may have been seen in approximately one-third of preoperative neonates with complex congenital heart defects [23–25]. The long-term implications of these findings are the subject of ongoing investigations, but they likely contribute to the suboptimal late neurodevelopmental outcomes experienced by some neonates with complex congenital heart disease.

Neonates with congenital heart defects that are associated with syndromes warrant genetic testing and counseling (e.g., interrupted aortic arch and DiGeorge syndrome; atrioventricular septal defect and trisomy 21). This testing is not done to exclude patients from surgery, but rather to help anticipate comorbidities, plan the postoperative care, and facilitate counseling for future pregnancies [26].

Neonates with critical congenital heart disease who are born prematurely are at increased risk for morbidity and mortality and often require extended hospitalization [27]. The care of these patients may be complicated by any of the problems associated with prematurity, including respiratory distress syndrome, necrotizing enterocolitis, and intraventricular hemorrhage. The musculature in the pulmonary arterioles is less well developed, predisposing patients with left-to-right shunting to a rapid decline in pulmonary vascular resistance and overcirculation. In general, attempts to delay surgical or transcatheter intervention while awaiting growth in such patients are likely to be unsuccessful, and early intervention is recommended [28,29].

Intraoperative Care

The monitoring devices to be used in the postoperative period are selected based on the patient's age, heart defect, and anticipated postoperative course. These devices are generally placed in the operating room usually in collaboration with the pediatric cardiac anesthesiologist (see Chapter 6, *Anesthetic Management for Pediatric Cardiac Surgery*). The information obtained from monitoring devices is extremely useful but is only reliable when obtained from appropriately calibrated instruments. The information obtained must be interpreted in the context of known normal values for patient age. Examples of normal resting blood pressure and normal postoperative heart rate for different patient ages are shown in Tables 7.2 and 7.3 [12,30,31].

Electrocardiographic Leads

The electrocardiographic (ECG) leads should be placed on the chest and limbs so that the patient's heart rate, rhythm, and ST segments can be monitored. The leads should be

Table 7.2 Normal values for blood pressure according to age. (Adapted with permission from Nadas *et al.* [31].)

Age (yr)	Systolic/diastolic pressure (mmHg)	Mean value* (mmHg)
Neonate	68/42	51
To 0.5	80/46	57
0.5–1.0	89/60	70
1.0–2.0	99/64	76
2.0–4.0	100/65	77
4.0–12.0	105/65	78
12.0–15.0	118/68	85
>15.0	120/70	87

*Mean arterial blood pressure calculated as diastolic pressure plus one third of pulse pressure.

Table 7.3 Ranges of heart rate during sinus rhythm in normally convalescing patients after open heart surgery. (Adapted with permission from Kirklin *et al.* [30].)

Age	Heart rate (beats/min)
0–1 month	120–190
1–6 months	110–180
6–12 months	100–170
1–3 years	90–160
3–6 years	80–150
6–15 years	80–140
>15 years	70–130

placed away from the area to be prepped and not too close to the electrocautery grounding pad.

Temperature Monitoring

Monitoring of a child's temperature in the operating room and postoperatively is crucial. The high systemic vascular resistance of a hypothermic child can prevent successful weaning from cardiopulmonary bypass. We monitor both the esophageal and rectal or bladder temperatures in all open-heart cases. The use of forced-air warming blankets in the operating room has been very successful in warming patients after hypothermic cardiopulmonary bypass and keeping them warm in a cold operating room [32].

Oxygen Saturation Probe

Use of a probe for monitoring O_2 saturation on a continuous basis is the standard of care for all infants and children undergoing cardiac surgery [33]. An O_2 saturation probe is simple to use, noninvasive, and relays continuous extraordinarily vital and reliable information. A light-emitting diode (LED) readout displays peripheral O_2 saturation at the same time an audible tone is emitted that is synchronized to the saturation percentage. The surgeon can tune in to the tone while the operation is proceeding and know immediately whether the O_2 saturation is decreasing as a result of surgical manipulation. The saturation monitor also gives some information about cardiac output. If the saturation monitor cannot pick up the pulse, either the child is cold and peripherally vasoconstricted or the cardiac output is not sufficient to generate a recognizable pulse waveform – a grave sign. The saturation probe should be used preoperatively, intraoperatively, and postoperatively and is especially valuable during transport.

Arterial Catheter

An indwelling arterial catheter is necessary for all open-heart operations and most major closed-heart procedures.

Table 7.4 Average normal ranges of intracardiac and intravascular pressures (mmHg). (Adapted with permission from Rudolph *et al.* [34].)

Location	Infants and children	Newborn period
Right atrium	a, 3–7; v, 2–5; mean, 1–5	Mean, 0–3
Right ventricle	15–30/2–5	35–65/1–5
Pulmonary artery	15–30/5–10 (mean, 10–20)	35–65/20–40 (mean, 25–40)
Pulmonary wedge	a, 3–7; v, 5–15; mean, 5–12	
Left atrium	a, 3–7; v, 5–15; mean, 5–10	Mean, 1–4
Left ventricle	80–130/5–10	

Use of an arterial catheter allows continuous monitoring of systemic arterial pressure and easy sampling for measurement of arterial blood gases and other laboratory values. A 20- or 22-gauge plastic angiocath catheter can be inserted into the radial or posterior tibial artery percutaneously or with a surgical cutdown. The dorsalis pedis artery and, in the newborn, the umbilical artery are alternative sites. We rarely use the brachial artery because of the risk of hand ischemia; the common femoral artery can be used if no other sites are available.

Venous Catheters

Adequate intravenous access, usually with two 20-gauge peripheral angiocaths, should be obtained before beginning any major cardiac procedure. Central venous access is required for complex procedures and in most neonates to monitor central venous pressure and administer medications (Table 7.4) [12,34]. Percutaneous catheters may be placed in the subclavian, internal jugular, or femoral vein. For over 15 years our practice has relied extensively and reliably on percutaneously placed subclavian venous catheters (usually on the left side). These catheters are easy to insert, are associated with a low incidence of infection, and provide reliable double- or triple-lumen access for the duration of the child's hospitalization. Other centers prefer the use of internal jugular catheters. The use of ultrasound may increase the rate of successful line placement and minimize complications during placement of central lines in the internal jugular veins [35].

Measurement of venous O_2 saturation in the superior vena cava approximates mixed O_2 venous saturation (SvO_2) and is useful for estimating cardiac output. In neonates recovering from single ventricle palliation, venous O_2 saturation will also aid in the calculation of the ratio of pulmo-

nary to systemic blood flow. Postoperative management centered on maximizing SvO_2 has been associated with improved survival following stage 1 Norwood palliation in some centers [36]. Thus care should be taken to select the length of a percutaneous catheter such that the tip will be positioned in the superior vena cava. Continuous assessment of superior vena cava O_2 saturation is now feasible following congenital heart surgery using oximetric catheters [37].

Atrial Catheters

Right and left atrial lines placed directly at the conclusion of cardiopulmonary bypass (CPB) are useful for measuring central venous pressure and left atrial pressure and are a reliable long-term source of venous access following complex procedures [38–40]. Two complications, however, have led us to abandon use of these lines and instead use percutaneously placed central lines. One complication is bleeding from the atrium at catheter removal. Such bleeding can cause cardiac tamponade that necessitates emergency mediastinal exploration. A second complication is unrecognized migration of the catheter out of the atrium and into the pericardial space. This complication causes infusion of intravenous or hyperalimentation fluid into the pericardium and insidious progressive cardiac tamponade.

With left atrial lines, meticulous attention must be paid to avoiding the introduction of any air or particulate matter into the line. These substances can cause critical coronary or cerebral arterial embolization. The left atrial line should not be used for routine administration of fluid or medications; if obstructed, this line should not be flushed. The left atrial line should be removed with the same precautions for bleeding as in removal of a right atrial line (sedation so the child does not cough or cry, having blood available, and ensuring there are no clotting abnormalities). We have only employed left atrial lines when the sternum is left open and have then removed them at the time of delayed sternal closure 2–3 days later.

Pulmonary Artery Catheter

Pulmonary artery catheters are uncommonly used in the current era following congenital heart surgery, and are generally reserved for patients with an elevated preoperative pulmonary vascular resistance or those in whom residual left-to-right shunting is anticipated (e.g., multiple muscular ventricular septal defects). A flow-directed Swan–Ganz catheter may be passed either through the subclavian vein or internal jugular vein into the pulmonary artery. Alternatively, the catheter can be placed directly into the pulmonary artery through the right ventricular outflow tract or through the right atrium at the time of surgery. The pulmonary artery catheter can be used for measurement of pulmonary artery pressure and cardiac output, or for quantification of residual left-to-right shunting. If placed directly through the right ventricle free wall, it should be removed 48–72 hours after the procedure, while the mediastinal chest tubes are still in place and while observing similar precautions for bleeding as with the atrial lines. In our clinical practice we use pulmonary artery catheters infrequently. We often use transthoracic echocardiograms to obtain an intermittent, noninvasive assessment of pulmonary artery pressures.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is a noninvasive monitoring technique providing real-time venous weighted regional oxygen saturations. Used as a trend monitor, these data provide validated, surrogate measures of cardiac output in pediatric patients during and after cardiac surgery [41]. The specific value of cerebral NIRS is the ability to obtain noninvasive, real-time information on the cerebral oxygen content that reflects both oxygen delivery and consumption. Alterations in regional somatic oxygen saturation reflect local perfusion changes and may be an earlier, more sensitive indicator of impending multisystem organ injury or low cardiac output [42].

Early recognition of changes in cardiac output by NIRS monitoring has improved timely, critical interventions in the care of our patients in both the operating room and the ICU. In spite of the limitations of NIRS technology, responding to the trended data can have a positive impact on patient outcomes [43]. As a result of our experience, we routinely place cerebral and somatic NIRS probes on all cardiac surgery patients at the beginning of the case, and follow the saturation trends as an early indicator of changes in cardiac output. Changes in the NIRS monitoring trends often occur before or in the absence of any other physiologic changes (Figure 7.1) [12,43].

Pacemaker Wires

Temporary pacing wires have diagnostic and therapeutic utility in complex pediatric cardiac surgical patients. Atrial electrograms may be directly recorded in patients in whom traditional surface electrocardiograms are nondiagnostic. Temporary pacing may be readily employed in patients with sinus node dysfunction or to restore atrioventricular synchrony in patients with junctional ectopic tachycardia or complete heart block. Burst pacing may be used to terminate re-entrant arrhythmias. Complications associated with these wires are rare but include tamponade with removal and retention [44].

Considering the above, at the conclusion of a cardiac procedure we do not routinely place temporary pacing

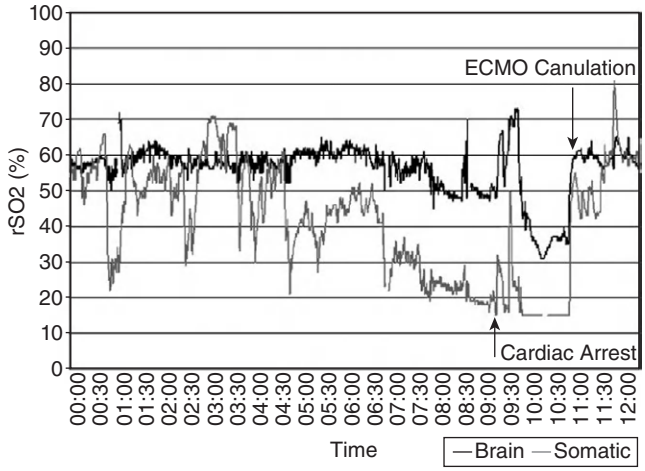

Figure 7.1 Real-time NIRS graph showing 2.5 hours of data that demonstrate acute decrease in rSO2 associated with chest closure in a newborn patient with hypoplastic left heart syndrome and resultant improvement with fluid resuscitation and increased inotropic support. (Reproduced with permission from Kane *et al*. [43].)

wires if the child is in normal sinus rhythm. If a child has evidence of intermittent or complete atrioventricular block, however, temporary atrial and ventricular pacing wires should be placed, typically on the right atrium and the anterior surface of the right ventricle. In certain instances, particularly if the patient is prone to atrial tachycardia or has sinus node dysfunction, the use of temporary atrial pacing wires may be indicated. Temporary pacemaker wires are anchored to the epicardium with fine sutures placed superficially to facilitate removal with minimal risk of hemorrhage. Some other centers agree with this strategy and do not employ routine temporary wires [45]. Other centers advocate routine placement of atrial and ventricular unipolar temporary pacing wires in all patients undergoing CPB [46]. If the patient remains in complete heart block for more than 7–10 days a permanent pacemaker should be placed and the temporary wires removed at that time [47].

Chest Tubes

Drainage catheters appropriate to patient size are left in place after all open and some closed procedures. We do not routinely place chest tubes after simple patent ductus arteriosus ligation or vascular ring division. We recently changed our practice from using rigid thoracotomy tubes with pleurovac drainage to using Blake drains with soft bulb suction except when there is a continuous air leak from the lungs [48]. For a larger child in whom neither pleural space has been entered, a single mediastinal tube is sufficient. When they are entered, the pleural cavities are drained separately through pleural chest tubes. In small infants, or when there is myocardial swelling, the mediastinal drainage tube can cause coronary arterial or cardiac compression. In this circumstance the mediastinum is best drained with a right pleural tube, which is inserted through the pleural space and then anteriorly into the superior mediastinum. The amount of blood lost through the chest tube(s) should be carefully recorded on an hourly basis.

Nasogastric Tube

The stomach should be routinely decompressed postoperatively with a nasogastric tube in all intubated patients. This step prevents respiratory embarrassment secondary to gastric distention, vomiting, and tracheobronchial aspiration. The nasogastric tube is generally removed when the endotracheal tube is removed.

Urinary Catheter

A urinary catheter is placed in nearly all infants and children undergoing an open cardiac procedure or a complicated closed-heart procedure. The measured urine output per hour is an excellent indicator of the adequacy of renal perfusion and cardiac output. Urinary output should be meticulously recorded on an hourly basis after the operation and should be at least 1 mL/kg/hour in a child with adequate cardiac output and preload. We use urinary catheters with a temperature sensor to avoid placement of rectal temperature probes.

Corticosteroids

Cardiopulmonary bypass is associated with systemic inflammatory response that contributes to dysfunction of multiple organ systems and prolongs postoperative recovery. In a randomized double-blind, placebo-controlled trial conducted at our institution, we demonstrated that the administration of dexamethasone before CPB led to an improved postoperative clinical course and a reduction in the post-bypass inflammatory response as assessed by cytokine levels [49]. We currently administer intravenous dexamethasone (1 mg/kg intravenously, not to exceed 20 mg) in the operating room as soon as the intravenous lines have been placed in all patients who are to undergo CPB. Some form of steroid administration is now used by nearly all pediatric cardiac surgical centers [50].

Routine Postoperative Care

Transport to the Intensive Care Unit

After the procedure the patient must be carefully monitored and transported to the ICU. A formal transition

process, derived from Formula One pit stop and aviation models, has been associated with a reduction in technical errors and handover omissions [3]. Before transport, it is helpful for a member of the operating room team to notify the ICU staff of the patient's status. At our center the ICU team receives a "face-to-face" report in the operating room before transport, including a detailed description of the operative findings and repair, the cardiopulmonary bypass, cross-clamp and circulatory arrest times (if any), an assessment of myocardial function coming off bypass, vital signs and filling pressures, and any pressure or O_2 saturation measurements or transesophageal echocardiogram findings. The anesthesia team conveys relevant data about vascular access, the airway and pulmonary function, and the anesthetic. Transportation is facilitated with a portable electrocardiogram and arterial blood pressure monitor along with an O_2 saturation monitor. Oxygen and emergency airway equipment are required for all patients. Battery-operated intravenous pumps are necessary to ensure uninterrupted delivery of fluids and inotropic agents. It is important to avoid hypothermia during transport. On arrival at the ICU, a thorough and systematic approach by trained ICU nurses prevents possible complications and avoids catastrophic situations. The sequence of care of a child is quite important and should begin with attention to the airway and ventilation followed by the cardiovascular system and various subsystems. While the child is being attached to the monitoring systems in the ICU, all staff should observe the patient constantly for signs of difficulties that might require alteration in the normal sequence of events.

Airway and Breathing

Maintaining airway patency and ensuring adequate oxygenation and ventilation are priorities for all patients. Physical examination as soon as the patient arrives in the ICU can reveal clinical signs of desaturation including perioral and/or peripheral cyanosis. Careful inspection for symmetry and adequacy of chest wall expansion and auscultation for bilateral breath sounds should be performed. Other signs of respiratory insufficiency in spontaneously breathing patients include tachypnea, retractions, nasal flaring, grunting, and, of course, apnea. A portable chest radiograph should be obtained for evaluation for pneumothorax, hemothorax, and atelectasis, and for confirmation of the position of the endotracheal tube (ideally in the middle third of the trachea) and the location of central and atrial lines. We obtain routine daily portable chest radiographs for all intubated patients [51]. Continuous pulse oximetry is used in the care of all patients. Selected patients receive continuous end-tidal CO_2 monitoring. Arterial blood gas is always performed.

Patients who are extubated before leaving the operating room are usually placed on supplemental O_2 via nasal cannula or face mask. The initial arterial blood gas for a child who is extubated frequently shows mild CO_2 retention. In the usual case, as the residual effects of anesthesia wear off, the CO_2 tension of arterial blood ($Paco_2$) normalizes. If $Paco_2$ does not become normal, or if the child starts to show signs of respiratory insufficiency, reintubation should be considered. Careful assessment to identify the cause of respiratory insufficiency may be helpful in avoiding reintubation. Inadequate reversal of muscle relaxants and the sustained effects of narcotics are two situations that are easily managed. Other patients may benefit from noninvasive measures such as continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) on a transitional basis. Acute upper-airway edema can be managed with nebulized racemic epinephrine. Some patients may benefit from breathing heliox (helium and O_2 in mixtures) as the edema resolves.

The care of patients who return to the ICU intubated can be complicated. Ensuring a smooth postoperative course requires a thorough understanding of cardiopulmonary interactions [52]. Positive-pressure ventilation and alterations in respiratory mechanics can have a profound effect on hemodynamics, particularly after repair of complex congenital heart defects. Changes in intrathoracic pressure can affect systemic venous return, right ventricular ejection, left atrial filling, and ultimately cardiac output. Appreciation of the unique effects of cardiopulmonary interactions on circulatory physiology following complex congenital heart procedures is essential when selecting ventilator strategy. It is imperative that the physician be present at the time of initiation of ventilatory support. Routine settings simply do not exist. Operating room ventilator and tubing characteristics may differ from those used in the ICU, requiring different settings from those used in the operating room. The presence of a large leak around the endotracheal tube, pleural effusions, chest wall edema, or abdominal distention can dramatically affect the adequacy of delivered breaths. Careful observation and monitoring are critical during this transition phase. In all cases the patient should remain intubated and ventilated until cardiac and respiratory functions are stable.

The usual starting tidal volume is approximately 10 mL/kg, and the ventilator rate in general ranges from 24 (newborn) to 8 (adult). A pressure or volume limited mode of ventilation may be used; with either mode, serial blood gases are obtained to monitor the effect of ventilation along with pulse oximetry and end-tidal CO_2 monitoring. Sedation and analgesia, as well as avoidance of patient/ventilator asynchrony and prevention of pulmonary hypertensive crisis, may all be achieved by continuous or intermittent intravenous infusion of morphine and/or midazolam. The importance of patient/ventilator synchrony cannot be

overemphasized. In the context of often times minimal cardiac reserve, the demands associated with excessive work of breathing and patient agitation can be deleterious. We commonly use morphine sulfate at 100 μg/kg/hour and midazolam at 50–100 μg/kg/hour. For neonates with delayed sternal closure, limited cardiac reserve, or severe pulmonary hypertension, temporary postoperative paralysis with vecuronium by continuous infusion of 100 μg/kg/hour is frequently used.

Ventilator strategy must be further modified on the basis of each patient's preoperative state and anticipated postoperative physiology. For children with postoperative pulmonary hypertension, ventilator settings are selected to achieve an O_2 tension of arterial blood (Pao_2)>100 torr, and a mild respiratory alkalosis. Strong consideration should be given to the early use of inhaled nitric oxide for the treatment of pulmonary hypertension [53]. A 24- to 48-hour period of sedation, paralysis, and full ventilation in our judgment has been associated with less risk of pulmonary hypertensive crisis when the paralysis is stopped and the child is weaned from the ventilator.

For patients who have a single ventricle and shunt-dependent pulmonary blood flow, the goals of mechanical ventilation are different. In these children we try to keep O_2 saturation at 75–80% to maintain a balanced circulation. Excessive ventilation in these patients may reduce pulmonary vascular resistance and lead to pulmonary overcirculation and low systemic output. After a superior cavopulmonary anastomosis (bidirectional Glenn), hyperventilation decreases cerebral blood flow with subsequent decreased blood flow through the superior vena cava to the pulmonary arteries. Therefore mild hypoventilation (Pco_2 48–55 mmHg) has been shown to result in optimal pulmonary blood flow [54,55]. After a Fontan procedure, pulmonary blood flow is passive, and we keep the positive end-expiratory pressure and peak inspiratory pressure at a minimum [56], and aim for early extubation [57]. This strategy minimizes respiratory inhibition of passive pulmonary blood flow.

Most centers are now successfully using protocols that lead to early extubation [58]. For many patients whose condition is stable, weaning can be a quick process. Pressure support and volume support are two ventilator assist modes that are patient triggered and therefore allow assessment of the patient's respiratory drive as well as effort. Flow-sensitive triggering versus pressure-sensitive triggering may facilitate the use of these assist modes in infants. Complex cases require more thought, supervision, and patience. If intubated for a prolonged period, a child may have postextubation vocal cord or subglottic edema. The high negative intrathoracic pressure generated during spontaneous breathing with upper airway obstruction increases afterload, and the increased load may be poorly tolerated by a patient with compromised ventricular function. To minimize such swelling in infants, we often give intravenous dexamethasone before extubation (0.5–1 mg/kg every 6 hours for four doses with the first dose 6 hours before extubation) [59]. Treatment with nebulized racemic epinephrine also is transiently effective in reducing airway edema. Racemic epinephrine (equivalent to 2.25% epinephrine base), 0.125–0.5 mL, is diluted with 2–3 mL water or normal saline solution and is administered by aerosol. Patients should be closely observed for tachyarrhythmias during these treatments and for development of rebound subglottic edema.

Cardiovascular System

The child who had an uncomplicated cardiac procedure with complete correction of the intracardiac defect and adequate myocardial protection should require little extra postoperative manipulation to have a normal convalescence. Standard measures that may be necessary, however, include the following. Blood loss through chest tubes may require replacement during the initial several hours to prevent anemia and hypovolemia. Patients who are hypothermic on admission to the ICU may be peripherally vasoconstricted and may be hypovolemic despite normal systemic arterial and atrial filling pressures. In these patients arterial hypotension should be prevented by adequate volume replacement as the body temperature becomes normal and the peripheral vascular bed dilates. Mild postoperative hypothermia is readily corrected in older children by use of warm blankets and in infants by use of overhead radiant heaters. Hyperthermia increases cardiac workload and O_2 consumption and may lower the threshold for seizure activity. Therefore hyperthermia should be managed early and aggressively with antipyretics (e.g., acetaminophen, ibuprofen, dexamethasone) and surface cooling. An initial 30–40 mg/kg loading dose of acetaminophen is more effective in reducing fever than a 15 mg/kg maintenance dose [60]. Hypovolemia also may be caused by changes in venous capacitance or by protein and fluid leakage into the interstitial, peritoneal, or pleural spaces. This condition should be managed by replacement of the sequestered volume with appropriate amounts of crystalloid, blood, or colloid solution. The standard fluid bolus is 5–10 mL/kg over 5–10 minutes. The hematocrit should be kept greater than 30% during volume administration because anemia decreases the O_2 carrying capacity. Patients who have had palliation only and are still cyanotic require a hematocrit of 40–45%. Care should be taken to avoid over-transfusion as severe polycythemia may increase systemic and pulmonary vascular resistance and interfere with capillary perfusion.

For children who do not follow the anticipated course after cardiac surgery, early consideration must be given to the accuracy of preoperative diagnosis and adequacy of surgical repair. Evaluation begins with an echocardiogram. Cardiac catheterization may be safely performed early after

surgery and often will identify residual lesions that are amenable to intervention [61,62].

Fluid and Electrolyte Replacement

Although there is a mild tendency toward sodium and free water retention following CPB, our routine has been to administer standard maintenance fluid therapy after cardiac surgery to help ensure that patients do not become hypovolemic. Extra intravascular fluid is then relatively easily removed with small doses of diuretics (furosemide, 1 mg/kg intravenously every 8 hours). The amount and composition of intravenous fluids may vary depending on the clinical situation and the serum electrolyte levels. For neonates we routinely use dextrose 10% in sodium chloride 0.45% with 20 mEq of potassium chloride per liter. In older children we use dextrose 5% in sodium chloride 0.45% with 20 mEq of potassium chloride/liter.

The formula for maintenance therapy with intravenous fluid is 50 mL of fluid/kg/day in the first 2 days of life. This dosage is increased stepwise to 100 mL/kg/day by the fifth day. For older infants and children, fluid is administered according to the child's weight. Between 0 and 10 kg, infants should receive 100 mL/kg/day. Between 10 and 20 kg, patients should receive 1000 mL/day plus 50 mL/kg/day for each kilogram over 10 kg. Children who weigh 20 kg and more should receive 1500 mL/day plus 10 mL/kg/day for each kilogram over 20 kg (Table 7.5) [12].

Although hypokalemia is known to contribute to ventricular irritability, especially for patients receiving digoxin, this is not as serious a problem in pediatric patients as it is in adults. Hypokalemia should be managed with supplemental intravenous potassium (0.5–1.0 mEq/kg over 2 hours) to keep the serum potassium level normal. However, care should be taken not to administer the potassium too fast or in too concentrated an infusion, or to administer liquid enteral potassium in individual doses exceeding 1 mEq/kg, because doing so can cause a hyperkalemic cardiac arrest. Hyperkalemia typically occurs only in infants and children who have postoperative renal dysfunction. Hyperkalemia should be managed by removing all potassium from intravenous fluids, and oral or rectal administration of sodium polystyrene sulfonate, 1 g/kg every 4 hours may be necessary (Table 7.6) [12]. Should hyperkalemia persist, the patient may need peritoneal dialysis or hemodialysis. Serum magnesium levels should also be monitored postoperatively.

Mild dilutional hyponatremia is almost uniformly present and necessitates no treatment other than diuretic administration and mild restriction of free water intake. Serum sodium levels less than 125 mEq/L may be associated with neurologic symptoms and seizures and should be managed by water restriction and cautious administration of normal saline or 3% normal saline. Hypernatremia is quite rare and usually occurs in patients in renal failure or in infants who have received large amounts of sodium bicarbonate. It should be managed with sodium restriction and liberal fluid intake.

Hypocalcemia occurs mainly in neonates and after transfusion of large amounts of blood products. Myocardial function in neonates is particularly dependent on adequate calcium levels. Serum calcium must be measured frequently and the level maintained within normal limits by intravenous administration of calcium gluconate (50–100 mg/kg intravenously every 6–8 hours) or calcium chloride (20 mg/kg/dose given every 6–8 hours).

Metabolic acidosis usually results from hyperchloremia as a result of fluid administration and ultrafiltration during surgery. However, the most clinically concerning etiology of metabolic acidosis is decreased cardiac output and impaired tissue perfusion resulting in lactic acid production [63,64]. Treatment requires simultaneous correction of the underlying hemodynamic disorder and intravenous administration of sodium bicarbonate (1 mEq/kg/dose). Sodium bicarbonate usually is diluted to 0.5 mEq/mL and administered no faster than 1 mEq/kg/minute. Rapid infusion of sodium bicarbonate has been associated with intraventricular hemorrhage in neonates [65]. Because the buffering action of bicarbonate causes the formation of carbon dioxide, it is important that the infant's ventilatory

Table 7.5 Fluids and electrolytes.

Patient size	mL/kg/hr	mL/kg/day	Type of fluid
Newborns			
Day 1	3	50–75 No electrolytes	D10W, no electrolytes
Day 2–3	4	80–100	D10W 0.45NS with 20 mEq KCl
Day 4–7	4	100	D10W 0.45NS with 20 mEq KCl
Non-newborns			
0–10 kg	4	100	D5 0.45NS with 20 mEq KCl/liter
10–20 kg	2	50 (plus 40 mL/hr for first 10 kg)	D5 0.45NS with 20 mEq KCl/liter
>20 kg	1	20 (plus 60 mL/hr for first 20 kg)	D5 0.45NS with 20mEq KCl/liter

Table 7.6 Medications and dosages.

ANTIARRHYTHMICS	
Amiodarone (Cordarone)	*Cardiac arrest situation:* Infant/child: 5 mg/kg IV bolus, may repeat 3 times Adult: 300 mg IV, may repeat with 150 mg IV in 3–5 minutes, maximum dose 2.2 g IV in 24 h *Non-arrest situation:* Infant/child: 1–2 mg/kg IV over 10–15 minutes, may repeat as needed every 30 minutes, up to 10 mg/kg/day Run IV drip at 5–15 μg/kg/min Adults: 150 mg IV over 10–20 minutes; follow with 250 mg IV over 4 h, then 750 mg IV over next 18 h, then continuous drip 0.5–1 mg/min IV Supplemental bolus doses of 150 mg over 10 minutes may be given for breakthrough ventricular fibrillation or ventricular tachycardia
Lidocaine	Infant/child: 1 mg/1kg IV bolus, may repeat once, follow with continuous infusion 20–50 μg/kg/min Adults: 1–1.5 mg/kg IV bolus, may repeat doses of 0.5–0.75 mg/kg IV q5 minutes to a total of 3 mg/kg. Follow with continuous infusion, 1–4 mg/min
ANTIHYPERTENSIVES	
Esmolol (Brevibloc)	*Postoperative hypertension:* Load: 500 μg/kg/min over 5 minutes with infusion of 125–500 μg/kg/min *SVT* Load: 100–500 μg/kg IV over 5 minutes followed by a continuous infusion 50–500 μg/kg/min
Nicardipine (Cardene)	Infant/child: 0.5–4 μg/kg/min continuous infusion Adult: 5–15 mg/hr continuous infusion
Captopril (Capoten)	Neonates: 0.1 mg/kg/dose PO q8h, titrate to 0.5 mg/kg/dose Infants: 0.1 mg/kg/dose PO q8h, titrate to maximum dose of 2 mg/kg/dose Children: 0.3–0.5 mg/kg/dose PO q8h, titrate to maximum dose of 2 mg/kg/dose
Enalapril (Vasotec)	*Infants and children:* PO: 0.1 mg/kg/day given qd or bid. Titrate as needed up to 0.5 mg/kg/day IV: start at 5–10 μg/kg/dose q8h, titrate to 20 μg/kg/dose *Adolescents and adults:* PO: start at 2.5–5 mg q12h, maximum dose 20 mg q12h IV: 0.625–1.25 mg/dose q8h, titrate as needed (maximum dose 5 mg IV q6h)
Amlodipine (Norvasc)	Children (6–17 yrs): (oral) 2–2.5 mg qd, dosed qd or bid Adults: 2–10 mg/day (oral), dosed qd or bid
DIURETICS	
Furosemide (Lasix)	PO: 1–2 mg/kg/dose q6–12h, maximum dose 6 mg/kg/dose IV: 1 mg/kg/dose q6-12 h, maximum dose 4 mg/kg/dose Continuous infusion: <10 kg: 0.1 mg/hr titrate up to 1 mg/hr >10 kg: 1 mg/hr titrate up to 10 mg/hr
Spironolactone (Aldactone)	Neonates: 1–3 mg/kg/day PO q12–24h Children: 1.5–3.3 mg/kg/day PO divided q12–24h (usually q12h) Adults: 25–200 mg/day PO divided q12–24h
Chlorothiazide (Diuril)	Neonates/infants <6 months: IV 2–8 mg/kg/day given bid oral 20–40 mg/kg/day, given bid Infants >6 months and children: IV 4–20 mg/kg/day, divided q6–12h oral 10–40 mg/kg/day, given bid Adults: IV 500–1000 mg IV/day, given bid PO 500–2000 mg/day, given bid

Table 7.6 (*Continued*)

Bumetanide (Bumex)	Neonates: 0.01–0.05 mg/kg/dose IV q24–48° Infants and children: 0.01–0.1 mg/kg/dose IV q6–24° (max 10 mg/day) Infusion (patient >10 kg) 0.02–1.0 mg/hr
Metolazone (Zaroxolyn)	Children: 0.2–0.4 mg/kg/day qd or bid, PO Adults: 5–20 mg/dose qd PO
DIGOXIN (LANOXIN)	
	Total digitalizing dose (TDD): ½ of TDD administered in the initial dose and then ¼ of TDD given in 2 subsequent doses at 6–12-h intervals. *Infants:* TDD: 25–35 µg/kg PO or 20–30 µg/kg IV Daily maintenance dose: 6–10 µg/kg PO or 5–8 µg/kg IV divided q12h *1 month-2 years:* TDD: 35–60 µg/kg PO or 30–50 µg/kg IV Daily maintenance dose: 10–15 µg/kg PO or 7.5–12 µg/kg IV divided q12h *2–5 years:* TDD: 30–40 µg/kg PO or 25–35 µg/kg IV Daily maintenance dose: 7.5–10 µg/kg/ PO or 6–9 µg/kg IV divided q12h *5–10 years:* TDD: 20–35 µg/kg PO or 15–30 µg/kg IV Daily maintenance dose: 5–10 µg/kg PO or 4–8 µg/kg IV divided q12h *>10 years* TDD: 10–15 µg/kg PO or 8–12 µg/kg IV Daily maintenance dose: 2.5–5 µg/kg PO or 2–3 µg/kg IV given once daily *Adults:* TDD: 0.75–1.5 mg PO or 0.5–1 mg IV Daily maintenance dose: 0.125–0.5 mg PO or 0.1–0.4 mg IV once daily
ANTIBIOTICS	
Amikacin (Amikin)	7.5 mg/kg per dose IV q8–12h *UTI*: 5 mg/kg/dose IV q12h *Note:* Measure peak and trough levels if patient has renal dysfunction or if therapy is to last more than 48–72 hours
Amoxicillin	*Endocarditis prophylaxis:* Infants and children: 50 mg/kg PO 1 hour prior to procedure Adults: 2 g PO 1 hour prior to procedure *Asplenia prophylaxis:* 25 mg/kg PO q day
Ampicillin	*Mild to moderate infection:* 50–100 mg/kg/day IV divided q6–8h *Severe infection:* 200–400 mg/kg/day IV divided q4–6h
Ceftriaxone (Rocephin)	50–75 mg/kg/day IV q12–24h
Cephalexin (Keflex)	25–100 mg/kg/day PO divided q6h
Ancef (Cefazolin)	Cephalosporin of choice for surgical prophylaxis Children <40 kg: 50 mg/kg IV Children >40 kg: 25 mg/kg (not to exceed 1 g) IV *Postoperative prophylaxis:* (x48°) 35 mg/kg/dose IV q8°

Promethazine (Phenergan)	0.5 mg/kg/dose IV q4–6h
OTHER	
Aspirin	10 mg/kg PO or PR qd
Magnesium	25 mg/kg IV
Decadron	CPB dose 1 mg/kg/IV, maximum dose 20 mg Pre-extubation 0.25–2 mg/kg/day divided q6° x24 hr
GASTROINTESTINAL MEDICATIONS	
Metoclopramide (Reglan)	0.1–0.2 mg/kg/dose PO/IV qid (maximum dose: 0.8 mg/kg/day)
Ranitidine (Zantac)	<16 years: PO 2–4 mg/kg/day given bid IV 0.5–2 mg/kg/day divided q8h >16 years: 150 mg PO bid or 50 mg IV q8h
Lansoprazole (Prevacid)	Infants: 3–12 months: 0.5–1.5 mg/kg/ PO qd Children <30 kg: 15 mg PO qd Children >30 kg: 30 mg PO qd
Pantoprazole (Protonix)	Children: 20–40 kg: 0.5–1.0 mg/kg/day IV >40 kg: 40 mg/day I
Sodium polystyrene sulfonate (Kayexalate)	1 g/kg PO q6h or PR q2h

status be adequate before administration. Tromethamine (THAM) may be used instead of sodium bicarbonate in patients with impaired ventilation. Other causes of metabolic acidosis include renal tubular acidosis, necrotizing enterocolitis, sepsis, and intraventricular hemorrhage.

Hyperglycemia

The management of hyperglycemia after cardiac surgery in adults and children has been the subject of intense investigation in recent years and remains controversial. In pediatric cardiac surgical patients, observational studies have found associations between hyperglycemia and adverse early postoperative outcomes [66–68]. However, neither intraoperative nor early postoperative hyperglycemia are associated with worse neurodevelopmental outcomes [69]. In a single-center randomized trial involving 700 critically ill children, the majority of whom were recovering from cardiac surgery, patients assigned to the strict glycemic control group had reduced markers of inflammation, shorter ICU length of stay, and lower mortality (3% vs.6%) [70]. Additional trials of glycemic control following pediatric cardiac surgery are ongoing (ClinicalTrials.gov protocol NCT00443599), and these results along with knowledge of neurodevelopmental outcomes are needed before glycemic control can be adopted as standard practice. The use of continuous glucose monitoring may minimize the risk of hypoglycemia in critically ill patients receiving insulin infusions [71].

Renal System

Hourly urine output is a valuable indicator of renal perfusion and cardiac output. Urine output of 1 mL/kg/hour in infants and young children and of 20–40 mL/hour in older children and adults is generally considered adequate. Decreased urine output due to impaired cardiac output is commonly encountered during the first 12–18 hours after complex cardiac surgery, but usually improves as the hemodynamic derangement is corrected and organ perfusion pressure is maintained. The most common cause of persistent poor urine output following congenital heart surgery is inadequate renal perfusion pressure, which is calculated by subtracting the central venous pressure from the mean arterial pressure. Even with adequate cardiac output, in some instances, diuretics are necessary to encourage diuresis and establish a negative fluid balance. Their use does not prevent renal injury or dysfunction [72]. The

starting dose of furosemide is 0.5–1.0 mg/kg intravenously per dose at 6–8-hour intervals. The dose then can be sequentially increased to a maximum dose of 10 mg/kg/day until an adequate diuretic response has been obtained or acute renal failure is considered to be present. Additional diuretics that we frequently use are spironolactone and chlorothiazide. In some patients a furosemide infusion (0.1–0.3 mg/kg/hour) establishes more consistent urine output without large fluctuations. A bumetanide drip or the use of fenoldopam (a selective dopamine-1 receptor agonist) are other considerations for patients with marginal urine output [73].

Nutrition

Oral feedings are begun gradually 6–12 hours after removal of the endotracheal tube. The tube is usually removed on the first postoperative day after extracardiac operations and simple open-heart repairs. One exception is coarctation repair, after which feedings are withheld until hypertension is controlled and bowel sounds are clearly active, usually 48–72 hours postoperatively. This strategy helps to prevent reactive mesenteric enteritis and its attendant complications. In infants, feedings are started with small amounts of formula. In the absence of gastric distention, vomiting, and diarrhea, the preoperative feeding formula is slowly resumed (Table 7.7) [12,74]. Older children without evidence of cardiac failure are rapidly advanced to a regular diet. A no-added-salt diet and restricted fluid intake are prescribed for children with signs of congestive heart failure. In Fontan circulation patients we limit free water intake to preserve sodium balance. Early consideration should be given to nasogastric feeding of children unable to resume oral intake within 24–48 hours postoperatively. If enteral feeding is not feasible, parenteral hyperalimentation is indicated (Table 7.8) [12]. Some patients are kept muscle relaxed with vecuronium in the postoperative period. This is not a contraindication to enteral feeding. A number of studies in children have demonstrated that estimates of caloric needs derived from standard equations are often inaccurate. In patients with a prolonged requirement for mechanical ventilation, resting energy expenditure should be periodically measured to avoid overfeeding or underfeeding [75].

Neonates with an umbilical artery line in place should be limited to trophic enteral feedings to reduce the risk of necrotizing enterocolitis (NEC). In contrast, most centers provide full enteral nutrition with a UVC line in place [76].

Table 7.7 Growth, nutrition goals, and caloric content of various formulae.

Calories	Infants	120 kcal/kg/day (should gain approx. 20 g/day)
	Others	1 kcal/mL fluid requirement
Protein	0–1 years	2.5 g/kg/day
	2–13 years	1.5–2 g/kg/day
	13 years	1–1.5 g/kg/day
Fat	0–1 years	0.5 g/kg/day prevents EFA deficiency (0.1 mL/kg/hr 20% IL)
	Infants	Up to 3 g/kg/day
	All others	4 g/kg/day

Caloric content of nutritional solutions	
Pedialyte	3 kcal/oz = 0.1 kcal/mL
Pregestimil (hydrolyzed protein, lactose free, contains MCT)	20 kcal/oz = 0.67 kcal/mL
Enfamil, Similac (milk protein based)	20 or 24 kcal/oz = 0.67 kcal/ml or 0.8 kcal/mL
Prosobee, Isomil (soy protein based, lactose free)	20 kcal/oz = 0.67 kcal/mL
Breast milk	22 kcal/oz = 0.7 kcal/mL
Similac Special Care, Enfamil premature	20 or 24 kcal/oz = 0.67 or 0.8 kcal/mL
Portagen (85% fat from MCT)	20 kcal/oz = 0.67 kcal/mL
Pediasure (isoosmolar)	30 kcal/oz = 1.0 kcal/mL
Pediatric Vivonex (hyperosmolar, minimal fat)	24 kcal/oz = 0.8 kcal/mL
Monogen (90% fat from MCT)	22 kcal/oz = 0.73 kcal/mL
Enfaport (84% fat from MCT)	30 kcal/oz = 1.0 kcal/mL
Rice cereal	9 kcal/tbsp
Fat solutions – MCT oil	115 kcal/tbsp = 7.7 kcal/mL
Polycose powder	24 kcal/tbsp = 1.6 kcal/mL

IL = interlipid.
EFA = essential fatty acid.
MCT = medium-chain triglycerides.

Table 7.8 Hyperalimentation: concentrations and goals.

Infants	**Goal**					
Enteral	120 Kcal/kg/day = 7.5 mL/kg/h (6 oz/kg/d) 20 kcal formula or 6.25 mL/kg/h (5 oz/kg/d) 24 kcal formula					
Parenteral	3.5 mL/kg/h D25 P2.5 plus 0.6 mL/kg/h 20% IL (this combination gives 110 kcals, 2.5 g protein, 3.0 g fat/kg per day)					
	Start D12.5 P1.0 plus 0.2 mL/kg/h IL. Increase glucose by 2.5% per day, protein by 0.5 g/day, and IL by 0.1 mL/kg daily					
Children	**Goal**					
Enteral	Same number cals as milliliters fluid requirement					
Parenteral	Same as above (protein cals not included). Start at D10 P1.0 plus 0.2 mL/kg/h 20% IL and increase as for infants to the following goals					
Wt (kg)	**15**	**20**	**30**	**40**	**50**	**60**
Dextrose solution	D25 P2.0	D25 P1.5	D25 P1.5	D25 P1.5	D25 P1.5	D25 P1.5
mL/kg/h	3.2 (4.4)*	2.8 (3.6)*	2.1	1.8	1.6	1.5
20%IL						
mL/kg/hr = kcal/kg	0.32 (0.8)*	0.28 (0.8)*	0.21 (0.73)*	0.18 (0.6)	0.16 (0.54)	0.15 (0.48)

Numbers in parentheses are for peripheral total parenteral nutrition with D12.5.
D25 = 25% dextrose.
P2.5 = protein 2.5 gr/kg/day.
*Increased volume and fat.

Signs of NEC include abdominal distention and discoloration, bloody diarrhea or guaiac-positive stools, metabolic acidosis, thrombocytopenia, and pneumatosis intestinalis seen on abdominal radiograph [77]. Treatment includes NPO status, insertion of a nasogastric tube to low intermittent suction, serial blood cultures, administration of broad-spectrum antibiotics, and frequent abdominal radiographs to monitor for perforation. Consultation from a pediatric surgeon should be obtained. Once bowel sounds are heard and the umbilical artery line is removed, enteral nutrition can be initiated, progressing to a goal of 120–150 calories/kg/day. Table 7.7 shows the nutritional goals and caloric content of several formulae [12]. Table 7.8 shows calculations for infant nutrition, both enteral and parenteral [12].

Infection Prophylaxis

Infectious complications are a major source of morbidity following pediatric cardiac surgical procedures. Surgical site infection occurs in 2–5% of children recovering from cardiac surgery. Infants and patients requiring longer cardiopulmonary bypass times, and those needing at least three red blood cell transfusions following surgery are at greatest risk [78]. Published guidelines regarding prevention of surgical site infections emphasize staff education and feedback, the appropriate use of prophylactic antibiotics and skin antiseptics, and the avoidance of razor use for hair removal [79]. Strict adherence to sterile technique during and after the operation is essential in the prevention of infection after cardiac surgery. Broad-spectrum bactericidal antibiotics, given during the perioperative period, have been shown to decrease the risk of infectious complications [80]. We use cefazolin, 50 mg/kg intravenously 30 minutes before the operation and then 50–100 mg/kg/day intravenously divided into 8-hour dosing intervals. Clindamycin (10 mg/kg/dose intravenously every 8 hours) is substituted for patients with known penicillin allergy (Table 7.6) [12]. The first antibiotic dose is given in the operating room as soon as the intravenous lines have been placed, preferably within 30 minutes before incision. We administer cefazolin every 4 hours in the operating room. This is continued on an 8-hour interval regimen until 48 hours postoperatively. Karl and associates performed a worldwide survey of 42 pediatric cardiac surgical units and developed the following conclusions based on the practices at those 42 centers [80]:

1. Perioperative antibiotic prophylaxis in cardiac surgery should be the standard of care.
2. Currently there is no consistent and conclusive evidence of marked superiority of second-generation cephalosporins over first-generation cephalosporins. Cost effectiveness may be the best way to decide.
3. There is consistent evidence indicating that antibiotic prophylaxis of 48 hours duration is effective, a low incidence of infection at the site of surgery being found in all studies using 48 hours of prophylaxis.
4. The duration of antibiotic prophylaxis should not be dependent on catheters, lines, or drains of any type.

5. Currently there is no consistent or conclusive evidence to support the administration of antibiotic prophylaxis in pediatric cardiac surgery for more than 48 hours.

Independent risk factors for bloodstream infections associated with a central line after cardiac surgery include admission weight <5 kg, higher severity of illness score in the first 24 hours after surgery, at least three postoperative red blood cell transfusions, and a requirement for at least 1 week of mechanical ventilation [81]. Staff education and feedback, and adherence to evidence-based guidelines regarding the sterile insertion, access, and maintenance of central lines can prevent many of these infections [82]. Urinary tract infections following cardiac surgery are most effectively prevented by prompt removal of the Foley catheter [83].

Sepsis should be suspected in the postoperative neonate if any of the following symptoms are exhibited: hypoglycemia, thrombocytopenia, acidosis, feeding intolerance, hemodynamic instability, hyperbilirubinemia, or elevated white blood count. Blood, urine, and endotracheal cultures should then be obtained and appropriate antibiotic therapy administered. Patients with asplenia are started on chronic prophylaxis with amoxicillin when their intravenous antibiotics are discontinued.

Postoperative Complications

Low Cardiac Output

Low cardiac output occurs in approximately 25% of newborns within 6–12 hours after surgery [84]. Cardiac output is determined by the product of heart rate and stroke volume, which in turn is determined by preload, afterload, and contractility. Causes of low cardiac output may include one or more of the following: 1) alteration in the heart rate or rhythm; 2) decreased preload from hemorrhage, excessive diuresis, insufficient fluid replacement, or cardiac tamponade; 3) increased afterload from pulmonary hypertension or peripheral vasoconstriction; 4) decreased myocardial contractility from acidosis, electrolyte imbalance, ischemia/reperfusion, a ventriculotomy, or inadequate intraoperative myocardial protection; and 5) suboptimal repair with residual intracardiac shunts, valvular lesions, or excessive pulmonary blood flow. Fluctuations in cardiac output can occur rapidly in the postoperative period, making frequent assessments imperative. Cardiac output assessment includes an evaluation of the child's capillary refill, peripheral pulses, urine output (at least 1 mL/kg/hour), arterial blood pressure, atrial filling pressures, acid–base status, lactate levels, and peripheral and core temperatures. We use cerebral and renal NIRS on all of our postoperative patients as a surrogate for mixed venous O_2 saturation. Initiation of treatment for low cardiac output is based on the identification of the causes.

Heart Rate

Normal postoperative heart rate varies according to the patient's age and size, as shown in Table 7.3 [12,30]. Treatment of neonates for low cardiac output differs from that in older children and adults because of differences in cardiovascular physiology. In neonates ventricular diastolic compliance is diminished and newborn infants have a limited ability to increase their stroke volume [85,86]. This decrease in compliance is related to a greater ratio of noncontractile to contractile mass in the neonatal heart [87]. Stroke volume remains relatively fixed at approximately 1.5 mL/kg. Because of the limited ability of the neonatal heart to increase stroke volume, cardiac output is rate dependent [88]. Sinus tachycardia with a heart rate up to 200 beats/minute is well tolerated in newborns and increases cardiac output. Heart rate may be optimized by pacing or intravenous infusion of chronotropic agents such as dopamine, dobutamine, and epinephrine. In our clinical practice we have found the combination of dopamine and dobutamine very effective in increasing heart rate and cardiac output in a child with intact atrioventricular conduction. In selected cases we have added epinephrine for further augmentation of heart rate. For patients with either complete or intermittent postoperative heart block, ventricular or preferably atrioventricular pacing at an appropriate rate is necessary to increase the cardiac output. Patients with sick sinus syndrome or sinus node dysfunction may benefit from atrial pacing.

Preload

Ensuring adequate circulating blood volume is essential to maintaining good postoperative cardiac output. Hypovolemia results in decreased ventricular filling and low cardiac output. Conversely, augmenting the end-diastolic volume increases the number of interactions between actin and myosin and results in a larger stroke volume and thus higher cardiac output. This is known as the Frank–Starling mechanism (Figure 7.2) [12,89]. Volume replacement therapy should be provided with close attention to filling pressure, arterial pressure, and physical signs such as liver distention and fontanelle depression. The filling pressure required to achieve the same degree of preload will change as myocardial dysfunction improves over time. Certain cardiac lesions will predictably require a higher filling pressure to overcome early diastolic dysfunction (e.g., tetralogy of Fallot, aortic stenosis, etc.). The type and amount of fluid replacement should be based on the hemoglobin level, hematocrit, albumin level, and percentage of volume loss. Transfusion should be considered when more than 10% of the child's blood volume has been removed, as in blood testing for neonates or chest tube loss for older children. Normal circulating blood volume for an infant is 95 mL/kg

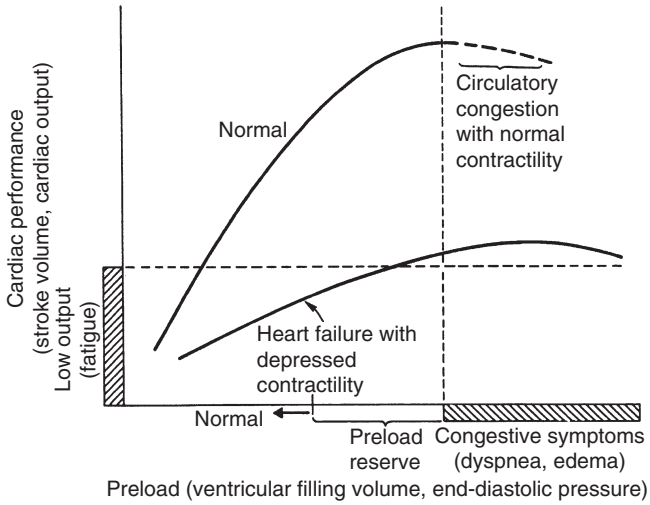

Figure 7.2 The Frank–Starling mechanism dictates that increasing preload will enhance cardiac stroke volume and thus cardiac output. Excessive preload will cause pulmonary congestion and decreased stroke volume. This relationship exists in normal hearts and in those with depressed contractility. (Reproduced with permission from Friedman *et al.* [89].)

and for an older child 75 mL/kg. Boluses of fluid are given in increments of 5–10 mL/kg over several minutes. However, increasing the filling volume to a left atrial pressure greater than 14–16 mmHg rarely produces additional increase in cardiac output, and a left atrial pressure greater than 20 mmHg can cause pulmonary edema [90]. Because of the large venous capacitance of infants, right atrial pressures may not necessarily reflect the volume administered and should not be used solely as an index of adequate volume replacement. In particular, if a child has evidence of facial puffiness, peripheral edema, or a full fontanelle, adequate volume replacement has probably been achieved. In neonates recovering from tetralogy of Fallot or truncus arteriosus repair, preload to the left ventricle, and thus cardiac output, may be maintained by routinely leaving a small atrial communication to allow right-to-left atrial shunting. This principle also applies to the use of fenestration in children undergoing Fontan surgery [91].

Afterload

Afterload is the sum of forces that oppose systolic performance. It is best estimated by systolic wall stress and vascular impedance, both of which are difficult to measure at the bedside. Afterload can be estimated by the resistance of the vascular bed (systemic or pulmonary) against which the ventricle is pumping. An increase in systemic vascular resistance or pulmonary vascular resistance can significantly reduce both stroke volume and the extent and velocity of wall shortening; the result is decreased cardiac output and ventricular function. Increased vascular resistance is common after CPB in neonates [84] and adults [92]. Physiologic factors such as hypoxia, acidosis, hypothermia, and pain can increase systemic and pulmonary vascular resistance. Such factors are more important in the care of newborn infants who have a very reactive pulmonary vascular bed. Elimination of these vasoconstricting factors is important in reducing afterload. Conversely, increased afterload may be a compensatory response necessary to maintain blood pressure in the setting of decreased cardiac contractility. Increased afterload also may be secondary to residual right or left ventricular outflow tract obstruction.

Regardless of cause, afterload can be pharmacologically decreased by vasodilatation of the vascular bed. For the past 15 years we have been routinely using milrinone after most complex procedures. Milrinone is a phosphodiesterase inhibitor that increases intracellular levels of cyclic adenosine monophosphate (AMP) which causes vasodilation of the systemic and pulmonary vascular beds. Milrinone also has inotropic and lusitropic (myocardial relaxation) properties [93]. Milrinone has been show in a multicenter trial to reduce the occurrence of low cardiac output syndrome following complex two ventricular repairs in infants and children [94]. Milrinone has been used successfully at doses of 0.25–1.0 μg/kg/minute titrated for effect. Peripheral vascular resistance (and systemic blood pressure) is also effectively lowered by intravenous infusion of the calcium channel blocker nicardipine, infused at 0.5–4.0 μg/kg/minute. Nitroglycerin is another direct smooth-muscle relaxant and potent coronary arterial vasodilator. Nitroglycerin is administered in a drip concentration of 1.0–5.0 μg/kg/minute and is titrated by observation of resultant blood pressure. Nitroprusside is another nitric oxide donor that may be used to lower vascular resistance. With the use of any of these vasodilators, volume replacement may be necessary to fill the expanded vascular space and maintain adequate preload. Severe hypotension can result from the use of these drugs. If hypotension occurs, the infusion should be reduced or stopped until adequate preload can be given. These vasodilators should only be used when the patient's arterial pressure is being continuously monitored with an arterial line.

In some patients decreased systemic vascular resistance after CPB leads to hypotension [95]. Risk factors may include preoperative heart failure and longer cross-clamp times. The cause of this state is unclear but may be related to release of inflammatory mediators or relative vasopressin deficiency. Published experience in the care of children [96] and adults [97] suggests that vasopressin infusion of 0.0003–0.002 units/kg/minute may be beneficial.

Positive-pressure ventilation has important effects on afterload of both the systemic and pulmonary ventricle. The increase in mean airway pressure will lead to reduced transmural wall stress and thus decreased afterload of the

systemic ventricle. This can be beneficial in patients with poor myocardial function or a volume-overloaded ventricle. In contrast, the elevated intrathoracic pressure associated with positive-pressure ventilation will increase afterload on the right ventricle which may be poorly tolerated in patients with dysfunction of the pulmonary ventricle or regurgitation of the right-sided atrioventricular valve or pulmonary valve.

Contractility

Cardiac contractility is the load-independent ability of the myocardium to generate force. Contractility may be chronically impaired preoperatively by pressure or volume overload related to the specific cardiac lesion. Contractility may be depressed intraoperatively by drugs, anesthesia, myocardial ischemia, extensive ventriculotomy, or myocardial resection. Contractility may be affected postoperatively by hypoxia, acidosis, and pharmacologic agents. In recent years, the use of modified ultrafiltration after CPB has been shown to improve intrinsic left ventricular systolic function, improve diastolic compliance, increase blood pressure, and decrease inotropic drug use in the early postoperative period [98]. In children the cardiac index tends to be lower 4 hours after the operation than it is soon after discontinuing CPB; it begins to increase to normal value after 9–12 hours [99]. If a child has evidence of low cardiac output after heart rate, preload, and afterload are optimized, myocardial contractility should be enhanced by pharmacologic means. In the care of most patients who have undergone a major cardiac surgical procedure our policy is to start pharmacologic support in the operating room while weaning from bypass rather than waiting for the signs of low output to appear. Several inotropic agents are currently available and each has its own characteristic effects that may be more suitable for use in various clinical situations. These medications and dosages are listed in Table 7.9 [12].

Table 7.9 Dosages of medications for inotropic support, afterload reduction, paralysis, and sedation.

Agent	Dosage
INOTROPIC SUPPORT	
Dobutamine	Range: 5–20 μg/kg/min; concentration: 600 mg/L in D10.2NS*
Dopamine	Range: 2.5–20 μg/kg/min; concentration: 600 mg/L in D10.2NS*
Epinephrine	Range: 0.01–0.4 μg/kg/min; concentration: 10 mg/L D10.2NS*
Isoproterenol	Range: 0.01–0.2 μg/kg/min; concentration: 10 mg/L D10.2NS*
VASODILATORS†	
Milrinone	Range: 0.2–0.7 μg/kg/min; concentration: 1 mL–5 μg/kg/min in 0.45 NS (compatible with other medications if mixed at site).* Double concentration at higher dose range
Nipride	Range: 1–5 μg/kg/min; concentration: 100 mg/L D10 W (protect metriset and IV tubing from light). Monitor liver enzymes*
Nitroglycerin	Range: 1–5 μg/kg/min; concentration: 1 mL–1 μg/kg/min (use nonpolyvinylchloride tubing) in D10.2NS*
PARALYSIS AND SEDATION	
Chloral hydrate	Range: 30–50 μg/kg/dose PR
Fentanyl	Range: 2–20 μg/kg/hr in D10.2NS, continuous infusion
Morphine	Range: 50–100 μg/kg/hr IV in D10.2NS, continuous infusion
Pavulon	Bolus 0.1 mg/kg Infusion 100 μg/kg/hr
Vecuronium	Bolus 0.1 mg/kg Infusion 100 μg/kg/min
Versed	Range: 50–100 μg/kg/hr IV in D10.2NS, continuous infusion
Tylenol	Range: 10–20 mg/kg/dose PR

*Concentration should be doubled or tripled according to hemodynamic status and/or fluid restriction.
†Nitroglycerin and Nipride are not compatible with other medications in this table.

Dopamine has both α-adrenergic and β-adrenergic receptor effects on the myocardium, depending on the dosage used. Doses in the range of 2–5 μg/kg/minute preferentially dilate mesenteric and renal vessels and increase renal blood flow. Doses in the β range (5–10 μg/kg/minute) tend to increase cardiac output with a slight increase in heart rate [100]. Dopamine at α ranges (10–20 μg/kg/minute) is usually avoided because of an increase in pulmonary vascular resistance. It appears that the myocardium of the neonate might be less sensitive than that of older children to the effects of dopamine. Dobutamine, another synthetic catecholamine, acts primarily on myocardial β-adrenergic receptors [101]. A benefit of dobutamine is that it increases contractility with little to no increase in systemic vascular resistance. The usual starting dose of dobutamine is 2.5–5 μg/kg/minute; the dose is then titrated to the desired effect. We have found that some patients respond to dobutamine with an unwanted increase in heart rate.

Isoproterenol, another β agonist, improves cardiac output mainly by increasing heart rate but also has its own direct inotropic effects. Milrinone, which acts mainly by afterload reduction, also exerts an inotropic effect independently. Patients who have marked myocardial dysfunction may respond to intravenous epinephrine at 0.05 μg/kg/minute. Such dosing primarily activates β_1 cardiac receptors, causing increased inotropism, and β_2 peripheral receptors, causing reduced afterload. Epinephrine is not frequently used at doses higher than 0.2 μg/kg/minute because of its marked α-adrenergic action at these doses and adverse effect on renal perfusion. However for some neonates high-dose epinephrine may be required for a short time. Calcium is a strong inotropic agent, but its action is brief. Neonates often require supplemental calcium on a scheduled basis or as an infusion. Digoxin improves cardiac contractility and can be used in patients who appear to require long-term inotropic support. The digitalizing intravenous dose is 40 μg/kg for children younger than 1 year, and 30 μg/kg for those older than 1 year (3 doses divided over a 24-hour period). The daily maintenance dose is one-fourth the total digitalizing dose: 10 μg/kg/day given in two divided doses (Table 7.6) [12].

There is good evidence that critically ill neonates on a high dose of inotropes benefit from supplemental hydrocortisone treatment [102,103]. Suominen and colleagues demonstrated that most of the hemodynamically compromised neonates who were unresponsive to high doses of inotropic agents and fluid resuscitation after heart surgery responded to hydrocortisone with improvement of hemodynamic parameters and a decrease in inotropic requirements [104]. The use of "stress dose steroids" for the patient who is not responding appropriately to inotropic support is now routine at our institution. We use 100 mg/m^2/day of hydrocortisone administered intravenously every 6 hours.

When medical therapy is ineffective in supporting cardiac output as evidenced by continued oliguria, hypotension, decreased mixed venous O_2, and increased lactate, the use of a mechanical circulatory assist device such as venoarterial bypass or left ventricular assist device is indicated.

In our practice the most useful mechanical assist device has been extracorporeal membrane oxygenation (ECMO). This modality was originally developed for neonatal respiratory failure but may be used for postcardiotomy cardiogenic shock in children or as a bridge to cardiac transplantation [105–107]. Survival rates of up to 60% have been reported [108]. ECMO provides effective support for postoperative cardiac and pulmonary failure refractory to medical management. Early institution of ECMO may decrease the incidence of cardiac arrest and end-organ damage, thus increasing survival in these critically ill patients [109]. Patients who are within approximately 10 days of surgery are cannulated via the sternotomy incision, whereas patients who are more remote from surgery tend to be cannulated from the neck. The femoral vessels may also be used for cannulation in patients weighing more than 10 kg. Despite full heparinization, the incidence of bleeding complications after ECMO in the support of these patients is relatively low. Use of ECMO as an adjunct to cardiopulmonary resuscitation is now becoming more widely used. In one multicenter study extracorporeal cardiopulmonary resuscitation resulted in hospital survival in 42% of infants and children with heart disease [110].

Left ventricular assist devices are useful in supporting patients with isolated left ventricular failure after cardiac surgery, particularly those who cannot be weaned from CPB after anomalous left coronary artery repair [111]. The Biomedicus (Medtronic, Minneapolis, MN) centrifugal pump can be used with left atrial and aortic cannulation [112]. Ventricular assist devices can also be used to provide longer term mechanical support in patients who require bridge to cardiac transplantation. We currently use two paracorporeal pneumatically driven devices. Thoratec Laboratories (Pleasanton, CA) produces such a device that can be used in patients as small as 25 kg. The Berlin Heart system offers a wide selection of blood pumps and cannulas specifically designed for infants and small children [113,114]. The Berlin Heart has been used in a 2.2 kg infant. In children requiring a bridge to transplantation, EXCOR (Berlin Heart, Inc. The Woodlands, TX) provided substantially longer support times than ECMO, without a significant increase in the rates of stroke or multisystem organ failure. Survival to transplant and long-term survival was higher with the Berlin Heart [115].

Cardiac Arrhythmias

Disturbances of the heart rhythm and rate are common after complex congenital heart surgery and may rapidly result in low cardiac output [116]. The cardiac rhythm cannot always reliably be determined by examination of the electrocardiogram tracing produced by routine bedside

monitors, and if there is any concern that the patient is not in sinus rhythm, a 12-lead electrocardiogram should be obtained. Temporary pacing wires may be used to obtain an atrial electrogram; alternatively a transesophageal pacing electrode may be placed. Establishing the correct diagnosis is essential to direct therapy. Consultation from a pediatric cardiac electrophysiologist is routinely obtained in our center for cardiac arrhythmias.

Supraventricular tachycardia (SVT) includes sinus tachycardia, atrial fibrillation, atrial flutter, automatic atrial tachycardia (AAT), orthodromic reciprocating tachycardia (ORT), antidromic reciprocating tachycardia (ART), junctional ectopic tachycardia (JET), and atrioventricular node reentry tachycardia (AVNRT). Sinus tachycardia may be secondary to hypovolemia, pain, anemia, or administration of inotropic drugs. It may also result from low cardiac output due to impaired myocardial contractility or cardiac tamponade. Identification of the etiologic factors guides appropriate therapy.

First-line treatment for most tachyarrhythmias includes correction of any electrolyte abnormalities, decreasing exogenous and endogenous catecholamines, and treatment of fever. Burst pacing via an esophageal pacing electrode or temporary atrial wires or a dose of adenosine (0.1 mg/kg IV) may acutely terminate many types of supraventricular reentrant arrhythmia. If these measures fail, reentrant SVT may also be acutely terminated by synchronized electrical cardioversion (0.5–1.0 J/kg). For persistent supraventricular arrhythmias, amiodarone or procainamide may be useful. JET is more difficult to manage because it does not respond to the various forms of cardioversion noted above [117]. For patients with temporary pacing wires, atrial pacing should be initiated at rates just faster than the junctional rate to restore atrioventricular synchrony. The rate of JET often slows with reduction in temperature to normal or even the use of mild hypothermia [118,119]. Amiodarone or procainamide may be useful in patients with refractory JET [119,120]. Our practice is to load with amiodarone 5 mg/kg IV in 1 mg/kg aliquots. Intravenous amiodarone may cause acute bradycardia and myocardial depression and care must be taken when administering intravenous boluses of this drug [121]. We have not used intravenous propranolol in the immediate postoperative period because of the danger of severe myocardial depression and cardiac arrest. If a beta blocker is considered necessary, intravenous esmolol is our current drug of choice because of its very short half-life.

Premature ventricular contractions (PVCs) may result from myocardial irritability in association with hypokalemia or hypomagnesemia and may be eliminated by correcting these electrolyte abnormalities. Infrequent unifocal PVCs are usually benign and may be observed. Persistent ventricular ectopy (more than six ectopic beats/minute) should be treated by an intravenous bolus of lidocaine (1 mg/kg) followed if necessary by continuous lidocaine drip (20–40 μg/kg/minute). Short runs of ventricular tachycardia are frequently controlled by lidocaine; however when ventricular tachycardia is persistent or associated with systemic arterial hypotension, it should be managed promptly with defibrillation. Persistent ventricular tachycardia is an ominous sign of impending cardiovascular collapse (often secondary to coronary insufficiency) and emergent evaluation is necessary. Long-term control of ventricular tachyarrhythmia may require administration of procainamide, amiodarone, or mexiletine.

Atrioventricular dissociation results in a loss of atrioventricular synchrony and a 20–30% decrease in end-diastolic filling, stroke volume, and cardiac output. Temporary epicardial pacemaker wires will allow sequential atrioventricular pacing, which may prove lifesaving to such patients. Sinus bradycardia and second-degree atrioventricular block may be similarly managed by atrial or atrioventricular sequential pacing. Complete heart block is treated acutely by temporary pacing. A permanent pacemaker should be inserted if normal sinus rhythm has not returned within 7–10 days of surgery [47]. We have favored the use of epicardial pacing in children who will require a lifetime of pacing with conversion to a transvenous system when the patient reaches adulthood. This strategy has been strengthened by the development of steroid-eluting epicardial leads that have been shown to have the same longevity as conventional endocardial leads [122].

Bleeding

Excessive postoperative bleeding occurs in 1–2% of patients undergoing congenital heart surgery. It is somewhat more frequent in severely cyanotic patients, polycythemic patients, and patients who are undergoing a reoperation [123]. Alterations in the normal hemostatic mechanisms occur during CPB. These changes may be attributed to oxygenator platelet adherence and mechanical trauma to the platelets and blood components by cardiotomy suction. Postoperative bleeding can result from inadequate heparin neutralization, thrombocytopenia, or perfusion-related dilution of clotting factors. More rarely it is caused by protamine overdose, fibrinolysis, or disseminated intravascular clotting. Disseminated intravascular clotting is usually associated with postoperative bacteremia and prolonged low cardiac output states. A surgical bleeding point may always be a possibility. Management of bleeding requires correction of the underlying cause, management of systemic hypertension, and simultaneous replacement of platelets and other deficient clotting factors. Underneutralized circulating heparin causes prolongation of the partial thromboplastin time and is corrected by administration of additional protamine. Thrombocytopenia (<50 000 platelets/mm^2) necessitates transfusion of platelets. Plate-

lets should not be administered too rapidly because of the risk of acute pulmonary hypertension with right ventricular failure. Surgical re-exploration is indicated whenever the hourly chest drainage in the absence of clotting abnormalities exceeds 3 mL/kg body weight/hour for 3 consecutive hours after surgery or if there is a sudden, marked increase in chest tube drainage of 5 mL/kg/hour in any 1 hour. Procrastination may result in fatal cardiac tamponade or further transfusion-related clotting abnormalities. At reoperation all suture lines and raw surfaces should be explored for the origin of bleeding. We have used fibrin glue with some success for suture line bleeding [124]. This "glue" is made by mixing cryoprecipitate and thrombin directly in the field at the site of bleeding but is now commercially available (Baxter Healthcare Corp., Westlake Village, CA). The product mixes human plasma, thrombin, and calcium, and it is sprayed in a thin layer on the affected suture lines.

The use of fresh whole blood has been shown to reduce the incidence of postoperative bleeding, particularly when multiple suture lines are involved, such as after the arterial switch procedure [125,126]. If fresh whole blood is not available (e.g., because of testing requirements for human immunodeficiency virus etc.), it is useful to have fresh frozen plasma, cryoprecipitate, and platelets available after CPB so that these factors can be administered before chest closure. Thus the neonatal population may achieve the greatest benefit from post-bypass fresh whole blood therapy [127].

For many years we used aprotinin (antifibrinolytic serine protease inhibitor) to reduce bleeding and the need for blood product use after pediatric cardiopulmonary bypass [128]. Because of concerns for renal failure and myocardial infarction in adults the FDA requested marketing suspension which prompted Bayer to remove the drug from the marketplace [129,130]. We now use epsilon-aminocaproic acid (Amicar) in all cardiopulmonary bypass patients. Amicar has recently been shown to be as effective as Aprotinin without the concerning complications [131] (Table 7.9) [12]. In cases with severe uncontrolled postoperative bleeding we have selectively used recombinant activated factor VII [129].

Cardiac Tamponade

Early postoperative cardiac tamponade results from persistent (usually excessive) surgical bleeding not properly drained by the chest tubes. Cardiac tamponade must be strongly suspected when chest tube drainage abruptly decreases or stops in a patient with previous significant bleeding. This complication can occur even when the pericardium has been removed or left wide open during the operation. External cardiac compression by blood or blood clots causes impaired diastolic filling, elevated venous pressure, paradoxic neck vein distention, systemic arterial hypotension, and a narrow pulse pressure. Arterial pressure decreases characteristically and shows a minimal response to volume administration. Cardiac tamponade demands prompt surgical re-exploration for evacuation of the pericardial hematoma and control of bleeding. For patients with a rapidly deteriorating hemodynamic situation the sternotomy may have to be opened in the ICU for removal of clots and relief of cardiac compression. An assessment can then be made about closing the chest at the bedside, leaving the chest open with a silicone skin patch (Silastic; Dow Corning Corp, Midland, MI), or returning the patient to the operating room. With the ready availability of echocardiography, any child with evidence of low cardiac output who has a suspected diagnosis of cardiac tamponade can quickly have this complication detected. The use of echocardiography helps prevent unnecessary opening of the chest of a patient who has low cardiac output because of myocardial dysfunction.

Some patients may have myocardial swelling and chamber dilatation that prevent closure of the chest because of hemodynamic instability. In these circumstances it may be advantageous to leave the sternum open and cover the mediastinum with an impermeable sheet of Silastic sutured to the skin edges [132,133]. This procedure may be done in critically ill patients in the operating room at the initial closure or after the chest is opened in the cardiac surgical ICU for tamponade or low cardiac output. Once myocardial swelling has resolved and cardiac and pulmonary function have stabilized, the sternum may be electively closed in the ICU within 48–72 hours. In one series delayed sternal closure was a risk factor for Gram-negative mediastinitis [134].

Delayed cardiac tamponade from post-pericardiotomy syndrome can occur several days or weeks after the operation and manifests with low-grade fever and chest pain. Physical signs may include tachycardia, decreased pulse pressure, pericardial friction rub, and, in advanced cases, signs of low cardiac output. The extent of pericardial effusion is easily evaluated by echocardiography. We obtain a discharge echocardiogram and an anteroposterior and lateral chest radiograph in all patients before they leave the hospital to rule out post-pericardiotomy syndrome. Symptomatic treatment with nonsteroidal anti-inflammatory drugs or a short course of steroids is generally effective [135]. Sizable pericardial effusions may require subxiphoid needle aspiration. If this is unsuccessful, percutaneous insertion of a pigtail catheter may be needed. Otherwise open pericardial drainage may be necessary either by opening the lower portion of the sternum or through a left thoracotomy, creating a pericardial window.

Pulmonary Hypertensive Crises

Pulmonary hypertensive crisis describes a serious syndrome characterized by an acute rise in pulmonary artery

pressure followed by a reduction in cardiac output and, in patients with residual intracardiac shunts, a fall in systemic oxygen saturation. Historically, pulmonary hypertensive crises were encountered in older infants and children who were recovering from repair of large left-to-right shunt lesions (e.g., truncus arteriosus, complete atrioventricular canal) or obstructed pulmonary venous return. Given that nearly all lesions with large left-to-right shunts at the ventricular or arterial level are now repaired in early infancy, pulmonary hypertensive crises are much less common, but may be life threatening in those patients in whom a crisis occurs. The pulmonary artery pressure may be essentially normal following the repair until an episode of pulmonary hypertension occurs. Pulmonary hypertensive crises may be precipitated by noxious stimuli (e.g., suctioning of the endotracheal tube), hypoxemia, hypothermia, or hypercarbia with resultant acidosis. Once the pulmonary hypertensive crisis begins it can be very difficult to break the vicious cycle of right ventricular dysfunction and low cardiac output. Treatment includes ventilation with 100% oxygen, hyperventilation, sedation with intravenous fentanyl or morphine, inhaled nitric oxide, and neuromuscular blockade. These crises may be fatal in spite of intensive therapy; therefore, their prevention is critically important. An important preventive measure in patients at risk is the initial maintenance of neuromuscular blockade and deep sedation for the first 24–48 hours following cardiac surgical intervention. This appears to minimize the incidence of pulmonary hypertensive crises. In infants and children at greatest risk of pulmonary hypertensive crisis, we also routinely use inhaled nitric oxide. In fact, inhaled nitric oxide has been the single most significant advance in the treatment of pulmonary hypertension [53,136]. It is a selective pulmonary vasodilator with essentially no systemic effects [137]. We have used nitric oxide in postoperative patients at doses of 5–20 ppm [138]. These patients must be monitored for methemoglobin toxicity (measured with arterial blood gases). In a randomized clinical trial, sildenafil, a selective phosphodiesterase type-V inhibitor, has been shown to facilitate weaning of children from inhaled nitric oxide [139]. Patients thought to need longer-term treatment also are transitioned to oral sildenafil [140]. Inhaled prostacyclin is an alternative pulmonary vasodilator that acts through cyclic adenosine monophosphate (cAMP)-mediated pulmonary vasodilatation. In children with inadequate response to nitric oxide, inhaled PGI_2 may be a useful alternative or adjunctive pulmonary vasodilator [141].

Cardiac Arrest

Cardiac arrest occurs in approximately 3% of all patients who are receiving care in pediatric cardiac ICU [142]. Common causes of cardiac arrest following pediatric cardiac surgery include progressive low cardiac output, severe pulmonary hypertension, arrhythmias, coronary ischemia, airway events, aortopulmonary shunt thrombosis, and cardiac tamponade. Many of these events are not sudden, and thoughtful and anticipatory circulatory and respiratory support as previously discussed likely prevents many evolving clinical situations from progressing to cardiac arrest. Although certain concepts in the management of cardiac arrest are based on pediatric advanced life support (PALS) guidelines issued by the American Heart Association, [143] special considerations are warranted for many patients recovering from cardiac surgery [142]. Resuscitative efforts should be directed by the most experienced team member, and this code leader should not become preoccupied with the performance of individual tasks. A patent airway and adequate ventilation is a priority. In nonintubated patients ventilation is started using a face mask and Ambu bag, followed by endotracheal intubation. If patients are already intubated, patency of the endotracheal tube must be ascertained. If obstructed, the tube should be replaced. The adequacy of ventilation is confirmed by end-tidal CO_2 detection, the quality of the (bilateral) breath sounds, and the inspiratory expansion of the chest. Note that in the absence of pulmonary blood flow, either because of an obstructed aortopulmonary shunt or cardiac arrest, end-tidal CO_2 will not be detectable even if the endotracheal tube is patent and its tip properly located in the mid-trachea. Care should be taken to avoid overventilation, which may increase intrathoracic pressure and impede pulmonary blood flow, particularly in patients with palliated single ventricle physiology.

Simultaneously attempts should be directed at restoring effective circulation. This is accomplished initially by external cardiac massage. In infants this is best done by placing both thumbs in front of the sternum and all other fingers on the patient's back. There should be no hesitation in performing closed cardiac massage in a patient who has had a recent sternotomy. The precordium should be compressed 100 times per minute (per PALS guidelines) while checking on the adequacy of massage by the quality of the femoral or carotid pulses, or by arterial pressure tracing when available. If an adequate cardiac output cannot be obtained with external cardiac compression, or if tamponade is suspected, the chest should be immediately opened and manual internal cardiac massage instituted. Epinephrine is the single most useful drug to assist in restoring cardiac action in a child who has experienced cardiac arrest. Epinephrine, 10 μg/kg, may be given either intravenously or by intracardiac injection via the left precordial or subxiphoid route. Injection directly into the heart is no longer practiced because of the possibility of injury to the coronary artery. For a patient without intravenous access, epinephrine may be given via the endotracheal tube at a dose of 100 μg/kg. Calcium chloride, 10–20 mg/kg, or calcium gluconate, 50–100 mg/kg, may be given as an ino-

tropic agent. Sodium bicarbonate at a dose of 1 mEq/kg is administered to normalize arterial pH.

Concomitant with air exchange and restoration of circulation, evaluation must be made to ascertain the cause of cardiac arrest. If acute hypoxia preceded the cardiac arrest in patients with a Blalock–Taussig shunt, the possibility must be considered that it has thrombosed and the chest must be opened to "strip" the shunt. Cardiac rhythm is determined by electrocardiogram. Ventricular fibrillation is managed with defibrillation (1–2 J/kg), which must be repeated until an organized heart beat is restored. Ventricular arrhythmias should raise suspicion for coronary ischemia or hyperkalemia. Ventricular ectopy and ventricular tachycardia may necessitate lidocaine administration (1 mg/kg intravenously). For patients with heart block who are dependent on temporary pacing, it should be ensured that the wires have not become dislodged, the battery expired, or the ventricular capture threshold did not exceed the programmed voltage output.

Survival rates following in-hospital cardiac arrest in children with heart disease range from 40–66% [144,145]. It is noteworthy that infants and children seem to tolerate longer periods of hypotension from a cardiac arrest than do adult patients without neurologic or other organ system damage. In one report of pediatric cardiac patients who experienced an in-hospital cardiac arrest, 83% of survivors were grossly neurologically intact at hospital discharge [144]. Clinical trials have shown that mild hypothermia reduces mortality and neurologic outcomes in adult cardiac arrest victims and newborns with hypoxic–ischemic encephalopathy [146,147]. Ongoing clinical trials will determine whether therapeutic hypothermia reduces mortality and improves neurodevelopmental outcomes following pediatric cardiac arrest. A rapid-deployment system of ECMO support is life saving in some patients, particularly those with acute shunt thrombosis [110,148].

Pulmonary Dysfunction

Respiratory dysfunction after cardiac surgery is common, multifactorial in origin, and results in significant postoperative morbidity. Because of the nature of cardiorespiratory interactions, any alteration in cardiac performance can have a secondary effect on the lungs. Preoperative, longstanding modifications in respiratory function often exist as a consequence of the cardiac anomaly. Excess pulmonary blood flow is associated with increased airway resistance and decreased pulmonary compliance [149]. Restrictive lung disease may be present in patients with prior thoracotomy or sternotomy. Significant impairment of pulmonary mechanics can result from the systemic inflammatory response that occurs with CPB [150]. The exposure of blood to the CPB circuitry and other factors (bleeding, end-organ ischemia, changes in body temperature) have been shown to trigger release of cytokines and cause complement activation [49,151]. The lungs are particularly susceptible to injury from this inflammatory cascade because they represent such a large vascular bed. Recent advances in perioperative ultrafiltration have shown promising results in attenuating these effects [152,153]. We have demonstrated an improvement in the postoperative alveolar-to-arterial O_2 gradient (A-aO_2) using a preoperative dose of intravenous dexamethasone [49].

Postoperative respiratory failure can result from endothelial dysfunction, left ventricular failure, pulmonary edema secondary to fluid overload, significant residual intracardiac left-to-right shunting, inadequate intraoperative left heart decompression, neuromuscular weakness, or a combination of these factors. Respiratory dysfunction can also be caused by retained tracheobronchial secretions, major atelectasis, phrenic nerve injury with diaphragmatic paralysis, sedatives and analgesics, and neuromuscular disorders affecting the respiratory muscles. When respiratory insufficiency is present, attempts at weaning the patient from the ventilator may result in tachypnea, labored breathing, cyanosis, arterial hypoxemia and hypercarbia, and respiratory acidosis. Under these circumstances, respiratory support should be continued until the underlying cause has been corrected and the patient can be safely weaned and extubated.

Tracheobronchial compression may be caused by vascular structures and, when suspected, bronchoscopy and/or computed tomography (CT) angiography are useful for evaluation. Diaphragmatic paralysis, if persistent for more than 1–2 weeks, can prevent weaning of an infant from the ventilator and should be managed with diaphragmatic plication, which often allows successful weaning from the ventilator [154]. In some patients who require extended respiratory support, tracheostomy must be considered to minimize complications associated with prolonged endotracheal intubation and facilitate rehabilitation. Patients who receive a tracheostomy after congenital heart surgery have few complications directly related to the tracheostomy and the majority are ultimately decannulated [155]. However, our experience shows that neonates and younger children can tolerate postoperative endotracheal intubation for several months with minimal complications. Over the past several years it has been very unusual for us to recommend a tracheostomy for a patient unless they are to be ventilator-dependent for an indeterminate period of time.

Renal Failure

Acute tubular necrosis after open heart surgery usually results from a period of inadequate renal perfusion pressure after cardiac surgery. Preexisting renal insufficiency, CPB-induced inflammation, and exposure to contrast or

nephrotoxic agents may also be contributory. Markers of impending renal failure include persistent oliguria and elevation of blood urea nitrogen (BUN) and creatinine, whose levels should be carefully followed. Biochemical acute kidney failure may be defined as an increase in serum creatinine levels to twice or more the preoperative level [156]. The most important goal in patients with evolving renal failure is to maintain a normal renal perfusion pressure, which is calculated by subtracting the central venous pressure from the mean arterial pressure. Abdominal compartment syndrome, due to bowel wall edema and ascites, may compromise renal venous drainage. In patients with low cardiac output and a tense abdominal wall, we have seen dramatic improvement in renal function following placement of peritoneal drains, even in the presence of minimal ascites. Volume and electrolyte status must be carefully managed. To avoid fluid overload, intravenous intake must be limited to replacement of insensible losses, urinary output, gastric, and chest tube drainage. Serum electrolytes, BUN, and creatinine levels should be measured initially every 4–6 hours for early detection of excessive azotemia, hyponatremia or hypernatremia, and especially hyperkalemia. Hyperkalemia (>6 mEq/L) may cause bradycardia, heart block, asystole, or ventricular fibrillation. Potassium must be removed from all intravenous fluids and from the diet. Acute treatment may require intravenous administration of calcium gluconate (30 mg/kg), sodium bicarbonate (1 mEq/kg), insulin, and glucose. A sodium polystyrene sulfonate (Kayexalate; Sanofi Winthrop Pharmaceuticals, Morrisville, PA) retention enema (1 g/kg) is frequently effective in temporarily lowering the serum potassium level. Persistent or increasing hyperkalemia demands peritoneal dialysis or hemodialysis. During the polyuric phase of recovery from acute renal failure, careful attention should be paid to urine output and serum electrolyte levels to avoid dehydration, hypovolemia, and electrolyte imbalance.

Infectious Complications

Moderate temperature elevation (37.9–38.5 °C) is common during the first and second postoperative days and is usually related to surgical tissue injury or atelectasis. High fever (>39 °C), however, should always raise the possibility of bacteremia or wound infection. Specimens of blood, tracheobronchial secretions, and urine should be obtained promptly for culture. Treatment with broad-spectrum antibiotics should be started early and modified later according to the results of bacteriologic and sensitivity studies. Positive blood culture results necessitate treatment with appropriate intravenous antibiotics for at least 10 days. Postoperative bacteremia is a catastrophic complication, because it can result in the development of infective endocarditis. Sternal wound infections occur in 2–5% of infants and children after median sternotomy [134,157]. Superficial wound infections occur in approximately 3–5% of patients and deep infection (mediastinitis) in 1–2% of patients [157]. Wound infections necessitate adequate drainage and intensive antibiotic treatment, especially in patients with intracardiac prosthetic patches or artificial valves. We previously treated deep sternal infections with muscle flaps [158], but since 2002 we have used vacuum-assisted closure (VAC) successfully in 16 of 19 patients with sternal infections. Central venous catheters are known to be associated with bloodstream infections. The prevention of central line-associated bloodstream infection can be reduced by a systematic, multidisciplinary initiative, as demonstrated by Costello *et al*. [82].

Septic shock can be caused by Gram-positive or Gram-negative bacterial infection. It is usually associated with arterial hypotension, peripheral vasodilation, splanchnic venous pooling, and oliguria. Septic shock is often complicated by disseminated intravascular clotting and consumptive coagulopathy. Initial empiric antibiotic therapy includes vancomycin (10–15 mg/kg/dose IV every 8 hours) and ceftazidime 100–150 mg/kg/day until the results of bacteriologic and sensitivity studies determine the specific antimicrobial therapy. Respiratory syncytial viral (RSV) pneumonia can also cause the signs and symptoms of septic shock with respiratory compromise. Diagnosis is made with a nasopharyngeal swab. Currently, there are no clearly beneficial therapeutic interventions for RSV aside from supportive care [159]. Palivizumab is currently recommended as a preventive strategy in high-risk patients [160]. Other supportive measures include maintenance of an adequate blood volume and perfusion pressure as well as inotropic and ventilatory support.

Central Nervous System

It can be difficult to assess the neurologic status of a neonate or child in the immediate postoperative period because of the residual effects of anesthesia. The neurologic assessment includes vital signs, pupillary response to light, withdrawal from noxious stimuli, and symmetric movement in all extremities. Neurologic complications can result from cerebral ischemia, global hypoxia, electrolyte imbalance, acidosis, hypoglycemia, hypomagnesemia, and cerebral emboli. Evaluation of seizure activity includes an electroencephalographic (EEG) study and measurement of arterial blood gas and electrolyte levels. Hypocalcemia, hypoglycemia, hypomagnesemia, and fever can be causes of seizures in neonates. Because of the immature myelination of the neonatal brain, focal seizures may be caused by metabolic or structural abnormalities. Focal seizures require neurology consultation and evaluation including computerized tomography or magnetic resonance imaging (MRI) of the brain. Seizures should be controlled immediately to

avoid interference with adequate ventilation and the cardiovascular stress of increased metabolic activity. Hypoxemia, acidosis, and electrolyte imbalance should be corrected. Fever should be controlled with antipyretics and cooling blankets. Shum-Tim *et al*. found that postischemic hyperthermia significantly exacerbates functional and structural neurologic injury after deep hypothermic circulatory arrest and should be avoided [161]. Lorazepam 0.1 mg/dose IV is used initially to stop seizure activity. Maintenance phenobarbital or phenytoin is then administered. The phenobarbital loading dose is 10–20 mg/kg followed by a maintenance dose of 5 mg/kg/day given every 12 hours. Phenobarbital can be a cardiac depressant and should be given cautiously in a patient with borderline cardiac output. Phenytoin loading dose is 15–20 mg/kg IV, followed by a maintenance dose of 5–10 mg/kg/day given every 8–12 hours. Phenytoin also has cardiac effects and is contraindicated if the patient has heart block or bradycardia. Gaynor and coworkers have emphasized that routine continuous EEG monitoring is necessary to rule out the occurrence of subtle seizures [162]. They noted that increased duration of deep hypothermic circulatory arrest (DHCA) was identified as a predictor of seizures.

Choreoathetosis is a rare complication of deep hypothermia (<25 °C) and circulatory arrest [163]. This disorder tends to develop 2–7 days after the operation and manifests as seemingly purposeless continued movements of the head, torso, and all extremities while awake but not while asleep. Patients with the full-blown syndrome are unable to swallow, support their head, or walk. The syndrome tends to resolve over months to years. The cause of choreoathetosis remains undefined, but it appears related to deep hypothermia (<25 °C), cooling with alpha-stat rather than pH-stat, uneven brain cooling, and aortopulmonary collaterals that "steal" blood flow from the cerebral circulation [164,165]. The incidence of this unusual complication has dropped dramatically in the past 10 years, probably related to more careful and even cooling/warming of the brain and less frequent use of DHCA.

Conclusion

The perioperative care of children undergoing congenital heart surgery can be complex and often is challenging. There is no substitute for repeated physical examination and vigilant serial observance of children in the postoperative period. The emphasis in the current era is on a team concept of care for these children [166]. Dramatic improvements in ICU management, including ventilator care, inotropic support, highly trained nurses, and improved monitoring techniques, have helped to optimize the results of congenital heart surgery procedures. Constant attention to detail is essential, and anticipatory rather than reactive care is the key to optimal postoperative outcomes.

CHAPTER 8

The Nurse Practitioner's Role in Patient Management

Nancy Benson, Denise Davis, Fejeania Hunter, Kim Teknipp, and Jamie Thomas
Center for Congenital Heart Surgery, Cleveland Clinic Children's Hospital, Cleveland, OH, USA

History of Nurse Practitioners in Cardiothoracic Surgery

Since surgeons began correcting congenital heart defects in the 1940s, this subspecialty has undergone formidable changes. Over the past seven decades, congenital heart surgery mortality rates have fallen from 80% to less than 5% as a result of improved technology, surgical techniques, and postoperative management [1]. With the institution of the intensive care unit came the development of critical care subspecialties and advanced practice nursing including the congenital heart surgery nurse practitioner (NP). The transition to incorporating NPs into the congenital heart surgery team came about by a decline in the number of residents and resident work hours, along with the acceptance of NPs to many medical institutions as integral members of the healthcare team.

Although the history of advanced practice nursing can be traced to the nineteenth century during the Civil War, the first pediatric NP program did not exist until the middle 1960s [2]. The most recent development in this field has been the inclusion of the acute care NP. Noticeable gaps in patient care lead to the creation of this role specifically for congenital heart disease (CHD) at Boston Children's Hospital in 1987 [3]. Since that time, NPs have become integral members of the congenital heart surgery team around the world [3].

Nurse practitioners specializing in pediatric and congenital heart surgery provide continual care for patients with CHD starting with the initial call to schedule surgery and continuing until hospital discharge and outpatient follow-up visits. Hravnak *et al*. described the core competencies of the acute care NP as direct clinical practice including guidance, consultation, research skills, leadership, collaboration, and ethical decision-making [4]. The cardiothoracic surgery NP, as a member of a multidisciplinary team, must look at each of these competencies as an essential part of patient care and professional responsibility. The priority to provide high quality hospital-based care while maintaining a holistic approach to the patient and family is the foundation of the NP role within the team [5].

Diagnosis

Congenital heart disease continues to be the most common birth defect with an occurrence of 8 per 1000 births [6]. More than a third of infants who die from a congenital anomaly have a heart defect as part of the complex pathophysiology that lead to their demise [6]. Furthermore, the incidence of chromosome abnormalities in infants with CHD is estimated at 5–10% [7,8]. The frequency of fetuses with chromosomal anomalies and cardiac defects is actually higher than those found in live births [8,9]. In addition, extracardiac malformations occur in at least 25% of infants with CHD [8].

Etiologies of CHD include prematurity, low birth weight, advanced maternal age, and multiple gestation [10]. Risk factors for CHD have been studied by many and include infant sex, ethnicity, environmental exposure, and possibly maternal/paternal age [10]. Supplemental research and examination will broaden the ability to make consistent hypotheses regarding risk factors for CHD. Early diagnosis and analysis of infants with CHD allows for accurate monitoring and treatment at birth.

Technological advances in fetal echocardiography allow pediatric cardiologists to diagnose CHD earlier in pregnancy and can be used at 12 weeks gestation [11]. Parents who have a child with a congenital heart defect are at an increased risk (3–4% or higher) of having another child with a defect [11]. These parents will want as much information as possible about the risks of having future children. Early fetal echocardiography can detect increased nuchal translucency, a thickened skin over the fetus' neck, which has been correlated with congenital heart abnormalities [11]. Early detection of a fetus with major structural cardiac anomalies permits the cardiologist to closely monitor the mother and fetus by reimaging during the second and third trimesters. Additionally, the cardiologist can implement a plan that ensures optimal delivery based on the severity of the cardiac defect.

With early diagnosis, the healthcare team has the best likelihood to prevent or minimize pathophysiology that may result from malformation [6]. Outcomes are improved for infants who are delivered at a tertiary center [6], and the infant benefits from prompt appropriate treatment, which is expedited by an expert medical team and can dictate whether there is a need for additional specialized care.

During the prenatal period, the NP establishes a relationship with the family, ensures effective communication, and acts as a liaison with the healthcare team. As part of the multidisciplinary team, the NP educates the parents concerning the diagnosis and preoperative management, identifies anticipatory needs, and arranges specialty service consults as warranted [12].

Preoperative Evaluation

The preoperative evaluation of the child with CHD begins with the initial contact with the family. This early communication may be in person or via telephone. Consideration of the family as a unit will ensure a smooth transition from preoperative evaluation through outpatient follow-up. The compilation of a thorough history ensures preoperative needs are addressed and fulfilled. Additionally, the NP becomes a resource to the family and maintains open communication with the healthcare team.

After preliminary communication about the need for surgery by their cardiologist, a preoperative encounter can be initiated to schedule surgery and obtain patient information. These details include past medical and surgical history, current or recent illnesses, hospitalizations, dental history, current medications, familial support, and financial means. The NP ensures proper identification of patient and family needs and referral to the proper individuals to meet those needs. The week before surgery, the family is contacted to discuss the child's present health, ensure no recent or current presence of viral illnesses, discuss discontinuing certain medications before surgery, and reminders regarding the preoperative visit. Final consult recommendations (e.g., neurology, genetics, hematology, infectious disease) should be collected and comprehensively reviewed the week before surgery to ensure the child's medical needs are addressed throughout the hospital stay.

The next appointment is the preoperative visit. This office encounter includes chest radiograph, laboratory work, preoperative education, history and physical, and evaluation by the anesthesiologist. The NP reviews laboratory results and chest radiograph evaluation and conducts a thorough history and physical within 30 days before surgery. The NP discusses with the parents any current health and medical concerns, their readiness for the upcoming surgery, and any educational needs of the patient and/or family. The preoperative visit may include consultation with the on-service cardiologist, anesthesiologists, child-life personnel, and social workers.

Preoperative teaching is done in great detail including reinforcement of the child's heart defect, the surgical process, and postoperative expectations. The discussion may include computer-generated diagrams, pamphlets, and/or heart models. This concrete visualization and representation of the process needed to repair the heart defect allows families to understand and have realistic expectations. Proper evaluation of the child's developmental level is ascertained and appropriate educational material should be used. Child-life personnel have a positive impact on children and their siblings when discussing the surgical process. Identification of feelings and expression of these feelings is encouraged. Child-life personnel specialize in helping these children discuss their feelings, which drastically reduces the stress level of both child and family.

Perioperative Process

Intraoperative Phase

On the morning of surgery, the child is accompanied to the operating room by parent(s) or caregiver(s), and care is transferred to the operating room staff. This experience has proven to be stressful and emotional for families. Extended family support is encouraged and helpful. A location where caregivers and their support system can remain during the child's surgery is beneficial in decreasing the anxiety that is present throughout the process. The NP provides the family with necessary updates throughout the intraoperative phase, including the anesthetic, commencement of cardiopulmonary bypass, and the final outcome.

Emotional support is provided to the family if the surgical outcome will not be optimal, including cases of delayed chest closure, extracorporeal membrane oxygenation support, or surgical demise. Toward the end of the surgical case, the surgeon discusses the operative details with the family. In the

case of poor outcome or death, the NP provides social and spiritual support as necessary.

Initial Postoperative Phase

Once the surgical procedure has been completed, the child is transferred to the intensive care unit. This transfer can be a physiologically stressful time for the child, where adequate assessment of hemodynamic support and pain management are vital. The NP communicates intraoperative concerns to the pediatric intensive care unit staff, writes postoperative orders, and assists with the admission of the child to the unit. Careful review of laboratory work, correction of electrolytes, treatment of coagulopathies, and blood administration is completed as indicated. Arterial blood gas measurements are reviewed to assure appropriate ventilation. Initial chest radiograph, after transfer, includes assessment of proper placement of lines and tubes. Pleural effusion, atelectasis, pulmonary vascular markings, heart size, and other abnormalities are noted, and appropriate treatments are started. The cardiac rhythm is assessed and a 12-lead electrocardiogram is obtained to rule out conduction abnormalities. Once this initial assessment is done, the parents are provided the opportunity to see their child.

Most parents require reintroduction to their surroundings, including the child's intravenous lines and tubes and their function to the child's recovery. Explanation of monitors will allow parents to understand what nurses and medical staff are doing to provide proper medical treatment to their child. The family should be introduced to the child's bedside nurse and be encouraged to ask questions. Nursing staff can promote family participation in their child's care by supporting them in simple tasks such as changing diapers, applying lotion, or even sponge bathing. This minimizes feelings of helplessness and allows a sense of accomplishment.

Subsequently, the NP monitors the child's progress and assesses potential problems by serial physical exams and attention to clinical signs. Common postoperative problems are managed and include low cardiac output, pulmonary edema, arrhythmias, and excessive bleeding. The NP confers with the surgeon, cardiologists, intensive care unit staff, and residents at daily rounds to develop a treatment plan for each child. The plan is communicated to the family at this time, and the NP provides emotional support as appropriate.

Postoperative Assessment and Complications

The NP must understand each patient's congenital heart defect, the preoperative clinical condition, the surgical procedure, and the potential postoperative sequela. The NP focuses on potential problems and proactively approaches preventing them.

Decreased Cardiac Output

The greatest concern of the postoperative period is maintaining adequate myocardial function and oxygen delivery to the tissues. The child with poor cardiac output will have cool extremities, decreased peripheral pulses, decreased capillary refill, lactate levels greater than 2 mmol/L, and poor urine output. Low cardiac output in the immediate postoperative period may result from hypovolemia, elevated systemic vascular resistance (SVR), arrhythmia, cardiac tamponade, and myocardial dysfunction. The management of low cardiac output requires replacement of intravascular volume, treating inappropriate SVR, and frequently supporting myocardial function with inotropic medications such as dopamine, milrinone, and dobutamine. It is also important that the child with decreased cardiac output be normothermic, well sedated, and maintain electrolytes in normal range, particularly calcium, magnesium, glucose, and potassium.

Arrhythmias

Hemodynamically significant arrhythmias occur frequently after congenital heart surgery in approximately 15% of patients [13,14]. Some examples of rhythm disturbances include heart block, junctional ectopic tachycardia (JET), premature ventricular contractions (PVCs), and supraventricular tachycardia (SVT). One study performed by Batra *et al*. [15], stated that surgical repairs with the highest risk for arrhythmia were Norwood procedure (90%), arterial switch operation (54%), and atrioventricular canal repair (37%). Among the group of 336 patients, PVCs (11%), JET (8%), nonsustained ventricular tachycardia (4%), and SVT (3%) were among the most common arrhythmias [15]. Close cardiac monitoring allows for frequent assessment of the child's rhythm and prompt intervention when necessary. Children who are at increased risk for arrhythmias may require pacing, and temporary pacing wires are used when available.

The most problematic and common arrhythmia that occurs in the immediate postoperative period, usually in infants after a complex repair, is JET. The loss of atrioventricular synchrony and decreased ventricular fill time can have a significant impact on cardiac output. Junctional ectopic tachycardia may not be obvious, so the NP must have a high index of suspicion in an infant with poor rate variability and decreased perfusion. A 12-lead electrocardiogram with atrial wire tracing is helpful when diagnosing JET. Treatment includes mild hypothermia, sedation, reduction of exogenous catecholamines, overdrive pacing and the use of antiarrhythmic medications, such as amiodarone [13].

Conduction defects can occur with procedures that relieve left ventricular outflow obstruction and where

closure of a septal defect is involved. Patients may require temporary pacing until normal sinus rhythm returns or a permanent pacemaker is placed. The recommended acceptable waiting period for recovery is 7–10 days. Children who have surgical heart block are at risk for long-term conduction abnormalities [16].

Fluids/renal Function

Hypovolemia and interstitial fluid accumulation occur from capillary leak in the first 24–48 hours after cardiopulmonary bypass [17]. Fluid status needs to be carefully evaluated and appropriate treatment given. Intravascular volume needs to be replaced with colloid and/or blood products titrated to appropriate filling pressures to maintain cardiac output. Diuretics are usually started on the first postoperative day to encourage mobilization of interstitial fluid. During this active diuresis, the NP must monitor electrolytes and replace where warranted. The patient response to therapy, physical exam, daily weights, blood urea nitrogen, and creatinine needs to be followed to prevent over-diuresis and dehydration. Fluid loss from chest tubes, peritoneal drains, nasogastric tubes, and diarrhea must be accounted for and replaced as necessary.

Temporary oliguric renal dysfunction is common after long cardiopulmonary bypass times for complex CHD in infants. Acute renal injury after cardiac surgery is a serious adverse event, which can significantly impact patient morbidity and mortality [17]. Generally, this recovers as the systemic inflammatory response resolves and cardiac output improves, usually 24–48 hours postoperatively. If oliguria persists with electrolyte abnormalities and/or severe fluid overload occurs, peritoneal dialysis can be helpful. Children who recover from hemodynamic instability with improved cardiac output usually have good renal function recovery [18].

Potential Neurological Complications

Children with CHD are at increased risk for neurological impairment, particularly brain injury after open-heart surgery [19]. The brain may be at increased vulnerability to injuries due to hemodynamic, ventilatory, and oxygen disturbances [19]. The initial postoperative period focuses on the physiologic effects after cardiopulmonary bypass. Neurological complications after surgery include seizures, embolic stroke, intracerebral hemorrhage, choreoathetosis, quadriplegia, and long-term neurodevelopment deficits, which appear later in childhood.

Some children with CHD are at particularly greater risk for suboptimal outcomes including premature and low-birthweight infants, children with chromosomal anomalies or syndromes, and more complex heart defects [19–21]. Any of these complications can lead to learning and behavior disabilities. Adverse neurologic outcomes are multifactorial and relate to both patient-specific factors (genetic predisposition, in-utero central nervous system development, socioeconomic level) and potentially modifiable factors. Potentially modifiable factors include intraoperative variables, cardiopulmonary bypass, deep hypothermic circulatory arrest, and perioperative factors. Perioperative factors include low cardiac output, hypoxemia, hypotension, prolonged hospitalization, and sepsis [19–21].

Pulmonary Complications

A systematic pulmonary evaluation is done with each assessment, including notation of ventilator settings, lung auscultation, nature of secretions, and evaluation of arterial blood gas measurements. This detailed review will assist in assessment of the child's readiness for extubation.

Most children can be extubated within 72 hours after surgery. Inability to wean or separate from mechanical ventilation may be related to pleural effusion, phrenic nerve damage, recurrent nerve damage, airway edema, bronchomalacia, airway compression from vascular structures or conduits, or residual cardiac defects [22]. Frequently, the case is multifactorial in a small malnourished child with residual cardiac defects. Children who require prolonged intubation can be at increased risk for ventilator associated pneumonia (VAP) and increased length of stay [23]. Additionally, prolonged ventilation is associated with greater medical complications and mortality rates [24].

The NP monitors for appropriate fluid and electrolytes and ensures appropriate nutritional support. The surgeon can be alerted if drainage of pleural effusions is indicated. The NP can assist in determining the cause of respiratory failure by astute serial physical exam during weaning and extubation. Did the child fail because of tachypnea, stridor, inability to handle secretions, or poor cough? Was paradoxical breathing noted or did the child gradually become fatigued with poor inspiratory effort? Ultrasound of the diaphragm or a consult with an ear, nose, and throat physician may be indicated to rule out phrenic or vocal cord damage.

Causes for pleural effusion or excessive pleural drainage include fluid overload, pulmonary edema, and capillary leak from cardiopulmonary bypass and increased venous pressure as seen with patients after right ventriculotomy (e.g., tetralogy of Fallot), cavopulmonary shunts, and the Fontan procedure. Small to moderate pleural effusions can usually be handled medically with diuretics. However, a large effusion should be drained, especially if the patient is symptomatic. Serial physical exams and chest radiograph should be done to monitor effusions and response to therapy.

Chylothorax is the leakage of lymphatic fluid, a creamy white fluid called chyle, into the pleural space owing to injury of the thoracic duct or because of increased pressure within the intrathoracic lymph system [25]. Excessive

chylous drainage can lead to hypoproteinemia, hypolipidemia, electrolyte loss, and immune dysfunction due to loss of T cells. Nutritional treatment consists of a diet low in long-chain triglycerides, and high in medium-chain triglycerides and protein. Electrolytes, serum protein, and albumin are followed and replaced as necessary. Some children require chemical or mechanical pleurodesis with parenteral nutrition. Octreotide, a somatostatin analogue, has been used in some institutions with some success in reducing chylous leakage [25].

Infection

Infections, particularly sepsis, can be a serious postoperative complication. Factors that increase the risk of infection include younger age, prolonged surgical procedure, prolonged intensive care unit course, prolonged mechanical ventilation, multiple lines and tubes, and delayed chest closure. Prevention and early treatment of line infections are particularly important for children who have intracardiac prosthesis or patches, as eradication of established infection on foreign material can be difficult.

A low-grade fever is common for 24 hours after surgery. However, if the fever is greater than 39 °C, infection should be suspected and cultures sent. Other signs of infection include changes in white blood cell count, a drop in platelet count, hemodynamic instability, and/or change in mental status. All intravenous sites and the child's incision should be inspected daily for signs of infection. Good handwashing, meticulous line care, and early removal of lines and tubes are important in preventing infection. Other causes of fever could be atelectasis, pleural effusion, pneumonia, postcardiotomy syndrome, urinary tract infection, gastroenteritis, and otitis media. Respiratory syncytial virus (RSV) and other respiratory viruses should be suspected if the child has upper respiratory infection symptoms, chest radiograph changes, or low oxygen saturation.

Risk factors for wound infection include delayed chest closure, exploration for bleeding, and reoperation. The most common organisms are coagulase-negative *Staphylococcus* and *Staphylococcus aureus*. Severe infection requires incision and drainage, and healing is by second intention.

Vacuum-assisted closure (VAC) is a new therapy for children with mediastinitis that has shown promise in improving outcomes. However, studies in children have been limited. A VAC dressing consists of a piece of foam with an open cell structure placed loosely in the wound [26,27]. A wound drain with multiple lateral perforations is placed on top. The entire wound is then covered with a transparent dressing. The drain tube is then connected to a vacuum source, which is set between 25 and 125 mmHg. Fluid is drawn from the wound through the foam into a reservoir for disposal. The transparent dressing prevents air entry and allows a partial vacuum to form within the wound, which promotes debridement and decreases tissue bacterial levels, increases blood flow, and promotes healing [26,27].

Nutrition

Children with CHD are frequently malnourished and have failure to thrive before surgical intervention [28]. It is well known that patients who are malnourished are at increased risk for poor wound healing, infections, and an inability to wean from mechanical ventilation. Therefore, it is essential in the postoperative period when the child is in a hypermetabolic state that nutritional support be started early to prevent complications. Parenteral nutrition is indicated when hemodynamic instability and poor gastrointestinal function prevent using the gastrointestinal tract. The use of trophic feeds in conjunction with total parenteral nutrition can help prevent gastrointestinal complications, improve immune function, and lessen the risk of bacterial infection [24].

Neonates with complex repairs involving the aortic arch, and single-ventricle patients with an aorta pulmonary shunt are at increased risk for necrotizing enterocolitis [25]. The usual feeding regimen begins with continuous nasogastric feeds with breast milk or 20 kcal per ounce formula. Feeds are slowly increased over 3–5 days with serial abdominal examination. The calorie density of the breast milk or formula then is advanced until the infant is receiving at least 120 kcal/kg/day. Infants with two-ventricle repair typically are managed with a combination of oral and nasogastric feeding. Oral feeding is attempted for 15–20 minutes with nasogastric supplementation thereafter as necessary. This allows the infant to learn oral feeding skills while ensuring adequate calorie intake. Breast feeding should be encouraged and supported as long as the infant is able to gain weight. Lactation consultants can assist mother and baby to establish breast feeding. Infants may have feeding difficulties owing to congestive heart failure, poor cardiac output, vocal cord paresis, uncoordinated suck swallow or feeding aversion [29]. Infants with delayed gastric emptying, severe gastroesophageal reflux, or vocal cord dysfunction may require a transpyloric feeding tube to allow for enteral nutrition.

Parents of children who are poor feeders need a tremendous amount of support. Mothers often feel frustrated and stressed if their infant does not feed well, and that can negatively impact bonding and nurturing. Nasogastric feeding sometimes can help with the stress of feeding and allow for more relaxed bonding between mother and child. However, their families may feel the stress of learning nasogastric feeding and become overwhelmed. Children who have ongoing protein loss from chest tube drainage and chylothorax require a diet high in protein and low in long-chain triglycerides.

Pain Management

Every patient who has cardiac surgery will experience some degree of pain and anxiety. A pain assessment should be performed with every set of vital signs and with every physical examination. Poor pain management can lead to physical and psychologic stress, which can lead to increased morbidity and mortality. There are several self-reporting pain assessment tools now available for all ages of patients [30]:

OUCHER
- Facial photographs (3–4 years and up)
- Linear analogue scale (6–7 years and up)

Wong-Baker faces
- Cartoon faces (3–4 years and up)
- Word descriptors and numbers (6–7 years and up)

Visual analogue
Finger span scale or word anchors (6–7 years and up)

There are additionally, several behavioral and physiologic pain assessment tools currently being used by patients of all ages [30]:

CRIES (crying, requires oxygen, increased vital signs, expression, sleepless; infants)
FLACC (face, legs, activity, cry, consolability; 2 months to 7 years)
OPS (objective pain scale; <3 years)
CHEOPS (Children's Hospital of Eastern Ontario Pain Scale: cry, facial, verbal, torso, touch, legs; 1–7 years).

Scales that allow a child to self report pain are preferred whenever possible. Older children should be familiarized with an age-appropriate pain assessment tool and plans for postoperative pain management [30] discussed before surgery. Older children can be instructed in the use of the patient-controlled analgesia pump. Usually, the initial postoperative pain management regimen consists of continuous opioid infusion (morphine or fentanyl for the first 24–48 hours) (see Chapter 7, *Perioperative Care*). Other sedation, like benzodiazepines, may be used as needed to maintain comfort during mechanical ventilation. Most children can take medications by mouth by the third postoperative day and can be switched to acetaminophen and/or ibuprofen with codeine or oxycodone for breakthrough pain.

Critically ill infants and children after complex repairs are at risk for pulmonary hypertensive crisis, junctional tachycardia, or postoperative bleeding resulting from hypertension and are kept sedated with high-dose opioid infusion and scheduled benzodiazepines. As the child becomes hemodynamically stable, the sedation is weaned. Children who have received large doses of narcotics and benzodiazepines for longer than 5 days are at risk for withdrawal if medications are abruptly stopped. A slow wean by decreasing the narcotic or lorazepam dose by 10% and increasing the time between doses will usually prevent withdrawal symptoms [30]. Child-life personnel are significant members of the multidisciplinary team who provide nondrug strategies to children. For instance, watching television or listening to music can be helpful to relieve pain and anxiety associated with minor problems such as intravenous starts and lab draws. Painful procedures, such as chest tube removal, usually require treatment with both a narcotic and anxiolysis. The presence of a parent is a great source of comfort for the child, and he or she should be encouraged to be with the child and participate in care as much as possible [31].

Discharge Planning

Discharge teaching for patients undergoing congenital surgery is continuous and should begin at the time of admission [1,12]. As overall patient acuity and complexity of care has increased, so have the details of discharge planning for this patient population [32]. The patient's age, nutritional needs, home medical equipment needs, communication with the primary care physicians, as well as plans to return to work and school all require careful consideration. It has been said that the NP involved with these patients essentially becomes a patient care coordinator at this time. The experienced clinical judgment of the NP as well as his/her background in patient education and clinical research, comprises the best candidate for discharge planning [32].

Neonatal Discharge Planning

Organizing the discharge of neonates after congenital heart surgery requires a high degree of care coordination. It has been shown that a systematic discharge plan not only improves the neonate's recovery at home, but also increases parents' confidence in caring for their child [33]. It is of utmost importance to determine patient as well as parent readiness for discharge planning process [12]. The neonate with CHD is deemed ready for discharge once vital signs (including saturations) are stable, body temperature is maintained without warmers, and the infant is gaining weight steadily with oral or enteral tube feeding [12]. The best method of determining parent readiness is to have the parent or designated caregiver "room-in" with the infant [12]. While rooming in, the parent can assume all of their child's care with back-up help from the floor nurse or cardiothoracic NP. Also during this time, the NP can review with the parents wound care needs, medication dosing and administration, in addition to providing education regarding postoperative complications to watch for once at home.

One of the most common problems infants with CHD face is feeding difficulties and growth delay, particularly those who remain cyanotic after initial surgery [34]. Many of these infants will require assistance with feeding via nasogastric tube. Persistent postoperative congestive heart failure, stress of surgery, and wound healing can increase the metabolic rate of children with CHD, thus increasing their caloric needs. Most neonates are sent home on calorie-dense formula or fortified breast milk to provide proper nutritional requirements. Some of these patients require up to 160 kcal/kg/day to gain sufficient weight [35].

There are several other issues requiring attention before discharge including sending all pertinent neonatal screening tests (e.g., hearing screen, phenylketonuria testing). Other genetic anomalies may be present and certain testing can be done to address these issues. Hearing screens are routinely recommended for newborns before discharge and are especially recommended for those newborns with CHD. Various syndromes associated with CHD, as well as various medications these infants need before and after surgery can lead to hearing loss [12]. A brainstem evoked auditory response (BAER) exam can be performed at the bedside. Immunizations should be given as recommended for these infants a few days before discharge to allow time to observe for adverse reactions [12]. The hepatitis B series should be initiated and, depending on the child's age at discharge, the pneumococcal and rotavirus vaccines should be considered [36]. If discharge is occurring during the fall and winter months, all neonates with CHD should begin receiving monthly RSV prophylaxis until the season is over [37]. Palivizumab and RSV immune globulin can be given during the RSV season up to the age of 2 years [37].

Additional matters to be addressed include car seat safety and cardiopulmonary resuscitation (CPR) education for caregivers. Many institutions require a car seat challenge for premature or special needs infants going home for the first time. Car seat challenges ensure the infant can maintain adequate oxygen saturations while positioned in an infant car seat for up to an hour. The parents should be instructed on proper car seat positioning and demonstrate competence in securing their child.

Cardiopulmonary resuscitation training is essential for parents and caregivers of infants with CHD. In-hospital resources can be used for CPR training, or community resources are available for CPR training for these families and caregivers. Extensive teaching is done before discharge, including what to do in case of an emergency.

Discharge Planning Past the Neonatal Period

Central Nervous System Concerns

Pain management remains a primary concern for parents of children with CHD. For younger patients, giving acetaminophen (15 mg/kg) every 6 hours is usually sufficient. Ibuprofen (10 mg/kg) can be alternated with acetaminophen dosing to give additional pain relief. Some children often require a mild narcotic regimen such as codeine (0.5–1 mg/kg/dose) every 6 hours or oxycodone (0.05–0.15 mg/kg/dose) every 4–6 hours. Older children and young adults may benefit from nonsteroidal anti-inflammatory agents such as ibuprofen or ketorolac provided they have normal renal function.

Education Point

Review expectations for pain management in an age-appropriate manner. Any increase in wound pain should be immediately reported to the surgical team.

Respiratory Concerns

Atelectasis is common postoperatively and usually resolves quickly in infants and younger children. Older children and adolescents should be encouraged to use bubbles, incentive spirometry, and other deep breathing exercises to assist in alveolar recovery. A repeat chest radiograph should be done at the postoperative visit to evaluate lung expansion and resolution of prior atelectasis. Some patients with increased pulmonary vascular resistance may require home oxygen therapy. Arrangements should be made before discharge from the hospital. Some institutions require home pulse oximetry, and parent education should be thorough regarding its use.

Education Point

Review signs and symptoms of pleural effusion. The surgical team should be notified immediately of increased work of breathing or retractions abnormal to the patient's baseline. Infants may develop poor feeding and tachypnea, both of which should be reported to the proper members of the health-care team.

Cardiovascular Concerns

An overview of cardiovascular symptoms that may develop postoperatively should be reviewed with the family. This includes assessment of perfusion, presence of edema, irritability, and lethargy. Cardiovascular medications, administration guidelines, and review of medication interactions should be reviewed with patients and families before discharge. Postoperative complications should be communicated with the child's primary care physician so recurrence of these can be monitored appropriately. Families of children with complex CHD, including single-ventricle pathology, require staged palliative procedures. The need for appropriate follow-up and referral should be reinforced.

Education Point

Review the symptoms of worsening condition such as tachycardia, chest pain, or cyanotic episodes. Review side effects of cardiovascular medications and possible drug interactions.

Gastrointestinal Concerns

A nutritional plan should be made in collaboration with a dietitian before discharge and written instructions reviewed with caregivers. Dietary regimens may include both oral and nasogastric feedings while the child transitions to full oral feedings. Nasogastric tube insertion and verification of placement should be demonstrated by caregivers as appropriate. Additionally, constipation from narcotic regimen may become an issue postoperatively. Proper use of stool softeners is examined and dosage recommendations reviewed with families.

Education Point

Review plans for stool softeners and dietary changes until normal bowel movement pattern returns. Fluids should be encouraged and development of diarrhea, vomiting, or refusal of intake should be immediately reported.

Renal Concerns

Patients typically require diuretics during the immediate postoperative period, with some children requiring prolonged use. The administration timing of diuretics should be considered in older children to avoid disruption of the sleep cycle. Occasionally, viral illnesses will cause children with CHD to become dehydrated. Referral to the cardiologist and primary care physicians should be encouraged early in the course of the illness for proper medication adjustments.

Education Point

Review dosing, side effects, symptoms related to electrolyte imbalances, and dietary changes that can prevent hydration issues.

Hematologic/Infectious Disease Concerns

Anemia may be persistent postoperatively and iron supplementation initiated until adequate hemoglobin levels are achieved. Immunizations remain important and children over 6 months of age should be receiving yearly flu vaccination. Children over age 2 should receive the meningococcal vaccine as well [36]. Immunocompromised patients, such as those with asplenia, will require daily antibiotic prophylaxis. If wound infection occurs postoperatively, children may require long-term intravenous antibiotics. Home care nursing may be required and these arrangements should be made before discharge.

Education Point

Review with families the American Heart Association Guidelines for bacterial endocarditis prophylaxis. Parents are instructed to call for any fever over 38.3°C in all postoperative patients. Ensure the family has access to an appropriate thermometer and instruct prompt measurement when a fever is suspected.

Integumentary Concerns

Proper wound care is of vital importance in children who have undergone any invasive surgery. Thorough education and wound care procedures should be demonstrated by caregivers. Showering will be postponed until suture removal is performed at the postoperative visit. Soaking underneath water and swimming are discouraged until wounds are fully healed. If prolonged dressing changes are required for delayed incisional healing, extensive education and demonstration of technique should be performed. In some cases, home care nursing may be used.

Education Point

Education regarding signs and symptoms of wound infection are reviewed. If disruption of healing is suspected, the surgical team should be notified immediately.

Medication Concerns

The home medication regimen is examined before discharge and an administration schedule developed with the family. Rooming-in will allow for proper assessment of the caregiver's ability to draw up and administer any liquid medications [12]. Explanation of medication necessity should be thoroughly reviewed with adolescents and young adults to ensure compliance.

Education Point

A written list of medications, dosage, route, timing of administration, purpose of use, and side effects should be provided to the family. Prescriptions should be filled before discharge so proper measuring techniques can be demonstrated with liquid preparations.

Final Discharge Details

The transition from hospital to home consists of communication with the surgical team to primary care physician and cardiologist. Both should receive copies of the operative note and discharge for the child's medical record. Notification of discharge date and follow-up plans should be communicated to the primary care physician and cardiologist. Outstanding issues including laboratory or radiology testing can be addressed with this communication. This exchange of information enables primary care physicians the opportunity to ask specific questions regarding their patients.

Parenting methods and discipline are often a common topic of concern for parents following cardiac surgery. Parents of children with CHD commonly fear disciplining their child, as concern exists of a worsening heart condition. Early on, whether by a cardiologist or NP, the parents should be encouraged to treat their child as normal as possible to avoid "vulnerable child syndrome". This syndrome occurs as a result of a parent's perception of the child as weaker owing to life-threatening illness despite the child's recovery. This leads to disruption in the parent-child relationship, which eventually causes behavior disorders [38].

Another topic of concern for the older child and adolescent is return to school and/or work. There is limited information in the literature regarding timing of postoperative return to work or school. Individual recovery periods and variability in complications after surgery need to be accounted for when deciding the proper timing for return to school and work. Once the child has had their initial postoperative visit with their cardiologist, a return to work/school date can be identified. School-aged children are excused from physical education for 6–12 weeks and are encouraged to avoid heavy lifting (backpacks) for at least 6 weeks. It may be helpful for the school to provide the child with a second set of books during this recovery period. The primary cardiologist routinely gives adolescents clearance to return to the work environment. Depending on the adolescent's occupation, 2–4 weeks is usually sufficient time for recovery. High-intensity labor positions may require a further return to work date, especially if heavy lifting is involved. Cardiac rehabilitation is recommended for the adolescent population, and proper referral should be made before discharge.

Various details are needed in order to organize the child's discharge from the hospital after congenital heart surgery. A holistic approach should be used when planning for each patient's transition from hospital to home. The NP has an extensive opportunity to be engaged in the discharge process for these families from admission to the hospital through discharge. The NP ensures a comprehensive discharge plan for each patient based on their individual needs. However, the NP cannot complete the patient's discharge plan alone. A multidisciplinary team including physicians, nurses, and therapists is needed to ensure comprehensive care is delivered after hospital discharge (Figure 8.1) [12].

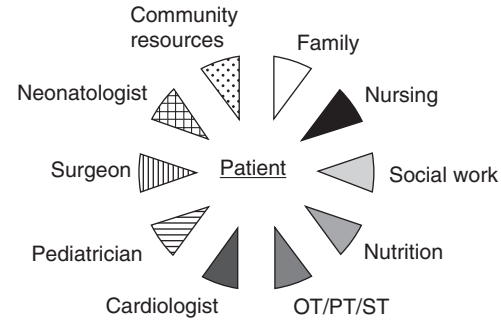

Figure 8.1 Multidisciplinary team. (Reproduced with permission from Dodds *et al.* [12].)

Patient and Family Satisfaction

The NP has a vital role in the assessment of patient and family satisfaction throughout the entire spectrum of care from preoperative diagnosis through postoperative follow up. Some quality improvement initiatives measure patient satisfaction data, including the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). Collectively, institutions are required to comply with National Patient Safety Goals, and accreditation status can be affected by this data. Proper examination of the hospital experience for patient's with CHD permits a thorough evaluation of the surgical process and supports restructuring when satisfaction needs are unmet.

The NP continues to be at the forefront of delivering education and dissemination of information to families and patients. The literature suggests that some of the most important domains of satisfaction identified by parents are medical care, professional support in terms of communication and information, and the parents' own role in pediatric care [39]. Past research suggests that communication, staff courtesy, compassion and respect, information provided to the family, and level of healthcare received by the patient were predictors of overall family satisfaction [40]. The NP has the ability to witness, assess, and shape the hospital experience for patients and families and is essential to providing good patient satisfaction outcomes.

The child's perception and experience are both relevant to satisfaction, as well as parental insight and contentment with the perioperative process. The child's needs should be met from initial contact to hospital discharge, including age-appropriate education. Patient satisfaction scores may

Table 8.1 Hierarchy of needs used to assess patient and family satisfaction.

Physiologic needs	Medication, oxygenation, pain control, diet, bowel pattern, sleep
Safety	Secured side rails, availability of nursing
Love/belonging	Presence of caregivers, nursing, child-life personnel, NPs
Esteem	Confidence, respect of others, achievement of medical tasks
Self-actualization	Delivery of medical facts, prognosis

reflect suitable pain assessment and management, patient safety, building trustworthy relationships, age-appropriate communication and rationale for care, and family/nursing presence at the bedside. The caregiver level of satisfaction can be optimized by adequate delivery of medical information, developing empowering relationships, and decisive fulfillment of family centered care. Ensuring that these needs are met may be done in systematic fashion. For instance, an adaptation of a hierarchy of needs is demonstrated as a tool that could be used to ameliorate the assessment of patient and family satisfaction (Table 8.1) with the highest priority being physiologic needs.

Physiologic needs including medication, oxygen requirements, pain control, diet intake, bowel management, and adequate sleep are fundamental tasks that require careful assessment and adjustment as warranted. This element of the child's needs assessment highly impacts the other issues of concern.

Safety becomes an important and prioritized point for children during the hospital stay. Hospital safety is important to patients and families and has been shown to be a predictor of positive outcomes [40]. Physical safety should be guaranteed, along with the feeling of being safe while being hospitalized. This can be accomplished with locked patient care areas and secured bed side rails. Children may or may not have continued presence of a caregiver during their hospitalization. The NP is an advocate for the child and encourages caregiver presence whenever possible. If the caregiver or extended family is unable to be present, the nursing staff and NP compensate for this deficit until discharge is possible.

The ability of children and adolescents with CHD to feel love and belonging in the hospital environment is of great importance and should be maintained. Caregivers who are unable to be present because of work schedules or care requirements of other siblings need reinforcement of holistic hospital care and recovery in their absence. Nursing staff, child-life personnel, and the NP may need to compensate for the absence of a consistent caregiver. Social work assessment is important in this situation.

The next phase of the needs assessment includes the child's self-esteem. This phase becomes a topic of interest in the older child. This age group has the ability to be active in their recovery process. Encouragement to be accountable for their nutritional and physical therapy needs can provide them with a sense of accomplishment and augment their healing time. Child-life personnel can be used when identifying the child's needs in collaboration with the NP. Providing rewards for accomplishing activities necessary for recovery (ambulation, bathing, medication intake, painful procedures) may be helpful.

The self-actualization phase includes assessment of child and caregiver, depending on the child's age and ability to understand and accept their medical diagnosis and prognosis. Delivery of information and discussion of medical facts with the family and child are common tasks needed for successful understanding of long-term outcomes.

A uniform way to evaluate parental or caregiver satisfaction can be done in addition to the child's assessment. The hierarchy of needs can be used and adapted for individual patients and families. The literature continues to have common themes for positive outcomes including delivery of medical information, building trustworthy relationships, and parental involvement in patient care. According to Dowling *et al*. [40], communication remains a powerful predictor of satisfaction and should be a key component of any initiative. The NP can modify and adapt a system that embodies the mission of their institution to ensure thorough needs assessment of their patient population. Evidenced-based research can allow for expanding on these processes and discovery of the best approach to ensure satisfaction.

Conclusion

Pediatric NPs bring their expertise in general pediatrics as well as in human development to specialty care in congenital heart surgery [3]. The NP role continues to evolve as new treatments become available, medical and surgical therapies progress, and the patient population lives longer. Judicious patient care assessment, coordination, and practice improvement enhance positive patient outcomes.

CHAPTER 9

Palliative Operations

Carl L. Backer[1] and Constantine Mavroudis[2]

[1]Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Chicago, IL, USA
[2]Florida Hospital for Children, Orlando, FL, USA

The word palliate originates from the Latin "palliare" (to cloak) and in medicine it is usually taken to mean the masking or lessening of an effect [1]. A palliative operation generally is one that provides symptomatic relief but leaves the main pathophysiology uncorrected. A palliative operation is one that affords relief (usually temporary) but is not a correction or a repair. In congenital heart surgery the two classic palliative procedures are the aortopulmonary shunt and the pulmonary artery band [2,3]. From a historical perspective, these were initially the only procedures available to treat many children with congenital heart disease. Over the past 50 years the advances in open-heart surgery, progressing to neonatal repair for many congenital heart lesions, have decreased markedly the indications for these palliative procedures. Although there are fewer and fewer indications for palliative procedures, there is a select, small group of patients for whom palliation is still (and may always be) necessary. The importance of the initial palliative procedure cannot be overemphasized. A poorly performed aortopulmonary shunt that destroys a pulmonary artery may prohibit the child from having a completion Fontan procedure. Hence, although these are older and seemingly less important procedures, they must be performed well to ensure a smooth eventual corrective procedure.

Some of the procedures reviewed in this chapter are now actually considered obsolete and are no longer performed. However, the surgeon must understand these procedures and their attendant complications because there are many surviving patients who have had these operations in the remote past but now require repeat surgical intervention. A thorough understanding of palliative procedures is necessary for appropriate staging and successful takedown at the time of correction.

In general, the goals of palliative procedures are to alter the hemodynamic physiology in such a manner as to make the cardiac malformation more tolerable, allow an improvement in the patient's condition, and allow continued growth until the child has complete correction. In the past, palliative procedures were performed on nearly all children and their complete "correction" was performed when they were older and larger. With improvements in cardiopulmonary bypass and in microsurgical techniques, the size of the patient is no longer as significant a consideration in deciding between palliation and complete repair [4]. Rather, it is the underlying cardiovascular physiology, in particular the normal high neonatal pulmonary vascular resistance, that usually mandates a palliative operation in the current era.

The two primary palliative procedures are the aortopulmonary shunts (Table 9.1) and the pulmonary artery band. Many of the aortopulmonary shunts noted in Table 9.1 are now obsolete and rarely used (Potts shunt, Waterston/Cooley shunt). Aortopulmonary shunts are designed to increase pulmonary blood flow in a cyanotic child with inadequate pulmonary blood flow. Pulmonary artery band is designed to limit pulmonary blood flow in a child with excessive pulmonary blood flow. A third palliative operation is the atrial septectomy, designed to increase mixing at the atrial level in patients with transposition of the great arteries or single ventricle and atrioventricular valve stenosis. The Blalock–Hanlon atrial septectomy was first reported in 1950 [5]. Interestingly, like many other "simple" congenital heart procedures, this is now most commonly performed using transcatheter techniques [6]. There are other more complex procedures that are considered palliative, such as the Norwood operation for hypoplastic left heart syndrome [7] and the Glenn procedure [8], but these are in general specific operative procedures for defined lesions

Waterston shunt	David Waterston	1962
Cooley shunt	Denton Cooley	1966
Modified Blalock–Taussig shunt	Marc de Leval	1976

and are discussed in detail in the chapters on those specific lesions. One palliative operation that has had a resurgence is pulmonary artery banding combined with a ductal stent for hypoplastic left heart syndrome, the so-called "hybrid" approach [9,10].

Pulmonary Artery band

Pulmonary artery banding was first reported by Muller and Dammann [3] in 1952 for children with a large left-to-right shunt or single ventricle and excessive pulmonary blood flow. For many years, pulmonary artery banding was the preferred initial palliation for any small child with a large left-to-right shunt and increased pulmonary blood flow. Examples of this would include ventricular septal defect, atrioventricular canal, and truncus arteriosus. However, as improvements in neonatal cardiac surgical techniques have taken place, pulmonary artery banding is now routinely used for only a very few specific lesions. These include (1) "Swiss-cheese" muscular ventricular septal defects; (2) multiple ventricular septal defects with coarctation; (3) single ventricle with increased pulmonary blood flow (i.e., tricuspid atresia type IIc) in preparation for eventual Fontan procedure [11,12]; (4) to prepare and retrain the left ventricle of a patient with transposition of the great arteries for the arterial switch procedure either (a) following late presentation after 6 weeks of age [13], or (b) following prior atrial repair [14]; and 5) to train the left ventricle in a patient with congenitally corrected transposition of the great arteries for a "double switch" [15,16]. Even these limited indications are controversial, and some surgeons recommend complete neonatal repair of coarctation of the aorta with multiple ventricular septal defects [17,18]. Others recommend a Damus–Stansel–Kaye procedure with aortopulmonary shunt instead of pulmonary artery band placement for single ventricle with increased pulmonary blood flow, especially when there is potential for subaortic obstruction [19].

Pulmonary artery banding in a child with normally related great vessels can be performed either through a left lateral thoracotomy or a median sternotomy incision. Although the left thoracotomy was historically the preferred approach, many surgeons now prefer the median sternotomy approach. The advantage of the left thoracotomy approach is that it frees the anterior mediastinum from adhesions at the time of reoperation. The advantage of the median sternotomy is it allows a safe and usually quite easy approach to the pulmonary artery even with the frequently varied location of the pulmonary artery in complex defects (e.g., heterotaxy, situs inversus, etc.). In addition, as the band is tightened, the saturations reflect only the banding and not also the effect of the lung compression from a thoracotomy. The bands we have used are either Teflon-impregnated Dacron (infants) or a strip of polytetrafluoroethylene (PTFE) (older children). Figure 9.1 [20] shows the approach for pulmonary artery banding through a median sternotomy incision. If a left thoracotomy is used, the pericardium is opened anterior to the phrenic nerve. Stay sutures are placed to hold the pericardium open. The left atrial appendage generally sits just at the site where the band is to be applied and it can be retracted with a stay suture if needed. Directly encircling a dilated, thin-walled pulmonary artery can possibly lead to unwanted pulmonary artery entry and thus needs to be performed with great care. The safest way to encircle the pulmonary artery is by the subtraction technique. This is illustrated in Figure 9.1A [20]. The band is first placed around both the aorta and the main pulmonary artery proximally. This initial maneuver also avoids the complication of encircling only the left pulmonary artery, which can happen with the thoracotomy approach. A plane is then developed between the aorta and the pulmonary artery with a combination of sharp dissection and electrocautery. A right-angled clamp is then passed around the aorta (not the pulmonary artery) and the free end of the band is grasped (Figure 9.1A2) [20]. The band is pulled through the space between the aorta and pulmonary artery and (by subtraction technique) encircles the pulmonary artery. The band is then sequentially tightened by placing multiple interrupted sutures in the band, as illustrated in Figure 9.1B [20]. An alternative technique to tighten the band is with serial hemoclips, each placed below the prior clip, leading to a progressively tighter band. A catheter is placed in the distal pulmonary artery to monitor the distal pulmonary artery pressure in comparison with the aortic (radial) pressure as the band is being tightened (Figure 9.1C) [20]. Once the band has been tightened to the desired degree, the band is fixed to the proximal pulmonary artery with several interrupted prolene sutures to prevent distal migration of the band and encroachment on the right pulmonary artery (Figure 9.1C) [20].

Placement of the band should result in an elevation of the aortic systolic blood pressure by 10–20 mmHg. For a patient who will eventually have a two-ventricle repair, the distal main pulmonary artery systolic pressure should be reduced to less than 50% of the measured aortic systolic blood pressure. For a patient who is going to undergo an eventual Fontan procedure, the lowest possible distal main pulmonary artery pressure that can be achieved with acceptable oxygen saturations is desired. Oxygen

C

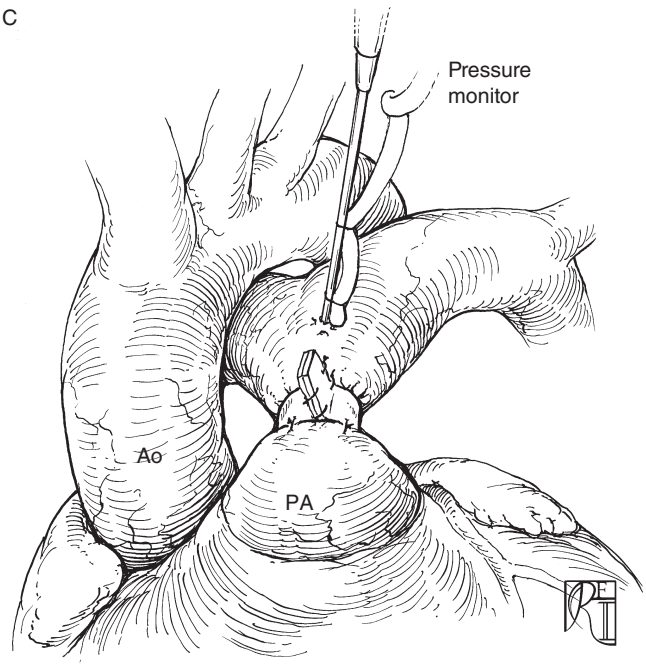

Figure 9.1 (*Continued*)

saturations for a patient who is going to undergo biventricular repair should be left at 95%. For the patient who is going to undergo a Fontan operation, the oxygen saturation should preferably drop to between 80% and 85%. It should be kept in mind that as the child grows, the band will by default become "tighter" and further drop the distal pulmonary artery pressure (and saturations). One possible complication of band placement is the above-noted encroachment on the right pulmonary artery. The band can pinch off the right pulmonary artery while allowing excessive blood flow to the left pulmonary artery. This results in right pulmonary artery stenosis and left pulmonary artery hypertension. Once the band has been secured in place, the pericardium is irrigated with saline, so there is less chance of intrapericardial adhesions at the time of intracardiac repair. If performed through a left thoracotomy, the pericardium is approximated with several interrupted polypropylene sutures, with care being taken to avoid injury to the phrenic nerve.

Although the concept of an externally adjustable pulmonary artery band has been around for many years, it is only recently that several alternative techniques have been reported with considerable improvement in results. Cormo has reported the use of a patented device: FloWatch-R-PAB (EndoArt, S.A., Lausanne, Switzerland) [21]. This is a small clip-like device with a telemetric-controlled incorporated electric micrometer. The meter drives a piston that changes the area inside the clip. Because this band compresses the pulmonary artery in a noncircular fashion, pulmonary artery reconstruction may not be required when it is removed [22]. Talwar reported a "double loop" of Ethibond suture passed around the pulmonary artery, through a pledget, and then up to the skin for external manual tightening [23]. In this series of 147 patients, the use of the adjustable pulmonary artery band was associated with a reduction in early multiple reoperations and band-related deaths. The total number of pulmonary artery band procedures reported in the Society of Thoracic Surgery (STS) congenital database was 739 for the period 2002–2005, corresponding to 1.9% of the total surgical procedures (739 of 38 431). The total number of pulmonary artery band procedures reported in the European Association of Cardiothoracic Surgery (EACTS) congenital database was 711, corresponding to 2.0% of the total surgical procedures (711 of 35 575). These figures contrast with the opinion that pulmonary artery band is an abandoned procedure [24]!

Another method of pulmonary artery band placement is the "intraluminal" technique. This technique is used only in patients who require cardiopulmonary bypass for other, simultaneous procedures. The technique utilizes a Gore-Tex patch with a calibrated precut hole in the center that is sutured as a patch in the main pulmonary artery. It results in a consistent and significant reduction in pulmonary artery pressure and flow. It essentially eliminates the problem of band "slipping" with resultant pinching of the right pulmonary artery. One of the advantages of this "band" is that it can be dilated with transcatheter techniques if the patient should become progressively cyanotic with growth. Pulmonary artery band takedown is performed by incising the pulmonary artery and resecting the Gore-Tex patch and then performing an end-to-end anastomosis. Many of the patients, however who have the intraluminal band go on to a bidirectional Glenn (Fontan strategy) in which case the pulmonary artery is transected at the site of the patch [25].

Pulmonary artery band takedown is performed at the time of intracardiac correction of the congenital cardiac lesion through a median sternotomy. Generally, the intracardiac repair is performed first, and the pulmonary artery reconstruction can be done while the patient is being warmed. All portions of the band should be removed because even a small portion of Dacron band left posteriorly can create scarring, which can cause late pulmonary artery stenosis. Removing the band completely, however, is not always adequate to prevent residual pulmonary stenosis at the band site because the pulmonary artery wall does not easily rebound open. If the band is left in place for only a period of weeks, simple removal is adequate. If the band is left in place for more than a few months, however, the area of banding must be either patched anteriorly or excised (Figure 9.2) [20]. The technique of excision of the scarred pulmonary artery banding site is shown in Figure 9.2A [20]. The area where the band was positioned is resected and then an end-to-end anastomosis is per-

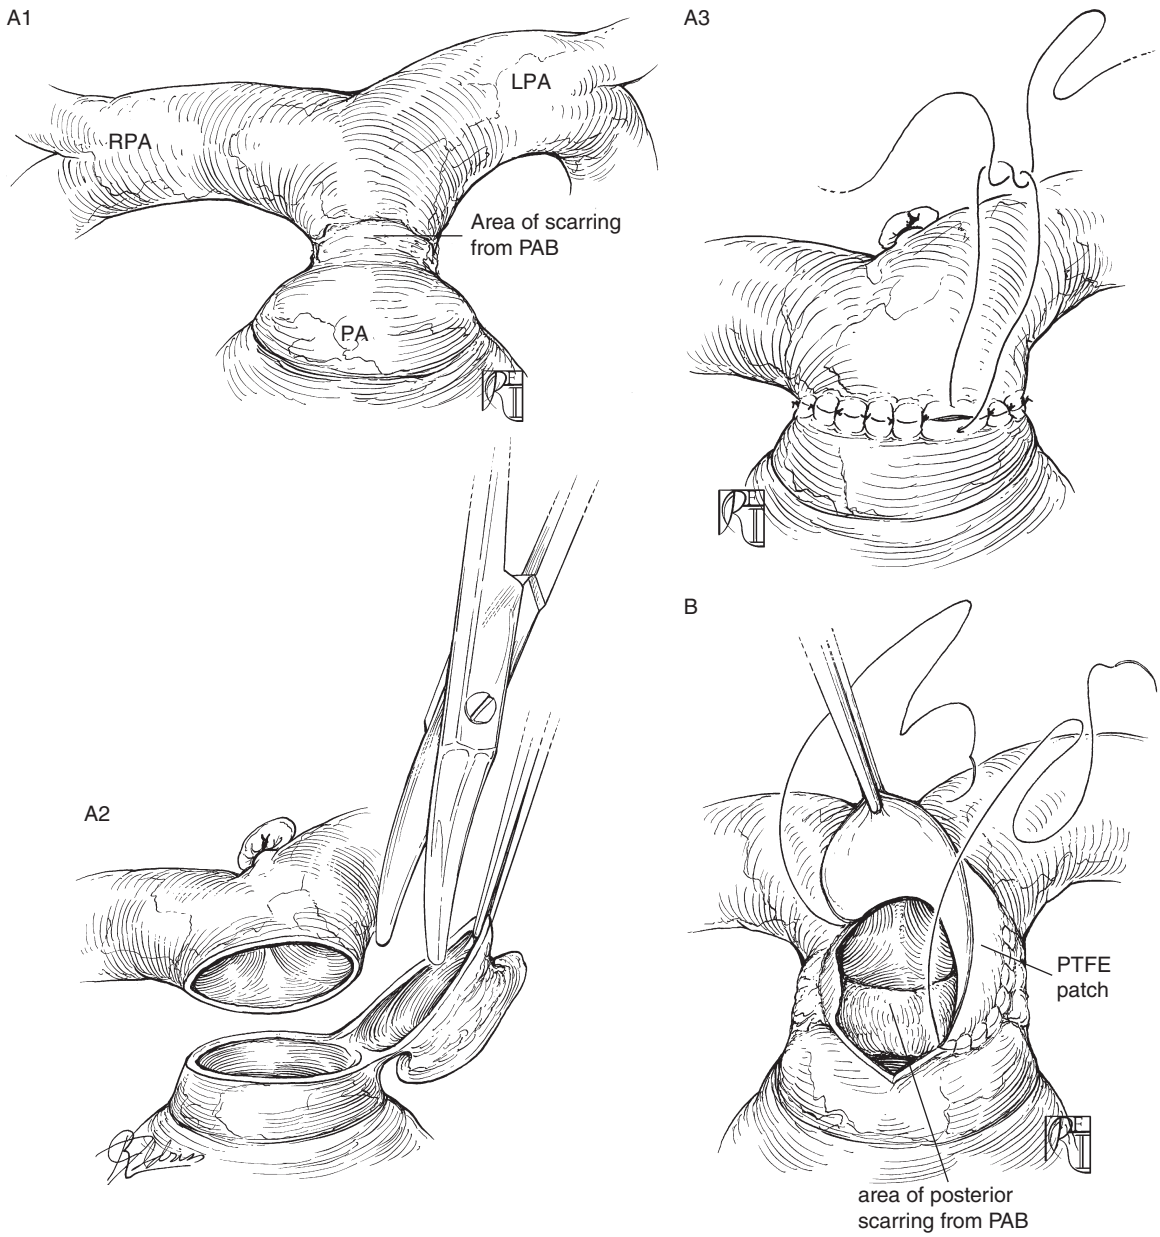

Figure 9.2 Takedown of a pulmonary artery band. **A,** Pulmonary artery transection, removal of the band site, and end-to-end reconstruction with interrupted absorbable suture. **B,** Takedown of a pulmonary artery band with anterior polytetrafluoroethylene (PTFE) patch placement. (LPA, RPA, left, right pulmonary artery; PA, pulmonary artery; PAB, pulmonary artery band.)

formed between the two remaining pulmonary arterial segments with interrupted, absorbable, fine monofilament suture. The distal right and left pulmonary arteries must be completely mobilized and the ligamentum arteriosum ligated and divided to provide a tension-free anastomosis. The patch technique is illustrated in Figure 9.2B [20]. A patch of either pericardium or PTFE is used to augment the pulmonary artery anteriorly over the posteriorly scarred area and allow flow into the right and left pulmonary arteries without hemodynamic obstruction to flow. This sometimes requires use of a "pantaloon" patch with extension into the right and left anterior sinuses of Valsalva. Although most surgeons have preferred to use a patch anteriorly, this usually still results in a mild main pulmonary artery stenosis and residual murmur. The use of transection of the site of the band and direct end-to-end anastomosis in most cases results in no gradient and no residual murmur. As mentioned previously, use of the newer adjustable bands may help prevent the need for pulmonary artery construction [22].

Aortopulmonary Shunts

Classic Blalock–Taussig Shunt

The Blalock–Taussig shunt was the first aortopulmonary shunt and was performed in 1944 by Alfred Blalock of the Johns Hopkins University Medical Center [2]. The classic Blalock–Taussig shunt is a direct end-to-side anastomosis of the transected subclavian artery to the pulmonary artery. Blalock had successfully created a left subclavian-to-pulmonary artery anastomosis while developing a canine model of pulmonary hypertension at Vanderbilt University. Helen Taussig suggested to Blalock that he apply his experimental procedure to patients who had cyanosis from insufficient pulmonary blood flow. The first operation was performed on 28 November 1944, on a 15-month-old girl with the diagnosis of tetralogy of Fallot and severe pulmonary stenosis. After that first successful case, hundreds of cyanotic children went to Baltimore for "the operation." In fact, between 1944 and 2006, 2016 patients had a Blalock–Taussig shunt at Johns Hopkins Medical Center [26].

The classic Blalock–Taussig shunt was typically constructed through a thoracotomy approach on the side opposite the aortic arch. When there is a left aortic arch, there is typically a right innominate artery, and using the subclavian artery on this side provides a gentle curve to the pulmonary artery. With a right aortic arch and mirror-image branching, the left innominate artery provides a similar gentle curve to the pulmonary artery. In contrast, the contralateral subclavian artery would require an angulation of the artery of nearly 180 degrees for the anastomosis. Figure 9.3 [20] illustrates the anatomy for exposure of the right subclavian and pulmonary arteries through a right thoracotomy. The branches of the right subclavian artery are ligated and divided along with the distal subclavian artery, and the subclavian artery is pulled through the loop formed by the right recurrent laryngeal nerve. The carotid artery is dissected out to provide more mobility. The azygos vein is doubly ligated and divided. The anastomosis is constructed to the main pulmonary artery with vascular clamps after 1 mg/kg of heparin is given intravenously. Care is taken to avoid the complication of performing the anastomosis to the right upper lobe branch. The subclavian artery will then lie in a groove just posterior to the superior vena cava and the phrenic nerve.

The classic Blalock–Taussig shunt does not require prosthetic material and provides a precise amount of pulmonary blood flow limited by the orifice of the subclavian artery. In addition, the shunt grows with the patient, providing more pulmonary blood flow as the child grows. However, the Blalock–Taussig shunt sacrifices the subclavian artery, which in a small number of cases can result in hand or arm ischemia [27]. The affected arm is usually shorter than the contralateral arm, is often somewhat cool to the touch, and will not have a palpable pulse. In addition, even with ample mobilization of the carotid artery and division of the inferior pulmonary ligament, the subclavian artery may still be so short as to cause the pulmonary artery to be "pulled" up and kink. Takedown of the classic right Blalock–Taussig shunt at the time of complete correction through a median sternotomy involves dissection posterior to the superior vena cava. The artery can then be encircled and double ligation performed. Because of the multiple disadvantages of the classic Blalock–Taussig shunt, we currently recommend the modified Blalock–Taussig shunt.

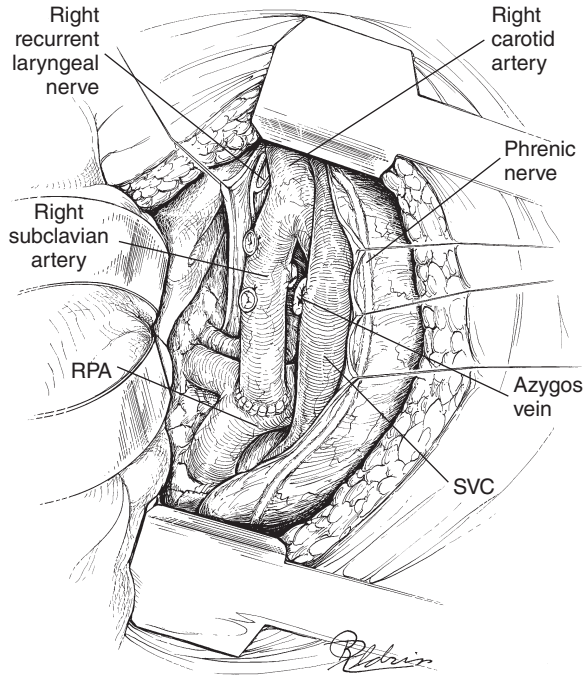

Figure 9.3 Classic Blalock–Taussig shunt (right thoracotomy). (RPA, right pulmonary artery; SVC, superior vena cava.)

Modified Blalock–Taussig Shunt

The use of a PTFE tube for an aortopulmonary shunt was first reported by Gazzaniga and associates in 1976 [28]. Three infants with pulmonary atresia underwent aorta-to-pulmonary artery shunt using an interposed 4-mm PTFE tube. DeLeval [29] coined the term modified Blalock–Taussig shunt when he reported on 99 patients operated on between 1975 and 1979 having a prosthesis of Dacron (13) or PTFE (86) interposed between the subclavian and pulmonary arteries. Shunt failure rate was 6%, and operative mortality was 8%. The advantages of the modified Blalock–Taussig shunt, which has now become the shunt of choice at most congenital heart surgery centers [30], include 1)

preservation of the circulation to the affected arm; 2) regulation of the shunt flow by the size of the systemic (subclavian or innominate) artery; 3) high early patency rate with expanded PTFE arterial prosthesis (Gore-Tex, W.L. Gore & Associates, Inc., Flagstaff, AZ); 4) guarantee of adequate shunt length; and 5) ease of shunt takedown. One disadvantage of the modified Blalock–Taussig shunt is the occasional leaking of serous fluid through the interstices of the fabric of the PTFE. This may result in excessive and prolonged chest tube drainage, localized seroma formation around the graft, or both [31]. This complication occurs in 3–5% of patients.

The modified Blalock–Taussig shunt can be performed through a right or left thoracotomy or a median sternotomy. The approach depends on the subclavian and pulmonary artery anatomy, the presence and location of a ductus arteriosus, the great vessel relationship, and surgeon preference. In the past several years, there has been a distinct trend toward performing the modified Blalock–Taussig shunt through a median sternotomy. This has been our approach of choice for the past 10 years. The sternotomy approach is technically less challenging and is associated with fewer shunt failures than the classic thoracotomy approach [32,33]. If necessary, the shunt can be performed with the use of cardiopulmonary bypass if the child has significant oxygen desaturation during the procedure. With a median sternotomy approach the side of the aortic arch is not a concern. The shunt can be placed to the main pulmonary artery if necessary. Access to the patent ductus arteriosus for ligation to remove a source of competitive flow is always possible. The potential theoretical disadvantage of increased adhesions at the time of sternal re-entry has not really been an issue [32].

For a thoracotomy approach, the latissimus dorsi muscle is divided; the serratus anterior is mobilized and spared. The thorax is entered through the fourth interspace. The lung is retracted anteriorly and inferiorly. The mediastinal pleura is opened posterior to the superior vena cava and phrenic nerve. The azygos vein is doubly ligated and divided. The subclavian artery is encircled with a vessel loop, with care being taken to avoid the right recurrent laryngeal nerve, which passes around the distal innominate artery at the takeoff of the subclavian and common carotid arteries. The right pulmonary artery is dissected free, with care being taken to identify the right upper lobe branch and main pulmonary artery continuation to the right lower and middle lobes. The right upper lobe and distal right pulmonary artery branches are encircled with vessel loops, which can then be occluded with small Rummel tourniquets. The patient is administered 1 mg/kg heparin intravenously.

The size of the PTFE graft selected is based on the size of the patient. Earlier series frequently used a 5-mm shunt. If the shunt is taken from the subclavian artery, this will regulate the flow. However, if the shunt is from the innominate artery (which frequently is the case with a median sternotomy approach), consideration must be given to using a smaller shunt as then the shunt size will regulate the flow. We generally use a 4-mm graft for (3.5–5.0 kg) infants, and a 3.5-mm graft for babies weighing less than 3.5 kg. We have downsized the shunts because most of these children go on to complete repair at 6–9 months of age and the shunt flow is adequate and not excessive (even if the shunt comes from the innominate artery). The PTFE is cut to size before the clamps are placed; the clamps distort the relative distance between the subclavian and pulmonary arteries. The graft is usually cut to give it a gentle curve, which allows for patient growth. It should not kink or distort the pulmonary artery, which can easily happen if the length is not accurate. We prefer the "stretch" PTFE that is more forgiving vis-à-vis length estimates. The PTFE graft is beveled as illustrated in Figure 9.4A [20], and an arteriotomy is created in the inferior aspect of the subclavian artery after placement of a vascular clamp. The PTFE graft is anastomosed to the opening in the subclavian artery with 7-0 polypropylene suture (Figure 9.4B) [20]. The clamp on the subclavian artery is left in place until the pulmonary artery anastomosis is completed. Repositioning the clamp to the PTFE graft may increase the risk of blood stasis and shunt thrombosis. The pulmonary artery is controlled with another vascular clamp. Rummel tourniquets are snugged on the right upper and lower distal pulmonary arteries. A longitudinal arteriotomy is created in the superior aspect of the right pulmonary artery. Using a single 7-0 polypropylene suture, the PTFE graft is anastomosed to the pulmonary artery (Figure 9.4C) [20].

When the clamps are released and flow established through the shunt, there should be a nearly instantaneous rise of approximately 15–20% in the patient's oxygen saturation as monitored by pulse oximetry. A thrill should be palpable in the shunt and in the distal pulmonary artery. It is important to maintain adequate systemic perfusion pressure before, during, and after the operation to prevent early shunt thrombosis. This may require the use of inotropic support (dopamine, epinephrine). Bleeding is controlled with Gelfoam soaked with topical thrombin. The heparin is not routinely reversed with protamine unless there is excessive bleeding from the suture lines. The graft should lie in a groove posterior to the superior vena cava, where it is accessible at the time of takedown. We routinely sedate and ventilate the child for the first 24 hours postoperatively. We also routinely give an aspirin suppository (10 mg/kg) in the operating room when the shunt is completed and then 10 mg/kg PO daily until shunt takedown [34]. The Boston Children's group [33] reported 104 patients who underwent placement of a modified Blalock–Taussig shunt. The chosen approach was thoracotomy in 52 patients, and median sternotomy in 52. There were ten shunt failures

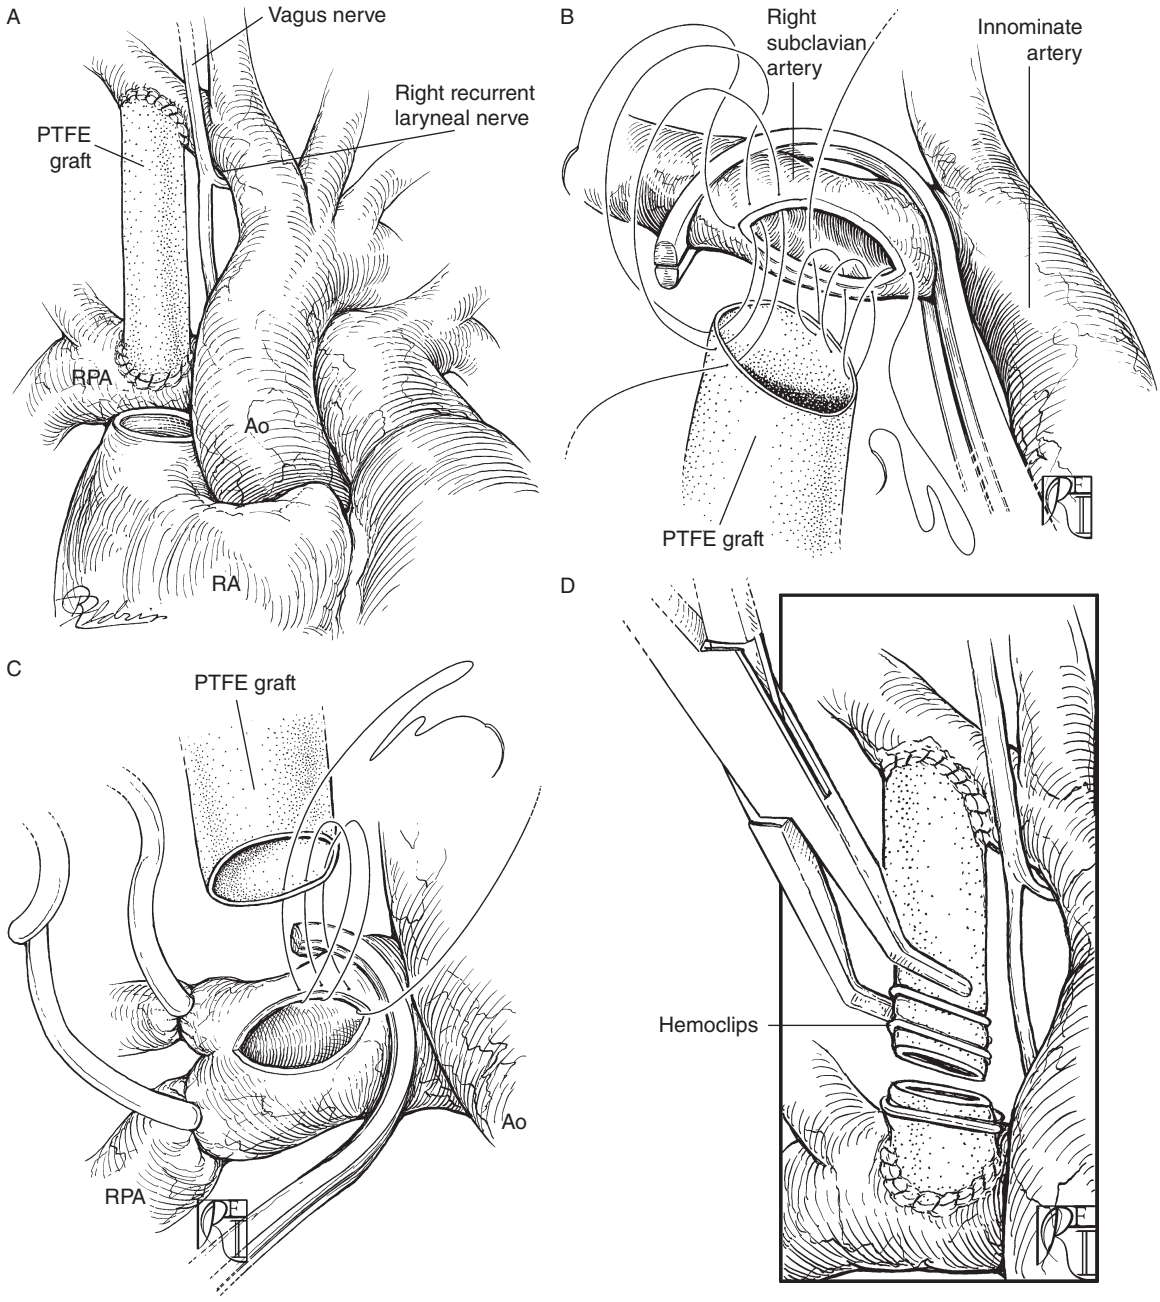

Figure 9.4 A, Modified Blalock–Taussig shunt using a polytetrafluoroethylene (PTFE) graft. Details of (**B**) proximal and (**C**) distal anastomosis for modified Blalock–Taussig shunt. **D,** Takedown of a modified Blalock–Taussig shunt with hemoclips and shunt division. (Ao, aorta; PTFE, polytetrafluoroethylene; RA, right atrium; RPA, right pulmonary artery.)

and three deaths in the thoracotomy group and four shunt failures and six deaths in the sternotomy group. They concluded that the median sternotomy approach was preferable. Alkhulaifi and colleagues [35] recently reported 79 neonates who had undergone modified Blalock–Taussig shunt placement. The shunts were placed via a right thoracotomy in 36 patients, through a left thoracotomy in six, and through a median sternotomy in 33 patients. Indications for a shunt were pulmonary atresia with intact ventricular septum, pulmonary atresia with ventricular septal defect, severe tetralogy of Fallot, double-outlet right ventricle with pulmonary stenosis, transposition of the great arteries with pulmonary stenosis, and single-ventricle equivalent. Hospital mortality was 4% and there were seven shunt-

related complications. Jahangiri and co-workers [36] reported 140 patients who had tetralogy of Fallot and had undergone a modified Blalock–Taussig shunt. All were done via thoracotomy. There were no hospital deaths and there was equal growth of the right and left pulmonary arteries, regardless of shunt location.

The takedown of a modified Blalock–Taussig shunt at the time of intracardiac repair through a median sternotomy is quite easily performed, particularly if the shunt was placed on the right side (Figure 9.4D) [20]. The shunt can be identified by dissecting the medial aspect of the superior vena cava posteriorly. Locating a shunt on the left side is more difficult, but it can be identified either by dissecting along the left pulmonary artery, along the aorta to the shunt, or by entering the pleural space and approaching the shunt laterally. A word of caution: the left-sided modified Blalock–Taussig shunt is often very close to the left phrenic nerve. The dissection will first encounter a thick fibrous "peel," which typically forms around the PTFE graft. Once the plane between the "peel" and the PTFE graft is entered, the dissection proceeds relatively quickly and enough graft length can be achieved for double hemoclip application proximally and single hemoclip distally. The graft should be divided between the hemoclips to prevent distortion of either the subclavian artery or the pulmonary artery as the patient grows and the distance between these two vessels naturally increases. No attempt is made to remove the proximal portion of the graft. In some patients the distal graft will require removal in order to facilitate performing a bidirectional Glenn anastomosis. However, if the operation involves repair at the site of the main pulmonary artery, the distal graft can be left in place and typically does not cause a residual peripheral pulmonary artery stenosis. Another word of caution regarding the takedown of these shunts. Preparation for cardiopulmonary bypass should be made prior to dissecting the shunt. For example, the aorta and right atrium should be accessible for cardiopulmonary bypass with purse strings placed and the pump primed. Sometimes dissection near the shunt dislodges the neointima causing acute desaturation, retrievable only by rapidly initiating cardiopulmonary bypass.

Waterston/Cooley Shunt

In 1962, David Waterston reported an aortopulmonary shunt that was an anastomosis between the posterior aspect of the ascending aorta and the anterior right pulmonary artery [37]. This procedure was performed through a right thoracotomy with the anastomosis posterior to the superior vena cava. Denton Cooley [38] reported the same technical shunt (right thoracotomy) but performed it in an intrapericardial fashion anterior to the superior vena cava. This shunt was initially widely used because of its ease of construction, preservation of the subclavian artery, and lack of need for prosthetic material. However, because of the significant right pulmonary artery distortion it creates, the distinct possibilities of excessive or inadequate pulmonary blood flow, and the success of the modified Blalock–Taussig shunt, it is rarely applied in the current era.

The technique for construction of a Waterston/Cooley shunt through a right thoracotomy is shown in Figure 9.5

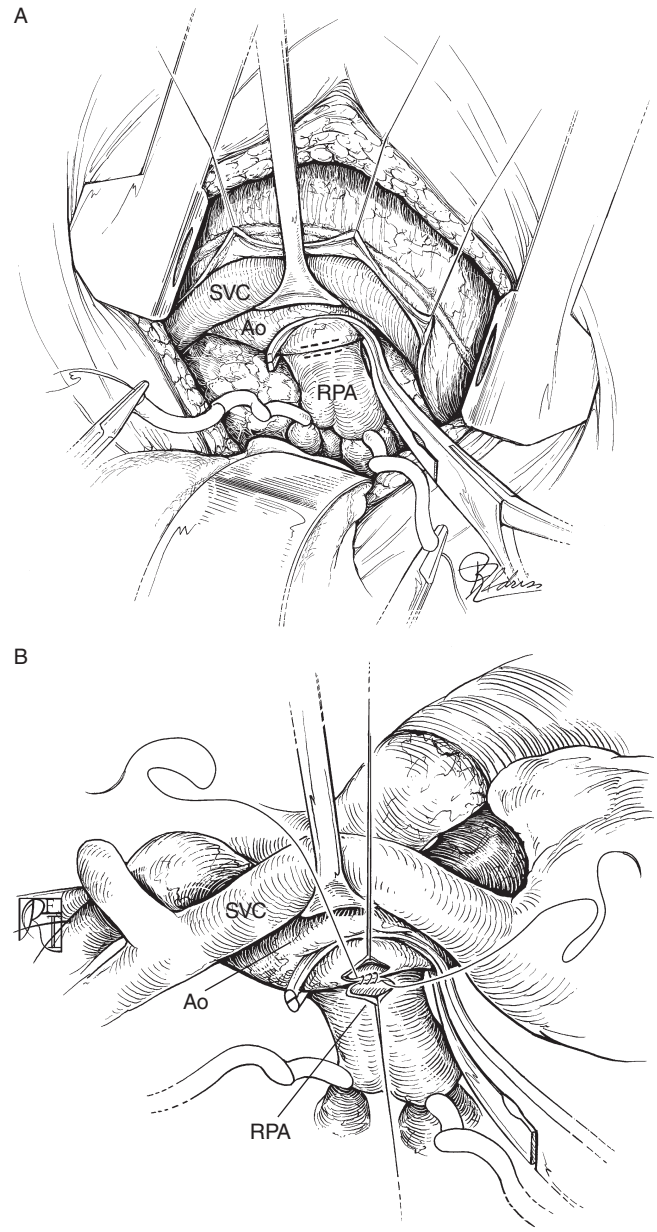

Figure 9.5 Waterston shunt. **A,** Clamps and Rummel tourniquets in place. **B,** Aorta-to-pulmonary artery anastomosis. (Ao, aorta; RPA, right pulmonary artery; SVC, superior vena cava.)

[20]. After mobilizing the right pulmonary artery, the distal pulmonary artery branches can be controlled with small Rummel tourniquets. Proximally, a Castaneda clamp is used to occlude both a portion of the ascending aorta and the entire right pulmonary artery. The aorta is rotated slightly anteriorly with a forceps so that a posterior rather than lateral portion of its wall is exteriorized by the clamp for the anastomosis. As illustrated in Figure 9.5 [20], matching incisions are made in the posterior aorta and anterior pulmonary artery. These incisions are between 3 mm and 4 mm in length, depending on the size of the patient. An anastomosis is then created with running polypropylene suture. The tourniquets are released and the clamp removed, and the oxygen saturation should increase appropriately.

A significant problem with the Waterston/Cooley shunt is that it is not as controlled a shunt as either the classic or modified Blalock–Taussig shunts. If the incisions in the aorta and pulmonary artery are too long and the anastomosis is too large, there will be excessive pulmonary blood flow with a risk of pulmonary vascular disease. If the incisions are too short and the opening is too small, there will be inadequate pulmonary blood flow and the patient will remain cyanotic. Another problem with the Waterston anastomosis is that as the patient grows and the aorta rotates, the anastomosis applies traction to the right pulmonary artery and kinks and distorts the right pulmonary artery. This may cause preferential flow to one lung and significant right pulmonary artery stenosis [39]. For this reason, almost all patients who have takedown of a Waterston shunt will require a major reconstruction of the right pulmonary artery.

The Waterston shunt is taken down at the time of intracardiac correction of the primary cardiac lesion through a median sternotomy (Figure 9.6) [20]. It is important to dissect the pulmonary arteries prior to cardiopulmonary bypass in order to occlude the pulmonary arteries on initiation of cardiopulmonary bypass to prevent pulmonary runoff with inadequate systemic perfusion. The repair is done with the patient on cardiopulmonary bypass with the aorta cross-clamped distal to the shunt. After cardioplegic solution has been administered (occluding the pulmonary arteries to prevent cardioplegic solution runoff), the aorta is separated from the right pulmonary artery with an incision made along the original anastomotic line. Typically, the aorta in these patients is large, and the opening in the aorta can be closed primarily with running suture. A PTFE or pericardial patch is then used to patch open the area of the right pulmonary artery where stenosis is usually created by the shunt. Another approach to the Waterston shunt at the time of takedown (originally described by Cooley) is to open the aorta anteriorly after the cross-clamp has been applied and close the opening from within the aorta itself. The aorta can also be completely transected to provide better exposure of the right pulmonary artery [40].

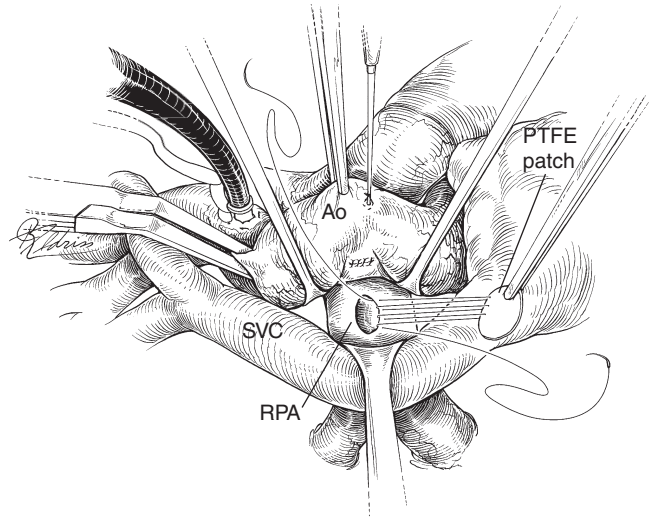

Figure 9.6 Takedown of a Waterston shunt with cardiopulmonary bypass and aortic cross-clamp, using a polytetrafluoroethylene (PTFE) patch to open the right pulmonary artery. The aortic opening has been closed primarily with a running suture. (Ao, aorta; RPA, right pulmonary artery; SVC, superior vena cava.)

The Waterston shunt has fallen out of favor because of the previously mentioned disadvantages and has been replaced in most centers by the modified Blalock–Taussig shunt. However, there are still a number of patients who have had this shunt who will require eventual takedown as described.

Potts Shunt

The Potts shunt (Figure 9.7) [20] is an anastomosis between the descending thoracic aorta and the left pulmonary artery performed through a left thoracotomy. It was first reported by Willis J Potts from Children's Memorial Hospital in Chicago [41]. This operation was first performed on 13 September 1946. The child was 21 months of age and weighed 8.3 kg. She had been cyanotic since 3 months after birth and had multiple hypercyanotic spells. She was intensely cyanotic and had severe clubbing. The Potts shunt was performed using a special clamp developed by Potts that only partially occluded the descending thoracic aorta to decrease the risk of paraplegia [42]. The proximal and distal left pulmonary artery were occluded. The anastomosis was performed between parallel 4-mm incisions made in the descending thoracic aorta and the posterior left main pulmonary artery. The completed shunt is shown in Figure 9.7A [20].

The Potts anastomosis was widely used at Children's Memorial Hospital; between 1946 and 1967, 659 such shunts were performed. The Potts shunt was technically easier than the classic Blalock–Taussig shunt and it pre-

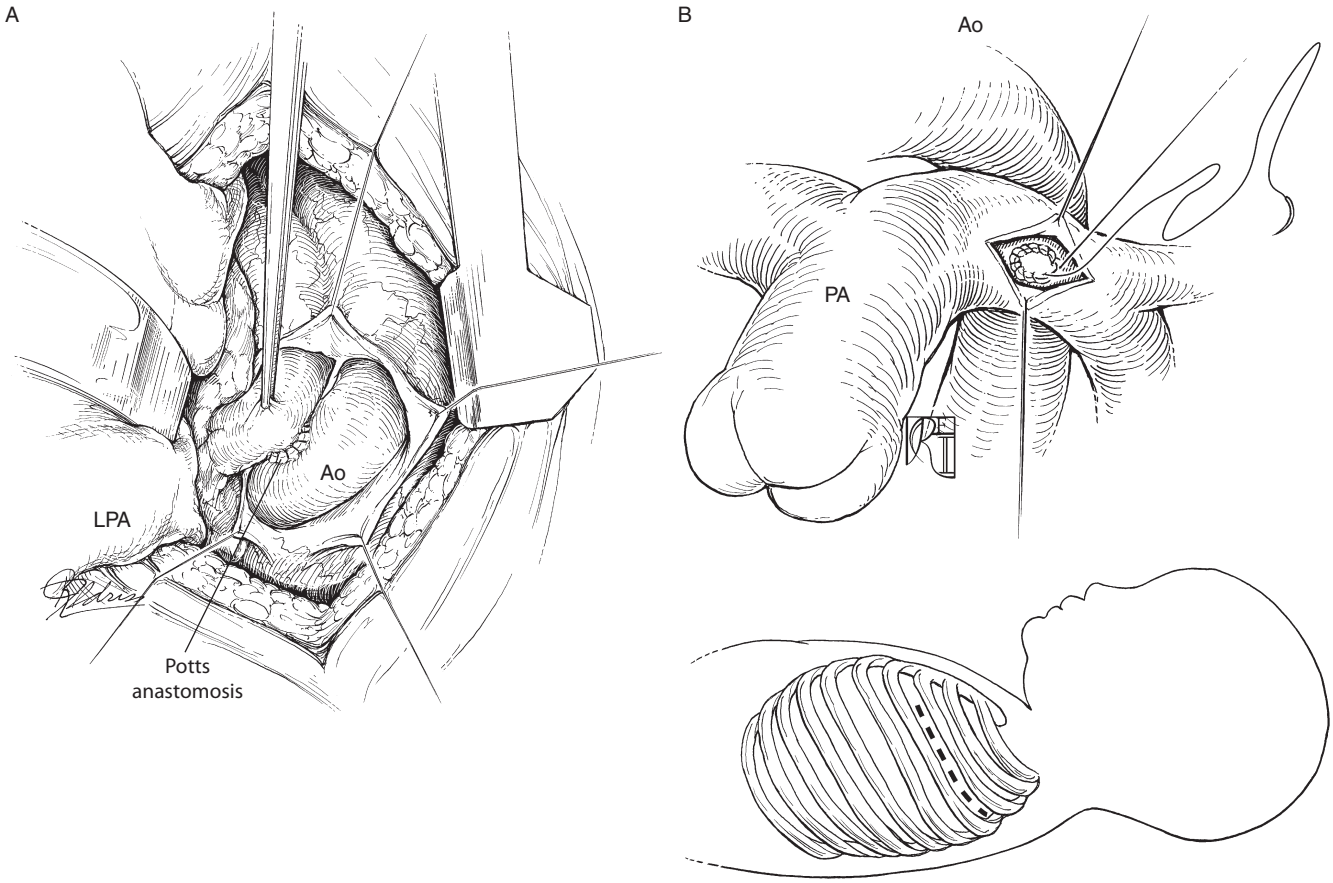

Figure 9.7 Potts shunts. **A,** Left thoracotomy showing spatial relationship of aorta to left pulmonary artery and completed anastomosis. Inset, Left thoracotomy. **B,** Takedown of a Potts anastomosis with placement of a polytetrafluoroethylene (PTFE) patch in the left pulmonary artery under circulatory arrest. (Ao, aorta; LPA, left pulmonary artery; PA, pulmonary artery.)

served the left subclavian artery. However, there were several serious complications that led to the abandonment of the Potts shunt. Many children developed large aneurysms of the left pulmonary artery that were very difficult to repair (Figure 9.8) [43]. Another complication was that the Potts shunt could be either too small and the patient remained cyanotic, or it was too large and caused congestive heart failure. The Potts shunt could not be used with a right arch (even with a right thoracotomy) because the right bronchus lies between the pulmonary artery and the aorta. The final and most significant problem with the Potts shunt was the difficulty in taking down the shunt at the time of complete correction of the intracardiac lesion [44]. Initial attempts at simply ligating the shunt resulted in uncontrollable hemorrhage in the operating room or in the immediate postoperative period. If the shunt was taken down with cardiopulmonary bypass and circulatory arrest, there was a risk of stroke from air embolism if the brachiocephalic vessels were not controlled. The preferred technique now is to use deep hypothermia and circulatory arrest, with adequate precautions taken to avoid air embolism to the cerebral circulation with the descending thoracic aorta opened. After cardiopulmonary bypass is initiated through a median sternotomy, the aortic–pulmonary anastomosis is digitally occluded with a finger from outside the pulmonary artery to limit the left-to-right shunt and improve the efficiency of cooling. The brachiocephalic vessels are encircled with vessel loops. The aorta is cross-clamped and the heart arrested with cardioplegic perfusion. The brachiocephalic vessels are snared, and circulatory arrest is commenced once the target temperature (18 °C) is reached. Only then can the left pulmonary artery be safely opened. Under circulatory arrest, the communication between the pulmonary artery and the aorta can be visualized and closed with a PTFE patch (Figure 9.7B) [20]. All air is evacuated from the ascending aorta before the snares are released to the brachiocephalic vessels in order to prevent cerebral air embolism.

Because of the complications of left pulmonary artery aneurysm, frequent excessive pulmonary blood flow with resultant pulmonary hypertension, and the difficulties in taking down the Potts shunt, this procedure is essentially

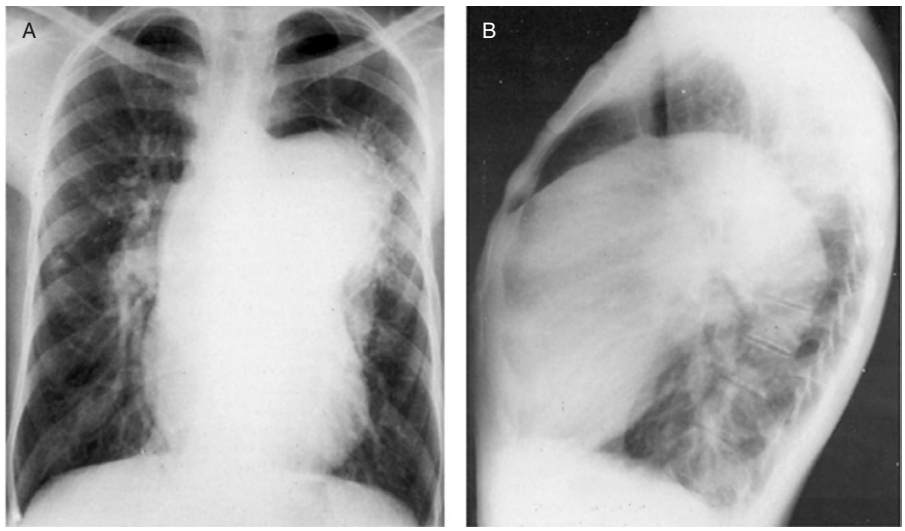

Figure 9.8 Chest radiographs (posteroanterior and lateral) of a 23-year-old patient with tetralogy of Fallot 16 years after a Potts (descending aorta-to-pulmonary artery) anastomosis. The left pulmonary artery aneurysm projects from the mediastinum into the left chest (**A**) and fills the anterior compartment (**B**). (Reproduced with permission from de Hoyos *et al.* [43].)

no longer performed at congenital heart surgery centers. This has been true for many years, and there are very few patients alive with an intact Potts shunt.

Miscellaneous Palliative Procedures

A palliative procedure performed to improve mixing of blood at the atrial level in patients with transposition of the great arteries or single ventricle with atrioventricular valve stenosis/atresia is the atrial septectomy. The Blalock–Hanlon atrial septectomy was first performed in 1950 and was done through a right thoracotomy [5]. A portion of the right and left atria are occluded with a single clamp, occluding also the right pulmonary veins. The right atrium is then opened within the confines dictated by the clamp, and a portion of intra-atrial septum is grasped, pulled up, and excised from within the clamp. The clamp is then repositioned so that the atrial septum falls back into the atrial cavity and the clamp is only holding the cut edges of the atrium, and the atrial suture line is closed. This procedure is generally no longer performed, and most patients now who require an atrial septal defect undergo Rashkind balloon septostomy [6]. The Rashkind septostomy is typically performed in an infant with transposition of the great arteries and intact ventricular septum. A balloon-tipped catheter is passed up the femoral vein across the patent foramen ovale and into the left atrium. The balloon is initially inflated in the left atrium and then rapidly pulled across the septum into the right atrium, tearing the atrial septum. For patients with a thick atrial septum that is recalcitrant to Rashkind balloon septostomy, open atrial septectomy with cardiopulmonary bypass is the safest procedure. The atrial septectomy can be performed either during a short period of aortic cross-clamping or with induced electrical fibrillation of the heart. The entire atrial septum within the fossa ovalis can be excised, with the surgeon taking care to avoid injury to the atrioventricular node or cutting outside the heart. Rashkind balloon septostomy in the cardiac catheterization laboratory now is the preferred approach for most cases.

Some patients with complex cyanotic congenital heart disease and suboptimal anatomy for complete correction undergo a Glenn operation (which is discussed in Chapters 28 and 31) or a Mustard procedure (Chapter 26) for palliation of their cyanotic heart disease. Ceresnak has described a palliative arterial switch procedure [45]. These patients will have an elevation in their oxygen saturations after these palliative procedures, but are not completely corrected. Other procedures that could be considered palliative procedures, that is, pulmonary and aortic valvotomy, modified Norwood, and bidirectional Glenn, are covered in other chapters. The hybrid procedure is probably the most notable recent "palliative" procedure and employs bilateral pulmonary artery bands and a ductal stent placed with transcatheter techniques in a "hybrid lab." This is discussed further in Chapter 31, *Hypoplastic Left Heart Syndrome*.

Conclusion

The primary palliative operations for children with congenital heart disease are aortopulmonary shunts and the

pulmonary artery band. The aortopulmonary shunt of choice currently is the modified Blalock–Taussig shunt performed with a sternotomy approach. This provides a controlled source of pulmonary blood flow, does not sacrifice the subclavian artery, and is quite easy to take down at the time of intracardiac repair. Pulmonary artery banding is selected for very few patients now, but is still indicated for patients with Swiss-cheese muscular ventricular septal defects, for some infants with single ventricle and increased pulmonary blood flow, and to prepare the left ventricle in select patients. Advances in percutaneously adjustable bands has improved outcomes in these patients. Hybrid techniques have also led to a resurgent interest in pulmonary artery band techniques. Surgeons need to be aware of the Waterston/Cooley and Potts anastomosis, the associated complications, and the techniques required to safely take these shunts down at the time of complete repair.

History

In the early part of the twentieth century, at a time when technology did not exist to operate inside the heart, morbidity and mortality remained extremely high for children born with congenital heart defects such as atrial (ASD) and ventricular (VSD) septal defects. By 1950 surgeons were successfully operating on patients with patent ductus arteriosus and aortic coarctation. Battlefield experience from World War II, with descriptions of successful removal of intracardiac foreign bodies [1], as well as early experimentation with hypothermia, as described by Bigelow and colleagues in 1950, set the stage for technology to pump oxygenated blood to artificially support a patient whilst a surgeon delved into the heart to repair complex congenital malformations. Although a group led by F. John Lewis [2] successfully closed an ASD using deep hypothermic arrest in 1951 and Gross and Watkins [3] described an atrial well technique in 1953, other groups began to use early forms of cardiopulmonary bypass (CPB) apparatus. The initial pump was devised by DeBakey in 1934 and was a hand-driven roller type pump. The initial systems incorporated this pump with oxygenation via either bubble or film oxygenators. Early attempts from 1951 to 1954 were commonly failures, with 18 patients described by various groups and with only one survival. The first successful human intracardiac operation was performed by J.H. Gibbon on 18 May 1953. Although this first patient in his series did survive, he went on to record five deaths resulting in his abandonment of the technique [4]. Failures were attributable to incorrect preoperative diagnoses, ventricular dysfunction at termination of bypass, hypovolemia, surgical errors, and ventricular failure within the convalescence period (Table 10.1) [4–10].

Whilst efforts continued to develop a feasible technique for CPB, Lillehei and colleagues described controlled cross circulation, with the initial procedure in humans being performed in early 1954 [11]. In this technique Lillehei used another human, usually the patient's parent, as a pump/oxygenator. The "donor's" femoral vessels were cannulated, and oxygenated blood was pumped into the patient allowing the surgical team to perform intracardiac surgeries [11]. His initial series recorded 18 deaths in 45 patients. Mortality was attributed to pulmonary complications including atelectasis, pneumonitis, and underappreciated pulmonary vascular changes; incorrect diagnoses; and surgical complications. Although there was no donor mortality, there was morbidity from air embolism from a large-bore peripheral intravenous (IV) line and marked decrease in venous return through the exchange pump. The mortality rate of 40% was clearly still extremely high, but was nevertheless a great improvement from the almost 100% mortality of early CPB cases. Indeed some commentators suggested that further research into a bypass machine be abandoned [12]. Approximately 1 year later, in May 1955, Kirklin and colleagues at the Mayo Clinic described a series of eight patients (five with VSDs, two with atrioventricular canal defects and one with tetralogy of Fallot) who were operated on using a CPB machine similar to that previously used by Gibbon. In contrast to earlier series, this series had a 50% survival. This was attributable to a better understanding of the patient's pathology, improved diagnostic testing, and a perioperative team including physiologists, pathologists, anesthesiologists, and surgeons. In the conclusion of his landmark paper Kirklin declared, "Use of this system established excellent conditions for precise, unhurried intracardiac surgery" [13]. The modern age of cardiac surgery had begun.

The Gibbons bypass machine incorporated three DeBakey pumps and a screen type oxygenator [14] instead of the film type oxygenator used in his original animal experiments, as the film type would not support oxygenation in an animal larger than a cat. By the mid to late 1950s three types of oxygenators were in clinical use: 1) The Mayo–Gibbon pump oxygenator, although commercially available, was cumbersome, difficult to clean, and required a large prime volume; 2) the Kay-Cross disc oxygenator, which was also cumbersome despite the introduction of simpler commercial versions, was favored by many clinicians due to the perception that it caused less blood component trauma, particularly in longer procedures; and 3) the DeWall-Lillehei bubble oxygenator, which began clinical use in 1955 by Lillehei, gained widespread popularity, and by 1976 was being used in an estimated 90% of cardiac surgeries [15]. The advantage of this oxygenator was that it used a small volume prime, negating the need for donor blood, and, importantly, was disposable. The disadvantage, however, was that blood constituent trauma occurred, particularly with lengthy procedures.

Although conceptualized in the mid 1940s, membrane oxygenation only came into vogue in the late 1970s to early 1980s. The most important factor for this was that early materials were unsuitable with respect to permeability, strength, and how thinly they could be manufactured without defect allowing for blood-surface interaction. With the advent of microporous, hollow-fiber membranes, clinical usage began to shift toward membrane oxygenators. These oxygenators were made of bundles of hollow fibers within a hard plastic shell. They had a large surface area-to-volume ratio and were thus extremely efficient at gas exchange. Because of other advantages, such as being easy to produce in large numbers as well as in different sizes with noncompliant blood/gas compartments, they were well suited to pediatric cardiac surgery.

Thus the stage was set by the early 1980s for surgeons to successfully attempt to palliate and cure complex congenital cardiac disease. Looking forward, the question of functional survival into mid life, neurological outcomes, and such technical questions as blood conservation, further decreasing the inflammatory response to bypass, and circuit miniaturization will come to the forefront of research.

Cardiopulmonary Bypass in Infants versus Adults

Summarized in Table 10.2 are many of the important differences that occur in the management of the very young for CPB as compared with the adult patient [16]. The most important of these are the routine use of hypothermia with or without circulatory arrest, the use of low perfusion pressures, and, of great clinical importance, marked hemodilution. Thus pediatric patients will be exposed to the extremes of physiologic tolerance. These factors coupled with immature organ systems place pediatric patients at great risk during the period of CPB. In addition to the aforementioned factors that can be directly compared between the two age groups, there are additional issues that further complicate the management strategy (Table 10.3) [6].

From the surgical perspective, several technical challenges exist including placement of both venous and arterial cannulae (with their potential effect on hemodynamics); the effect of collateral vessels on both blood return to the heart (making visibility a challenge) and the phenomenon of stealing blood from vital organs (making organ preservation difficult) [17]; coronary anomalies (which accompany many of the congenital lesions); and multiple suture lines in patients with multifactorial coagulopathy.

Physiology of Cardiopulmonary Bypass

The safe conduct of CPB in the neonate and infant requires a comprehensive understanding of the physiologic associations that occur. These variables include circuit design, hemodilution, choice of cannulae, degree of hypothermia, acid–base strategies, and flow rates, which include the decision to use deep hypothermic circulatory arrest.

Hypothermia

The rationale for the use of hypothermia during CPB is myocardial and other vital organ protection. To this end

Table 10.2 Differences between adult and pediatric cardiopulmonary bypass. (Reproduced with permission from Dinardo [16].)

Parameter	Adult	Pediatrics
Hypothermic temperature	Rarely <25–32 °C	Commonly 15–20 °C
Circulatory arrest	Uncommon	Common
Pump prime		
Dilutional effect on blood volume	25–33%	200–300%
Additional additives	Blood, albumin	
Perfusion pressure	50–80 mmHg	20–50 mmHg
Influence of pH management	Minimal at moderate hypothermia	Marked at deep hypothermia
Measured $PaCO_2$ differences	30–45 mmHg	20–80 mmHg
Glucose regulation		
Hypoglycemia	Rare – requires liver injury	Common – ↓ glycogen stores
Hyperglycemia	Frequent – insulin bolus or infusion	Less common – rebound ↓↓ glucose

Table 10.3 Unique pediatric characteristics.

Smaller circulating blood volume
Higher oxygen consumption
Reactive pulmonary vascular bed
Intra- and extracardiac shunting
Altered thermoregulation
Poor tolerance for microemboli

three distinct methods are used: moderate hypothermia (25–32 °C), deep hypothermia (18–20 °C), and deep hypothermic circulatory arrest (DHCA) where circulation is shut down completely at 16–18 °C. There has been increasing interest in the use of normothermic CPB. Normothermia and moderate hypothermia are used on cases where the surgeon is able to safely cannulate both vena cavae to operate within the heart. This of course can be done even on the smallest of patients, bearing in mind that the cannulae may cause vena caval obstruction and impaired drainage that can adversely effect both the cerebral and abdominal perfusion independent of perfusion pressure. Deep hypothermia with reduced pump flow to as low as 25–50 mL/kg/min will allow the surgeon to perform corrective surgeries with only minimal return of blood to the surgical field whilst at the same time maintaining vital organ perfusion. DHCA is used for the repair of complex intracardiac lesions as well as reconstructions of the aorta. Once circulation has been stopped, the surgeon is able to remove all cannulae and work in a completely bloodless and unobstructed field. An alternative for aortic surgeries is DHCA with retrograde cerebral perfusion with an arterial cannula in the innominate artery and venous drainage either via pump suction in the open atrium or a cannula placed in the superior vena cava (SVC). Flow rates of 20–50 mL/kg/min to a perfusion pressure of 30–50 mmHg are used [18].

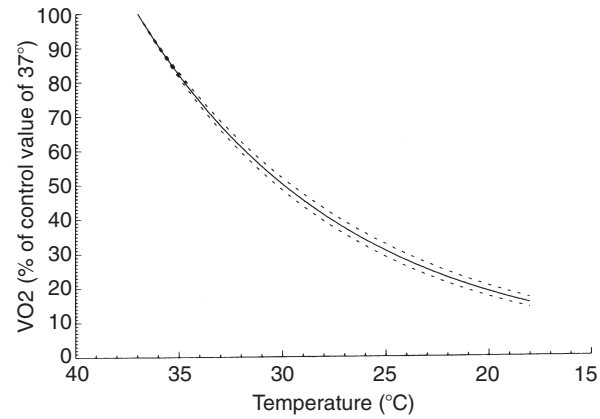

Figure 10.1 Whole body oxygen consumption (VO_2) as a function of body temperature.

The principal clinical effect of hypothermia is the reduction in metabolic rate and molecular movement. As temperature is lowered, both basal and functional cellular metabolism is reduced, and the rate of adenosine triphosphate (ATP) consumption is decreased. Whole-body oxygen consumption decreases directly with body temperature (Figure 10.1) [6,19,20,21]. The cerebral metabolic rate ($CMRO_2$) has been found to exponentially decrease as temperature decreases throughout the clinically relevant temperature range of 37 °C to 18 °C [22,23]. The reduction in $CMRO_2$ has been calculated to be between 82% and 87% of baseline in the canine model and the pediatric population, respectively [22]. This relationship between temperature and metabolic rate can be quantified by calculating the Q10, which is a temperature coefficient defined as the ratio of metabolic rates at two temperatures separated by 10 °C. This has been calculated in adults to be 2.4–2.8; in the pediatric population, it has been shown to be 3.65. This indicates that there is a greater decrease in metabolic rate in neonates, infants, and children compared to adults as they

become more hypothermic. In clinical terms this translates into better brain and organ protection with hypothermia in the pediatric population [22]. At deep hypothermia cellular metabolism is so low and membrane fluidity is reduced to such a large extent that cellular basal metabolic needs and cellular membrane integrity can be maintained for a relatively long period of time (Figure 10.2) [6,24]. Despite these beneficial effects cerebral blood flow (CBF) autoregulation is lost at deep hypothermia and becomes proportional to mean arterial pressure (Figure 10.3) [6,22]. In those patients who underwent deep hypothermia with low-flow bypass, CBF will return to normal with rewarming and may even exceed it in the post-bypass phase. Interestingly, in the group of patients who undergo DHCA it appears that CBF does not return to normal, remaining low into the post-bypass period. One study suggested that this may last for up to 40 hours post bypass despite adequate perfusion pressure [25]. Two apposing explanations exist for this phenomenon: the low CBF may be a function of a low metabolic demand seen post DHCA, or this prolonged low CBF is secondary to a pathologic no-reflow phenomenon as a result of a primary cerebral vascular abnormality secondary to DHCA [22,25,26].

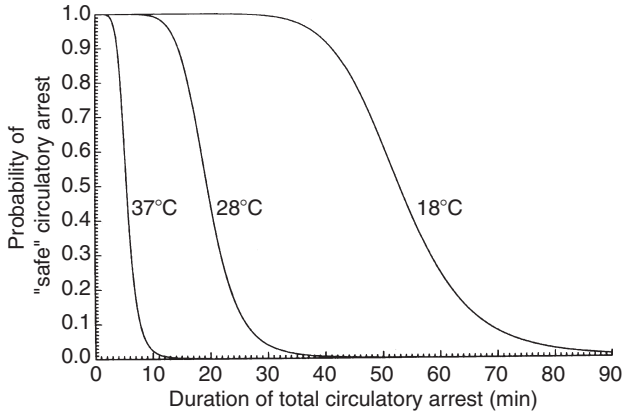

Figure 10.2 The probability of safe circulatory arrest is related to the duration of arrest and the temperature at which it occurs. (Reproduced with permission from Kirklin *et al.* [24].)

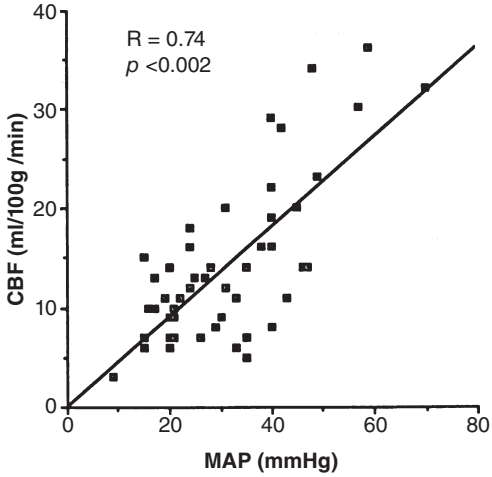

Figure 10.3 Data obtained from a human infant demonstrate that cerebral autoregulation is lost at deep hypothermic temperatures (<22 °C) with cerebral blood flow (CBF) related in a linear manner to mean arterial pressure (MAP). (Reproduced with permission from Greeley *et al.* [22].)

In contrast to the role that hypothermia plays in cerebral protection, it is less important in protection of the myocardium; indeed it has been suggested that electrical quiescence accounts for ±90% of myocardial protection at normothermia [27]. It has been found that a decrease in perfusion temperature has a possible deleterious effect on the myocardium as it leads to abnormal calcium and sodium handling. As Na^+/K^+ ATPase inhibition occurs with a falling temperature it gives rise to an increase in intracellular sodium. This may then result in an increased activity of the Na^+/Ca^{2+} exchanger, with an increase in intracellular calcium [28]. This may play an important part in the development of an entity described as rapid cooling contracture, which is thought to play a role in post-bypass myocardial dysfunction. Experimental evidence suggests that rapid cooling of the myocardium, such as occurs with hypothermic CPB and cold cardioplegia, may result in an exacerbation of injury [29–31]. The increase in intracellular calcium will lead to an increase in ATP use, a decrease in ATP synthesis, activation of calcium-dependent degradative enzymes, and an increase in free-radical reactions [31]. Clinically this will be translated into an increase in contractility and a decrease in both systolic and diastolic function. Further evidence suggests that these changes in compliance of the myocardium will also increase resistance to coronary blood flow [32]. This effect of cooling on myocardial performance may be more pronounced in the neonatal and infant period, as the lower total body and cardiac mass make these patients susceptible to more rapid temperature changes [31].

The adverse effects of rapid cooling have been demonstrated experimentally in the kidneys, liver, and lungs as well. In clinical practice, however, many variables are involved and there does not seem to be readily apparent injury to the patient from rapid cooling [33–34]. It does appear that the neonate is able to tolerate the stress of profound hypothermia without difficulty. The reason for this may be the fact that neonates possess different ionic channel density or have different membrane function than do older patients. These theories remain speculative.

In summary hypothermia preserves organ function by maintaining cellular ATP stores despite reduced oxygen delivery, reducing excitatory neurotransmitter release and preventing calcium entry into the cell. In neonatal and

infant congenital heart surgery, the use of some form of hypothermia remains commonplace. It aids in preservation of organ function during ischemia, allows the surgeon to operate in a potentially bloodless field, and increases the safety of CPB.

Pulsatile versus Nonpulsatile Flow

Whether pulsatile flow has improved outcomes over nonpulsatile flow remains an open question. The basis for this stems from the suggestion that nonpulsatile perfusion may be associated with microcirculatory dysfunction and, thus, may be important in the genesis of post-CPB myocardial, cerebral, and renal dysfunction [35]. The desirability of pulsatile perfusion has been contemplated and studied since the introduction of extracorporeal circulation in the 1950s.

The difference between these two modes of perfusion is not simply the generation of a pulse pressure. Pulsatile flow also depends on creation of an energy gradient; thus pump flow as well as arterial pressure must be included [36]. This relationship was described by Shepard in 1966 [37] and is known as the energy equivalent pressure (EEP) formula:

$$\mathrm{EEP} = \left(\int \mathrm{fpdt}\right) / \left(\int \mathrm{fdt}\right)$$

Thus it is the ratio of the area under the hemodynamic power curve ($\int fpdt$) and the area under the pump flow curve ($\int fdt$) where f is the pump flow rate, p is the arterial pressure (in mmHg) and dt indicates that the integration is performed over time (t). Because EEP is measured in mmHg, a comparison can be made between it and mean arterial pressure (MAP). The difference between these two measurements is the energy generated by the bypass machine – be it a pulsatile or nonpulsatile device [36]. This difference must then be applied to the surplus hemodynamic energy (SHE) formula:

$$\mathrm{SHE} = 1332(\mathrm{EEP} - \mathrm{MAP})$$

The unit of measure of this formula (SHE) is the erg, which represents energy. Pulsatile flow is best represented by an energy gradient rather than a pressure gradient, and pulsatile perfusion produces more SHE units than nonpulsatile perfusion [38]. This improved generation of energy units may translate into improved regional and global blood flow to vital organs [39]. The converse is also true that when there is no difference in energy level generated between pulsatile and nonpulsatile flow then there is no difference in vital organ blood flow (Figure 10.4) [35–40].

As has been mentioned above, pulsatile flow appears to improve organ flow during CPB and function in the post-CPB period. In a pilot study of 50 patients Alkan and colleagues described improved myocardial function in the pulsatile group based on the observation that this group of patients required less inotropic support and at lower doses [41]. The same investigators found equivalent findings in a follow-up study of 215 patients [39]. This was similar to experimental findings of improved myocardial blood flow and function even after up to 60 minutes of DHCA [42].

Cerebral blood flow patterns have also been studied, and experimental animal models have been used to find differences in flow techniques. It is noted that both methods of perfusion show decreased flow when compared to pre-CPB cerebral blood flow. The findings showed that cerebral hemispheric, basal ganglia, brainstem, and cerebellar flows were better maintained in the pulsatile group. This was found at normothermic CPB, pre DHCA, post DHCA, and even post CPB. An important factor related to these findings is that cerebral vascular resistance is found to be lower under pulsatile perfusion during and after normothermic CPB [38]. Interestingly authors involved in this work have conducted other studies that do not agree with these findings; however, despite this they make a point of concluding that in their opinion pulsatile flow remains a better choice based on its ability to generate more hemodynamic energy, which in turn may maintain the microcirculation to a greater degree [40–43].

Postoperative ventilation and the effects of CPB on pulmonary function are important clinical markers in patients undergoing cardiac surgery. In their large clinical study, Alkan and colleagues found that time to extubation and length of intensive care unit (ICU) stay was significantly shorter in the pulsatile perfusion group, from which it can be concluded that pulmonary function was improved in this group [39]. Renal function was also a marker analyzed in this study, and it was found that, although the serum creatinine was similar in both groups, urine output was significantly improved in the pulsatile group. Indeed it has been shown that pulsatile perfusion increased renal and specifically renal cortical flow. Pulsatile perfusion also played a role in decreasing edema and ischemic changes found in renal tubules as compared to nonpulsatile flow [44].

One of the biggest problems faced by clinicians when patients are placed onto CPB is the inflammatory cascade that is initiated secondary to the exposure of patient's blood to the foreign surface of the bypass circuit, surgical trauma, ischemia/reperfusion hemodilution, hypothermia, and possibly changes related to the artificial nature of perfusion – the end result being organ dysfunction that affects the myocardial, pulmonary, hepatic, and renal systems. Damaged endothelium releases increased amounts of cytokines, including interleukin 8 (IL-8), and increased release of IL-8 is frequently used as a measure of inflammation. The use of pulsatile CPB has been associated with a lower concentration of IL-8, leading authors to speculate

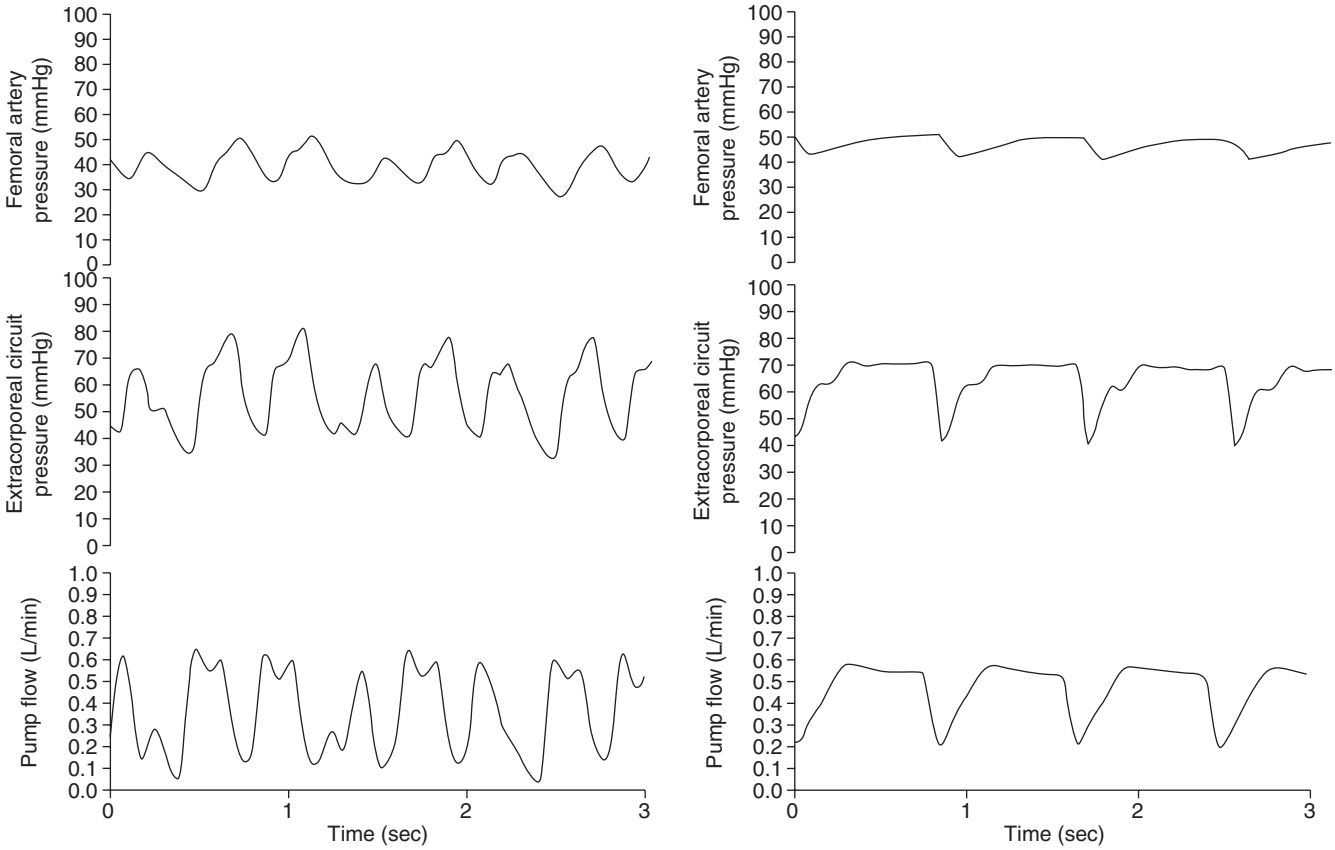

Figure 10.4 Femoral artery pressure, precannula extracorporeal circuit pressure, and pump flow during (left) pulsatile and (right) nonpulsatile cardiopulmonary bypass in a neonatal piglet. (Reproduced with permission from Undar *et al.* [35].)

that this may improve outcomes with regard to function and microcirculation of vital organs [32,36].

Despite encouraging experimental and clinical results with the use of pulsatile flow, this technique has not yet been brought into broad use. Multicenter trials have been called for but have not yet been reported. As such, nonpulsatile flow remains the perfusion technique most widely used in pediatric cardiac surgery.

Strategies for Blood Gas Management: alpha Stat and pH Stat

Another topic of considerable debate in pediatric CPB is the question of interpretation and management of pH, most specifically at deep hypothermia. In adult patients undergoing CPB, the most common cause of brain injury is related to the delivery of embolic material to the cerebral vasculature. The etiology of brain injury in children is thought to result from hypoperfusion during periods of low flow or DHCA [45]. As has been mentioned, many pediatric cardiac surgeries are performed under conditions of decreased flow rates with moderate to deep hypothermia in an effort to protect against vital organ injury. It would thus follow that strategies that result in the lowest $CMRO_2$ would offer the best protection.

The temperature at which the pH is reported is of fundamental importance. Within the body, maintenance of electrochemical neutrality is necessary to ensure that cellular protein and enzymes function optimally. This neutrality occurs when there are equal concentrations of positively and negatively charged ions within aqueous solutions. As the temperature begins to drop, the dissociation constant of aqueous systems will increase and thus the concentration of H^+ begins to decrease. As pH is the inverse log of H^+ and as electrochemical neutrality must be maintained, the pH of the solution will increase. Electrochemical neutrality is also maintained within cells; thus we can hypothesize that the pH within cells is a pH of neutrality. We would then assume that to maintain neutrality the intracellular pH would change with a change in temperature. Analysis of ectothermic animals shows that intracellular pH remains at or near this pH of neutrality even as body temperature drops. For this to occur, two additional processes must take place. The first is a buffer system with a

pK value close to that of the intracellular pH and whose pK changes as temperature changes. The buffering capacity of the imidazole of the amino acid histidine has these characteristics. Histidine is found commonly within intracellular proteins and enzymes. The term "alpha" refers to the degree of dissociation of the imidazole, that is, the ratio of unprotonated to total imidazole; under normal conditions within the intracellular compartment this has a value of 0.55. This dissociation (and hence the alpha value) will remain constant over a range of temperatures as there is a proportional change of the neutral pH of water, the pKa of imidazole, and the tissue pH. The second necessary process is that the CO_2 content of the blood must remain constant as body temperature drops. This is the "alpha stat" condition. If, however, the pH remains constant during hypothermia, then the alpha number of the imidazole will change and thus there may be a change in protein structure or enzyme function. This is known as the "pH stat" condition. In this management technique, CO_2 is added so that the pH will remain constant through the range of hypothermic temperatures (Figure 10.5) [46].

Into the 1990s, based on adult studies and strategies, the alpha stat technique was thought to have a better neuroprotective outcome. Despite the lack of prospective data, it gained widespread use amongst institutions performing cardiac surgeries on children [45]. In a neurodevelopmental follow-up of 16 patients who had undergone Senning operations, Jonas and colleagues reviewed perfusion techniques and pH strategy. They found that the use of alpha stat strategy before DHCA was associated with poorer developmental scores and postulated that the lower CBF associated with alpha stat may result in inadequate cooling. Despite the groups being of different ages at the time of assessment and despite the fact that it was underpowered, this study hinted at a possible need to change strategies in the pediatric population [47]. Another more devastating neurological complication of pediatric cardiac surgery is the development of choreoathetosis. In two studies, one from the above group, patients underwent DHCA and later went on to develop choreoathetosis. After analysis apart from the use of DHCA it was found that all of the affected patients were managed using alpha stat [48,49]. Laboratory studies with neonatal piglets and DHCA times varying from 60 to 90 minutes have demonstrated that the use of pH stat appears to offer better cerebral protection. In the studies referenced, the markers used to compare the two management strategies included microvascular diameter during cooling and rewarming, cerebral tissue oxygenation, brain cooling, and metabolic markers of ischemia (e.g., extrastriatal dopamine production) [50–52]. The effects on brain cooling include a faster rate of cooling that is uniform across all regions of the brain, especially the cortical white matter [53]. The results of these showed pH stat to be superior in all of the aforementioned categories in the cooling phases of DHCA as well as in the recovery phase.

In the first prospective trial into the use of pH stat management in the cooling phases of DHCA, du Plessis and colleagues found that there was a greater degree of cerebral cooling, as measured by tympanic membrane temperature, in the pH stat group. This they attributed to increased CBF that appeared to be equally distributed throughout the brain. In keeping with these data, this group also had recovery of electroencephalogram (EEG) activity more rapidly than those in whom alpha stat management had been used. EEG-confirmed seizures were also increased twofold in the alpha stat group [45]. Although a later section of this chapter will be dedicated to the discussion of near infrared spectroscopy (NIRS), in our current context it is important to note that monitoring studies have been undertaken in which there is evidence to suggest that the use of alpha stat is associated with lower signals during cooling. This indicates that this method results in insufficient CBF and oxygenation [54,55]. In 2003 Bellinger and colleagues from the group at Boston Children's Hospital presented 1-year follow-up data on a large group of patients who had been exposed to either alpha stat or pH stat management. These data showed that despite apparent advantages of pH early post-CPB, neurodevelopmentally there was no difference between the groups. Despite this the use of pH stat for cooling remains the management of choice.

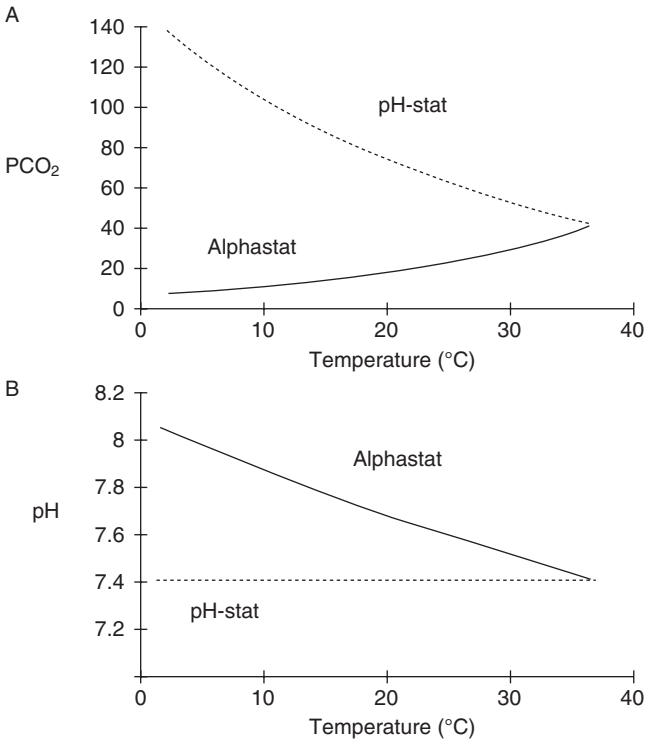

Figure 10.5 The effect of temperature on blood plasma pCO_2 (**A**) and pH (**B**) comparing the alphastat and pH-stat protocols of acid–base management. (Reproduced with permission from Tallman [46].)

The effects of pH/CO_2 on other organ systems have also been studied. Myocardial protection is also obviously of great concern to the entire care team. In a study performed by Nagy and colleagues in which troponin I was used as the marker of myocardial injury, it was found, across a spectrum of patients that included pulmonary hypertension and cyanotic congenital heart disease (CHD), that those in whom pH stat was used had better myocardial performance after CPB [56]. They postulated that pH stat may induce a more even myocardial temperature during cooling due to hypercapnia-induced vasodilation. Oxygen delivery may also be improved as the oxygen–hemoglobin dissociation curve shifts rightwards with the increase in CO_2. Lastly they suggested that the hypercapnia-induced inhibition of pyruvate dehydrogenase, which leads to a decrease in lactate production, may also be of great benefit. As a secondary outcome their study also suggested that postoperative ventilation and length of ICU stay may be shorter with pH stat. Improved myocardial performance had also been found in the du Plessis study where there appeared to be a higher cardiac index within the first 18 hours after CPB with lower inotropic use, less hypotension, and metabolic acidosis compared to the alpha stat group. These patients also had significantly less mechanical ventilation and ICU stays [45].

Despite these advantages there is concern that the use of pH stat may result in a change in the internal pH (pHi) of cells that would lead to a prolonged depletion of high-energy phosphates during rewarming, which in turn would lead to cellular damage. Experimental evidence, however, seems to suggest that the pHi of cells is regulated independently of the extracellular environment. Hiramatsu and colleagues showed that the pHi was alkalotic irrespective of the use of alpha stat or pH stat strategies during the cooling phase, but that it tended towards acidosis with the onset of DHCA [50]. The data then suggested that there was a quicker recovery of both pHi and ATP using the pH stat technique. As mentioned before, this was on the basis of a greater oxygen reserve secondary to increased blood flow and oxygen delivery in the cooling phase. In conclusion it would seem that the evidence presented here would undoubtedly indicate that a prudent approach would be for the use of pH stat management during the cooling phase of deep hypothermic CPB; indeed, there is also some evidence from these studies that this strategy should be employed in the rewarming phases as well. Many centers, including our own, use alpha stat during rewarming to good clinical effect.

Neurological Injury and Protection

As has been stressed throughout this chapter, protecting vital organs and especially the brain is of paramount importance. To this end investigators are continuously searching for ideal monitoring tools to ensure that there is minimal morbidity during all phases of CPB as well as into the recovery phase, as our perioperative management may directly correlate with long-term neurodevelopmental outcomes. Unlike in the adult population, where neurological injury commonly involves thromboembolic stroke, in the pediatric population the injury results in more subtle problems such as with attention, fine and gross motor control, visual motor integration, and executive functioning. The end result of these problems is school failure and low self-esteem. This "developmental signature" is similar to that seen in very low birthweight, premature infants [57].

It is quite alarming to note that long-term follow-up has found that neurodevelopmental impairment occurs in approximately 50% of children who have cardiac surgery as newborns or young infants [58]. Many studies of neurodevelopmental outcome after cardiac surgery in infancy have focused on injury during the intraoperative period as the likely cause of adverse outcomes. However, there is increasing evidence that brain development is abnormal in children with CHD, and injury often can be identified before surgery. Patient-specific factors such as genetic abnormalities, socioeconomic status, and maternal education are more important determinants of neurodevelopmental outcomes than are intraoperative management strategies [49]. From Table 10.4 it can be seen that a number of factors influence neurological outcome [59].

pH stat blood gas management
Cerebral ischemia
Steal
Hemodilution
Free radicals/reoxygenation

Preoperative Factors

Neonates with CHD have a higher incidence of cerebral dysgenesis than those in the general population [59]. The era of staged reconstruction of hypoplastic left heart syndrome (HLHS) began in the late 1970s, with this diagnosis being fatal prior to this time. In a series of postmortem examinations from the early to mid 1980s, the authors found 29% of the patients had either minor or major central nervous system (CNS) abnormalities. They also found that the absence of dysmorphic features did not preclude CNS abnormalities [60].

Periventricular leukomalacia (PVL) (Figure 10.6) is one of the most frequent and severe neuronal injuries specific to the neonatal brain [61]. It is caused by necrosis of deep white matter adjacent to the lateral ventricles. The mechanism is thought to be related to injury to immature oligodendrocytes. In early life the brain undergoes an intensive period of neuronal development and axonal growth. It is during this period that the brain is susceptible to ischemia–reperfusion injury due to its fragile vascularity, high metabolic activity, and immature autoregulation. At this time oligodendrocytes myelinate developing axons throughout the CNS, thus making the white matter particularly susceptible to oligodendrocytic injury [59]. PVL occurs not only in the period surrounding CPB but also in premature infants and after such insults as hypoxia, hypoglycemia, and meningitis. The incidence prior to CPB has been estimated to be between 16% and 25% [62,63] with this rate increasing to between 54% and 73% [61,63] post CPB based on magnetic resonance imaging (MRI) studies. The study subjects included a group of patients undergoing Norwood operation with regional low-flow cerebral perfusion, whilst the other cohort included patients with one or two ventricles with or without aortic arch obstruction. In this latter group, only 1 out of 23 (4%) of the older infants developed PVL [61]. In recent years MRI as well as prenatal ultrasound has been used to assess CBF. Fetal echocardiography has demonstrated that there are changes in the cerebral vascular resistance that vary according to the specific cardiac defect. Thus CBF and oxygen delivery may be impaired in fetuses with CHD, resulting in abnormal brain development [64]. Preoperative MRI has found similar anatomic findings to those already mentioned, with one study finding an incidence of >50% of neonates with a wide range of CHD having structural brain abnormalities, with PVL in 28% and microcephaly in 24%. The important point from this study, however, was that CBF was decreased from normal in the cohort and that, in some cases, flow was critically low at <10 mL/100 g/min [65]. Apart from abnormal intracardiac shunt these neonates have ductus arteriosus-dependent aortic or pulmonary blood flow, which leads to diastolic hypotension that may lead to compromised CBF. Other important preoperative factors may include the need for balloon atrial septostomy in those with transposition of the great vessels with resultant embolic events [66] and ongoing systemic inflammation secondary to endotoxin translocation from mesenteric hypoperfusion [58].

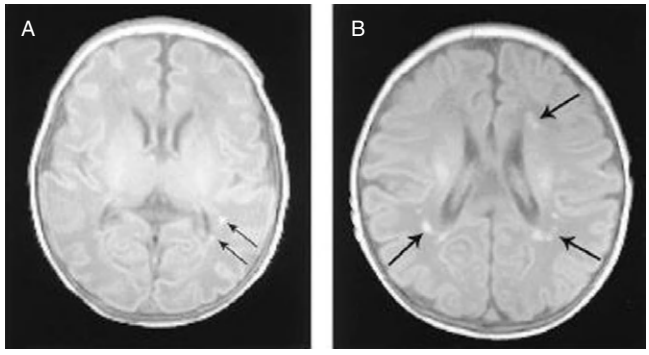

Figure 10.6 MRI evidence of periventricular leukomalacia. **(A)** Axial MRI image (T1-weighted) demonstrating two small areas of increased signal intensity in the periventricular white matter consistent with PVL, classified as mild (arrows). **(B)** Axial MRI image (T1-weighted) demonstrating multiple larger areas of increased signal density in the periventricular white matter consistent with PVL, classified as moderate (arrows).

There are also genetic factors that play a role in the genesis of neurological damage. These include underlying congenital defects such as the presence of a VSD and aortopulmonary collaterals, abnormalities of cerebral vasculature, and genetic factors such as prothrombotic disorders and polymorphisms of apolipoprotein E (APOE). An important factor in neuronal repair, APOE also aids in regulation of cholesterol metabolism. There are three common isoforms of APOE (E2, E3, and E4) that are encoded by three alleles (ε2, ε3, and ε4). Research has shown that the APOE genotype has a strong association as a determinant of neurological recovery following CNS injury. In a study of 244 patients who had undergone repair of CHD ≤6 months of age with or without DHCA, Gaynor and colleagues found that in those who carried the APOE ε2 allele had significantly lower Psychomotor Developmental Index (PDI) than those who carried the other two alleles. It is important to note, however, that in this study all of the patients, irrespective of allele type, scored lower on PDI and Mental Developmental Index (MDI) than expected for their age [67]. A follow-up study by the same group at the Children's Hospital of Philadelphia enrolled a cohort of 550 patients all of whom had surgical procedures <105 days of age. The preoperative diagnoses included HLHS, tetralogy of Fallot, VSD with and without coarct, and transposition of the great arteries (TGA) with and without VSD. Of this original group 359 returned and participated in the study

at 1 year of age. Of the original cohort 49 patients had died (21 during the original hospitalization and 28 following discharge) and a further 142 did not return. Apart from motor and cognitive testing the patients also underwent genetic screening. The genetic evaluation was considered normal in 257 of the patients. As in the previous study the overall scores of the PDI and MDI were lower than the population norms. Risk factors for low scores amongst this cohort included confirmed genetic syndrome, lower birthweight, small head circumference at 1 year, preoperative intubation, longer hospital stay, use of extracorporeal membrane oxygenation (ECMO) or a ventricular assist device (VAD), and the presence of the APOE ε2 allele. Interestingly the investigators found that a higher hematocrit after hemodilution was associated with higher scores and the use or duration of DHCA was not associated with worse outcomes. Based on their findings the investigators advised preoperative genetic consultation that risk stratification be performed for those with positive genetic screens [59].

Intraoperative Factors

Despite the above-mentioned factors, the intraoperative period is still a time of great risk to the child. In two contrary sets of data, two apparently different neurological outcomes were found. In a study performed in patients undergoing ASD closure via surgical- versus catheter-based closure, there was a significant decrease in intelligence quotient [68]. In the other study, presented by Quartermain and colleagues as a scientific abstract at the 2008 American Heart Association's Scientific Sessions in New Orleans, a cohort of 41 patients from 5 to 18 years of age all of whom underwent CPB for closure of simple atrial or ventricular defects or simple valve surgeries showed no decrease in neurocognitive function [69]. The study group was compared with a similar group of patients undergoing noncardiac surgery.

Factors that will likely result in poorer outcomes include anesthetic-related issues encompassing a decrease in cardiac output with decreased oxygen delivery at the time of transition from negative- to positive-pressure ventilation and the negative inotropic effects of anesthetic agents. Hypoxia may worsen before establishment of CPB, particularly in those with ductal-dependent flow, as the surgeon dissects around the ductus, resulting in vasospasm. Once on CPB numerous factors may occur, including malposition of both the arterial and venous cannulae with resultant poor flow characteristics and venous drainage leading to cerebral hypoperfusion; embolic phenomena, including air and thrombus, may occur despite meticulous circuit check, adequate anticoagulation, and de-airing of the heart once repair is undertaken; the inflammatory response set up by CPB; the effects of DHCA with ischemia–reperfusion injury and uneven cerebral cooling; hemodilution; pH management; and the effect of collateral steal of blood away from vital organs [58,59]. Once weaning from CPB has taken place, it is the effects of continued myocardial dysfunction with decreased oxygen delivery and hypoxia that may lead to ongoing brain injury. From 2–5% of patients require the use ECMO for postcardiotomy support [70], which itself has significant morbidity and mortality with up to 50% of survivors showing neurodevelopmental problems [71].

Postoperative Factors

In the postoperative period, ongoing low cardiac output and hypoxia result in continued neurological damage. Other factors that may play an important part in the genesis of damage during this period include hyperthermia, endocrine abnormalities, acid–base disturbance, and disruption of cerebral vasoregulation. In this latter etiologic factor autoregulation is disrupted after CPB; thus it is important to maintain adequate cerebral perfusion pressure. Longer postoperative length of stay has consistently been shown to be associated with worse neurodevelopmental outcomes, suggesting that events in the postoperative period modify the risk of an adverse outcome.

Neuromonitoring and Neuroprotection

As can be seen from the above discussion a multitude of factors can result in neurological injury either on their own or in combination. Neuroprotection should begin from birth. In the preoperative period clinicians should be aware that severe hypoxia, low perfusion pressure in the form of low diastolic pressure secondary to ductal runoff, low cardiac output states, respiratory alkalosis, and hyperthermia may be variables in neurological injury. In the transition to the operating room and controlled ventilation, clinicians should be attentive to changes that result in the aforementioned factors. How then can we protect the brain?

In recent years interest has been focused on neurological monitoring with NIRS, transcranial Doppler, electroencephalography, and jugular venous saturation alone or in combination as opposed to using surrogate markers of perfusion pressure, mixed venous saturation, and acid–base status [72]. NIRS provides a real-time, noninvasive assessment of regional cerebral oxygenation and has been validated with jugular venous saturation [72]. In this method a venous weighted approximation of tissue oxygen saturation is measured with a venous : arterial blood ratio of 85 : 15. This technology uses modifications of Beer's equation. Photons are injected through the skin, penetrate through tissue, and then return, whereupon the oxyhemoglobin saturation of tissues at a depth of 2 cm from the skin is measured. Subtraction of the shallow light path from the

deep light path results in the approximation of brain oxygenation [72]. The INVOS 5100 (Somanetics, Inc, Troy, MI), which is approved by the United Stated Food and Drug Administration (US FDA) for use in adults and children, calculates a regional cerebral saturation index (rSO_2i) by computing the ratio of oxyhemoglobin to total hemoglobin. It has range of 15–95%. These monitors are best used as trend monitors, with a fall of 20% from baseline being significant [73]. Factors that affect cerebral oxyhemoglobin saturation include cerebral perfusion pressure, CBF, arterial oxyhemoglobin saturation, $PaCO_2$, and cerebral metabolic rate. The baseline values have been quantified with 70% being normal in adults. Normal and acyanotic children have similar values. In a study by Kurth *et al*. where cerebral oxygen saturation was measured preoperatively the mean saturation was found to be between 43% and 57% for a wide range of cyanotic heart disease [74]. The one group that fell outside this range comprised six patients with a diagnosis of pulmonary atresia and with an average saturation of 38% [74]. Studies looking at single-ventricle patients and from laboratory studies suggest that a saturation below 30% results in anaerobic metabolism [74,75]. It thus becomes obvious that many patients that we take care of must have saturations that fall below this anaerobic threshold. The question that would thus be answered by the use of this technology would be when does anaerobic metabolism occur, for how long, and what do our interventions do to either improve or worsen the situation? In this regard NIRS has been used to guide safe duration of DHCA, proper placement of cannulae, and also optimum flow during low-flow cerebral perfusion at deep hypothermia [76–78]. Some investigators have also suggested the use of concurrent cerebral NIRS and the placement of a probe over the anterior abdominal wall or renal bed to monitor the somatic bed [79,80]. Based on the assumption that the invasive technique of jugular venous bulb saturation (SjO_2) gives an extremely accurate measurement of cerebral oxygenation and metabolism, there are a few pitfalls in using NIRS. This includes a better correlation between SjO_2 and NIRS with patients <10 kg, which can be explained by an increased skin and skull thickness in larger children, the relatively small area of cerebral circulation, and the possible contribution of extracerebral tissue to the signal [81].

EEG monitoring is theoretically attractive for the detection of hypoperfusion or ischemia on the basis of altered signals. It is, however, not routinely feasible as the technology is bulky and the signals may be affected by the electrical interference of electrocautery, patient temperature, anesthetic agents used, and CPB itself. EEG is useful, however, for quantification of anesthetic depth, occurrence of electrical silence with DHCA, and of course the presence of epileptiform activity in the postoperative period, which may indicate neuronal damage [73]. The Bispectral Index (Aspect Medical Systems, Newton, MA) uses processed EEG signals to compute a number in the range of 0 (complete EEG silence) to between 90 and 100, which is found in awake patients and thus has been used as a adjunct for anesthesiologists to predict the likelihood of recall under anesthesia. The monitor is easy to use in both the placement of the electrode and in the read-out display itself. An added advantage of this monitor is the ability to see an unprocessed EEG in real time, which can give an indication of burst suppression or electrical silence – an obvious advantage when patients are being cooled to deep hypothermia [82]. The BIS value is reported to decrease with hypothermia and thus decreasing anesthesia requirements. Conversely, upon rewarming BIS values increase, possibly reflecting a change in consciousness level [73].

Transcranial Doppler (TCD) provides a real-time monitor of CBF velocity and the occurrence of embolic phenomena during CPB. The instrument uses pulsed wave ultrasound, usually at 2 MHz frequency. The units display the frequency of the Doppler signals; peak systolic and mean flow velocities (cm/second); and the pulsatility index, which is the peak velocity minus the end-diastolic velocity divided by the mean velocity [82]. The added advantage of the device is the identification of microemboli via high-intensity transient signals that are displayed with an audible click for each event. The most consistent and reproducible technique is to monitor the middle cerebral artery through the temporal window, which is located superior to the zygoma and anterior to the tragus. The values reproduced are trended throughout the case; and a drop of 60% in the peak velocity is considered a moderate drop in perfusion whilst a drop of 80% is considered a severe drop. Clinically both an inflow arterial obstruction, which will be seen by a drop in the peak Doppler signal, or an outflow obstruction, which is diagnosed by a decrease in the diastolic flow signal, can be appreciated. The respective etiologies are malposition of the arterial cannula, arterial line obstruction, changes to perfusion pressure, and changes in the flow rates or, alternatively, obstruction to venous drainage from the head by superior vena caval cannula malposition, kinking of the venous line, or after the creation of a superior cavopulmonary anastomosis [72]. High-intensity transient signals at a rate of >1/minute are considered significant [72,82], but as has been mentioned previously with regard to the etiology of adverse neurological events in children being different to that in adult CPB, the embolic count has not been shown to correlate with early neurological outcome in infants and children [73].

Jugular venous bulb saturation (SjO_2), as its name implies, measures the saturation of the venous blood by the placement of a retrograde venous catheter into the jugular venous bulb located approximately just cephalad of the C1C2 disc. The jugular veins drain almost all blood from

the brain, but it has been shown that up to 6.6% of this blood comes from extracranial sources, which include the emissary and frontal veins, and the facial vein, which contributes the most extracranial blood [83]. Another potential anatomic problem with this monitoring technology is that blood does not drain equally into the two jugular venous bulbs. Indeed mixing of blood from the cortical and deeper regions of the brain is incomplete. Autopsy studies have shown that blood draining from the subcortical areas draining via the straight sinus flow to the left lateral sinus whilst blood from the cortical areas drained mainly to the right lateral sinus. Despite this, sampling from normal individuals has shown that saturations at the level of the internal jugular vein are equal on both sides [83]. In the pediatric population the use of SjO_2 has been studied in the context of optimal cooling time in those undergoing DHCA. As the temperature drops the brain will extract less oxygen as its metabolic demands fall. Under optimal conditions as the temperature falls the SjO_2 rises until the difference between the arterial saturation and the jugular venous saturation becomes minimal [84]. At this point it can be concluded that the metabolic rate of the brain has reached a nadir where maximal protection is occurring. One acknowledged negative in the use of this technology is that it is invasive; thus investigators have performed comparative studies between SjO_2 and NIRS to assess whether the noninvasive infrared technology produces similar results. Studies demonstrate that although there appears to be a good correlation between the two modalities [85–88] certain limitations are evident: accuracy of NIRS at low SjO_2, difficulty in assessing whether cerebral metabolism has nearly ceased as NIRS values may not read >90%, and accuracy of NIRS at low flow rates. The best correlations between the modalities occur with patients who are less than 10 kg. Authors conclude that these patients have decreased skull and scalp thickness allowing for a larger area of deeper brain structures to be scanned [86,87].

From this discussion it can be understood why some centers use triple-modality neuromonitoring: NIRS, jugular venous oxygen, and EEG. The advantage of this is that the monitoring is noninvasive and relatively easy to apply. Once an abnormality is detected adjustments in patient positioning, cannula position, blood pressure, hemoglobin, $PaCO_2$ and depth of anesthesia may be all that is needed in the prevention of potential neurological injury [58,72,73,82]. In an early study, Austin and colleagues performed this triple monitoring on 250 patients. The initial phase was an attempt to validate this triple monitoring, so the investigators did not treat any changes that were observed as this phase. The findings were that 12 of 46 (26%) of these patients developed early postoperative neurological problems inclusive of seizures, coma, hemiparesis, and movement, vision, or speech disorders. In the group in which interventions were performed when a problem was found, the complication rate decreased to 7 out of 130 patients (6%). Of note in the study was that in the remaining 74 patients in whom no changes were detected 5 patients had adverse outcomes. Of the monitoring modalities EEG found 5% of the abnormalities whilst NIRS and TCD found 58% and 37%, respectively [89]. In a recent meta-analysis by Hirsch and colleagues studying NIRS alone, the authors concluded that although a useful adjunct it is of greater clinical relevance to combine modalities. Their study found that despite measuring regional cerebral saturation, there was a paucity of data to show improved neurological outcome based on these numbers alone. It appears therefore that this may give added support to the multimodal approach [90].

As discussed in prior sections of this chapter and alluded to in this section, neuroprotection does not involve a single strategy but rather is a multifactorial approach. Table 10.5 illustrates a comprehensive strategy.

Table 10.5 Comprehensive strategy for brain protection.

CPB factors
Adequate perfusion pressure
Adequate DO_2 as measured by SvO_2/ABG
Limit Inflammatory response – steroids/leukocyte depleting filters/ heparin coated circuitry
Use of filters to avoid air / particulate emboli
Ensure adequate anticoagulation
pH stat management for any temperature ≤normothermia
Hematocrit ≥30 (≤1 year of age) / ≥25 (≥1 year of age)
Hyperglycemia
Hypothermia
DHCA
Adequate cooling times of at least 20 minutes
Hyperoxygenation prior to arrest
Limit time to ≤40 minutes
Alternative perfusion strategies:
Intermittent cerebral perfusion
Low flow CPB
Antegrade cerebral perfusion
Monitoring
Near infrared spectroscopy (NIRS)
Electroencephalography (EEG)
Transcranial Doppler (TCD)

Postoperative Factors

The prevention of neurological damage must be vigorously continued in the postoperative period. Cerebral autoregulation is not normal in the post-bypass period, and adequate perfusion pressure is reliant on systemic arterial blood pressure. In conjunction with this hypocarbia and alkalosis are best avoided as these may decrease CBF. Other important factors include the early treatment of hypoxia, hyperthermia, acid–base disturbance, and electrolyte abnormalities. NIRS monitoring is as useful in guiding therapy postoperatively as it is intraoperatively. Despite this the impact of postoperative NIRS on neurodevelopmental outcome remains unclear [58].

Myocardial Protection

In comparison to the adult heart, the pediatric heart undergoing surgery will suffer more complex interventions with greater temperature fluctuations. The ability of the myocardium, therefore, to withstand these perturbations and function adequately to deliver oxygen to the body will be directly related to the adequacy of myocardial protection. A large number of surgical interventions are carried out in the neonatal or early infant period when the myocardium may not be able to adequately deal with the stressors of CPB, hypothermia, and ischemia. An important factor in this is its immature metabolic capacity that in turn may affect the response to ischemia during the myocardial standstill that is frequently required during surgical repair of congenital defects.

Experimental evidence suggests that because of myocardial immaturity there is a more rapid accumulation of lactate, which results in earlier inhibition of glycolysis, which in turn results in a decrease in high-energy phosphates such as ATP. At a cellular level this results in an increased number of actin–myosin complexes that cannot dissociate. The decrease in ATP will also result in a decreased ability of the sarcoplasmic reticulum to take up calcium [91]. As the immature myocardium relies heavily on glucose as its major substrate and also has a greater reliance on extracellular calcium for calcium-mediated excitation coupling, the problems related to this metabolic immaturity are clear [92,93]. The end results are earlier ischemic injury compared with adults and possibly explain why certain pediatric patients have increased morbidity and mortality. Most of the laboratory data investigating this has been obtained on normal hearts and it is thus unclear what the ischemic tolerance is when there are preexisting conditions such as cyanosis, hypertrophy, hypoxia, volume or pressure overload, and acidosis. Many of these conditions may be present and may compromise myocardial protection in neonates and infants who require surgical correction of their heart defects. Infants and children with chronic cyanosis as a result of inadequate pulmonary blood flow often have increased bronchial collateral flow. This increased blood return to the left heart can result in insufficient myocardial protection by warming the heart and washing out cardioplegia [94]. Hypertrophied ventricles also may have inadequate myocardial protection and subendocardial ischemia during prolonged arrest periods. It has been found that up to 90% of patients who do not survive the perioperative period show some form of myocardial necrosis that exists in the absence of coronary artery obstruction. This necrosis may effect the entire subendocardium and lead to endocardial fibrosis with late myocardial dysfunction [95].

As mentioned previously in this chapter electrical quiescence provides the cornerstone of myocardial protection. This coupled with the principles of hypothermia have been in practice since the 1960s in an attempt to protect the myocardium during periods of ischemia. Cold crystalloid cardioplegia was applied to pediatric surgery and remains in use today by many pediatric cardiac surgeons. Intraoperative myocardial protection can be viewed to have a number of components of which cardioplegia plays the most important part, with perfusion technique, surgical precision, and anesthetic management also playing important roles.

The principles that guide the composition of cardioplegia include: 1) the ability to produce rapid cardiac arrest; 2) hypothermia; 3) metabolic substrates; 4) appropriate pH; and 5) membrane stabilization (ie, low Ca^{2+}, Mg^{2+}, steroids, O_2 radical scavengers) [96]. The only monitor for the efficacy during CPB of the cardioplegia is electrical quiescence as we do not have a readily available test of myocardial metabolic status. The quality of cardioplegia can, however, be assessed in the immediate period after CPB by myocardial function, inotropic requirements, and troponin I level. Despite the theoretical efficacy of the troponin I level interpretation is difficult and influenced by type of cardiac defect, the myocardial incision, the assay system used, and the use of dexamethasone during CPB [97].

Historically crytalloid cardioplegia has been used. Examples of this include the del Nido solution, favored at Boston Children's Hospital and the Children's Hospital of Philadelphia, and St Thomas solution, which is used elsewhere. The del Nido solution contains Na^+ of 153 mmol/L, K^+ of 24 mmol/L, Cl^- of 132 mmol/L, Ca^{2+} of 0.4 mmol/L, Mg^{2+} of 6.2 mmol/L, lidocaine of 140 mg/L, and mannitol of 2.6 g/L. St Thomas's solution contains Na^+ of 129 mmol/L, K^+ of 16 mmol/L, Cl^- of 140 mmol/L, Ca^{2+} of 1.2 mmol/L, Mg^{2+} of 16 mmol/L, and no mannitol or lidocaine. A significant difference between these rwo solutions is the concentration of Ca^{2+}, although the St Thomas solution is still a normocalcemic value for ionized calcium. It has been found that high levels of intracellular Ca^{2+} during ischemia and reperfusion lead to increased cellular injury

[96]. The neonatal myocardium may be at increased risk for this effect as it possesses a diminished capacity to sequester calcium. Experimentally it has been found that in nonhypoxic hearts either normocalcemic or hypocalcemic cardioplegia results in preservation of myocardial and vascular function. In contrast to this in patients with hypoxic stress (i.e., cyanotic heart disease), hypocalcemic cardioplegia allows for repair of hypoxic myocardial damage, whereas normocalcemic cardioplegia is associated with increased cellular injury manifest as myocardial and endothelial dysfunction post-bypass. Another difference between these two solutions is the concentration of Mg^{2+}. At a myocardial level the increased Mg^{2+} will inhibit the entry of Ca^{2+} into the cell, offsetting the higher Ca^{2+} in the St Thomas solution. Another added benefit is that the higher Mg^{2+} cardioplegia has been associated with a decrease in post-bypass arrhythmia [96]. In early animal experimentation it was found that magnesium enrichment of hypocalcemic cardioplegia offered myocardial protection and functional preservation; however, when it was added to normocalcemic cardioplegia these positive effects did not occur [98].

There are three phases of cardioplegia described: induction, maintenance, and reperfusion. Induction of cardioplegia covers the initial dose that results in electrical silence given soon after initiation of CPB. All hearts receive noncoronary collateral blood flow via pericardial connections, and in some patients with aortopulmonary collaterals this may be more significant. The presence, size, and number of these vessels may be variable; thus the flow may be of sufficient volume to wash out the cardioplegia. This will result in an increase in myocardial temperature as the collateral flow will bring blood to the heart that is at the temperature of the systemic perfusate and also, importantly, a possible return of electrical activity. This is the rationale to give intermittent doses of cardioplegia every 10–30 minutes [95–97]. The periodic cardioplegia will result in: 1) maintenance of arrest; 2) restoring myocardial hypothermia; 3) buffering acidosis and washing away acidic metabolites; 4) replenishing high-energy phosphates; and 5) counteracting edema with hyperosmolarity [95]. This is therefore the maintenance phase of cardioplegia. The reperfusion phase is a critical time as the mode of reperfusion appears to be more important than the duration of ischemia. In a study performed on 103 patients with both cyanotic and acyanotic CHD, one group received intermittent boluses of cold cardioplegia whilst another group received the same cardioplegia strategy to which was added 300 mL/m^2 of the same cardioplegia solution at 35 °C just prior to aortic cross-clamp removal. This is known as terminal warm blood cardioplegia (TWBCP) and is often used in adult cardiac surgery. The use of TWBCP was associated with higher numbers of patients resuming spontaneous sinus rhythm, decreased inotropic use to wean from CPB (although nearly all patients in the study required inotropic support postoperatively in the ICU), improved lactate extraction, and decreased troponin T and heart type fatty acid binding protein. The latter two markers are indicative of cellular damage and necrosis. It would thus appear that the use of TWBCP may provide additional protection by improving myocardial aerobic energy metabolism and decreasing cellular damage [99].

Three additional factors play an important role: adequate distribution of coronary flow, delivery pressure of the cardioplegia, and the question of crystalloid versus blood cardioplegia. To be effective the cardioplegia must be adequately distributed to the myocardium. Although pediatric coronary vessels do not suffer from occlusive disease there are certain pathologic conditions where retrograde perfusion may be a better choice: severe aortic insufficiency, arterial switch operation, and severe ventricular and septal hypertrophy. The delivery pressure of the cardioplegia may also influence myocardial damage. Despite the requirement that the cardioplegia be delivered at a certain pressure to ensure adequate distribution, care must be taken not to perfuse the myocardium at too high a pressure as this may itself lead to myocardial and vascular endothelial cell damage, increased edema, and decreased ATP levels. A pressure of 30–50 mmHg has been shown to be adequate [95]. The last factor of importance is the question of crystalloid versus blood cardioplegia. The use of blood cardioplegia results in myocardial arrest in an oxygenated state with no loss of ATP in the period of electrical activity prior to arrest. This is contrasted to the use of crystalloid where there is a high loss of ATP during this same period. In addition to this when warm blood cardioplegia is used as induction it can resuscitate injured myocardium, which allows it to better tolerate subsequent ischemia. Several authors and commentators have concluded that there appears to be a distinct advantage in the use of blood cardioplegia over crystalloid be it at cold or warm temperatures [95–97,100–103]. The investigators found improvements that included lower coronary sinus lactate, improved cardiac index, better echocardiographic evidence of left ventricular function, increased heat shock protein (produced in myocardial cells in response to stress), and decreased troponin I release, which may correlate with less myocardial injury.

In completion of this topic on myocardial protection perfusion technique, surgical and anesthesia factors must be mentioned. Although a more in-depth discussion will follow, the effect of appropriate perfusion is considerable. With respect to myocardial protection, the effect of perfusion is to maintain perfusion pressure to the coronary vessels, to adequately remove excess body water that may affect post-bypass myocardial performance, and to limit the inflammatory cascade triggered by the institution of

CPB. The surgeon is clearly in a unique position to directly affect the outcome of the attempts to preserve myocardial integrity. Surgical technique must be meticulous so as not to cause unnecessary trauma to myocardial tissue, which may result in global dysfunction, heart block, or coronary artery problems that include kinking, transaction, or air embolism owing to inadequate ventricular de-airing. Anesthesia factors that may aid myocardial protection include a thorough understanding of the underlying physiology both before and after surgical intervention, ventilator settings that will aid and not impede myocardial function (e.g., attempts to keep pulmonary artery pressures low so as to offload the right ventricle), and timely use of inotropic, inodilator, vasodilator, or antiarrhythmic therapies. In conclusion, as with protection of any organ system, a more multimodal approach will offer the best result.

Pulmonary Effects of Cardiopulmonary Bypass

The institution of CPB, as with other organ systems, has potential deleterious effects on the lungs. In the preoperative stages, particularly in those with increased pulmonary blood flow, the patient may suffer pulmonary edema that will require intense medical therapy before surgery. Indeed there is a group of patients who will present to the operating room owing to failed drug therapy thus placing them at a physiologic disadvantage before the impact of CPB. In another group of patients, because pulmonary blood flow has been unrestricted over time (e.g., trisomy 21 patients with uncorrected left to right shunts), the arterial media undergoes hypertrophy with resultant vascular reactivity and pulmonary hypertension. These changes may affect the management of patients at the termination of CPB. In some this may be severe enough that the patient may suffer acute right ventricular failure resulting in a failure to wean from CPB and necessitating the use of acute extracorporeal support. Other patients in whom vascular reactivity and pulmonary hypertension may be an issue in weaning from CPB include neonates, by virtue of their pulmonary vasoreactivity as a carryover from the fetal circulation, and those patients in whom there is an obstruction to pulmonary venous drainage, be it at the level of the pulmonary veins or because of restrictive atrial septa associated with left-sided obstructive lesions. The lungs may be a source as well as a target of the inflammatory response associated with CPB [104]. The result of this is capillary leak and extravasation of fluid into the alveolar spaces with resultant poor oxygen exchange and a detrimental effect on pulmonary mechanics. Etiologic factors associated with capillary leak include hemodilution with resultant decrease in oncotic pressure; ischemia-reperfusion injury; and the sequestration of activated neutrophils, cytokines, complement, and leukotrienes within the pulmonary vascular bed during the period of CPB. The institution of CPB decreases perfusion pressure through the pulmonary capillary bed. Under normal physiologic conditions continuous perfusion aids in alveolar stability; thus, when this ceases with CPB, changes occur in the architecture of the alveolar wall leading to a loss in its stability. It thus follows that there is a marked change in resting alveolar volume and with that gas exchange [105]. Clinical studies performed on children in the peribypass period have demonstrated that there will be an increase in the functional residual capacity (FRC) after median sternotomy. This could be explained by the decrease in the effect of chest wall recoil. As pulmonary flow ceases on CPB and the alveoli collapse there will be an associated decrease in FRC. This decrease is reversed with the reinstitution of flow but is decreased to below resting levels with chest closure. It was postulated that this is due to the effect of chest drains, inflammation, and the presence of extravasated fluid [105].

The use of modified ultrafiltration (MUF) at the termination of bypass has greatly improved pulmonary function and thus oxygenation/ventilation at this critical phase of congenital cardiac surgery. The effect of MUF that is directly related to pulmonary function is due to a reduction in total body water and an associated decrease in lung water. This will lead to improved lung compliance and decreased airway pressure [106]. In addition the use of MUF has been shown to decrease inflammatory markers and this may therefore affect the capillary leak that plagues the lung during CPB [107]. In addition the use of steroids has been shown to improve postoperative pulmonary function [104]. The clinical result is faster time to extubation, decreased mechanical ventilation, and decreased ICU time [106,108].

Although practices vary widely, it is our preference to attempt extubation soon after arrival to the ICU in a wide variety of patients from the early neonatal period up to adults presenting for revision of palliative repairs. The group of patients in whom every attempt is made for early extubation is the single-ventricle population presenting for cavopulmonary anastomosis and Fontan completion. It has been well established that physiologically these patients are at a distinct disadvantage with positive-pressure ventilation, as this will interfere with passive venous flow through the capillary bed and thus affect oxygenation and ultimately cardiac output. In a study in which 79% of patients were extubated in the operating room following cardiac surgery, increased bypass time, age <1 year, and high inotropic support were factors that were found in those not extubated [109]. Although performed on patients who underwent only ASD or VSD repair it was found that there did not appear to be any cardiovascular instability in those extubated within 6 hours of returning to the ICU [110].

Renal Function and Protection on Cardiopulmonary Bypass

The development of acute kidney injury (AKI) is multifactorial and can be subdivided into preoperative, intraoperative, and postoperative causes. The etiologies of the preoperative injury are mainly associated with neonates and infants as their renal physiology is immature. Glomerular filtration rate (GFR) is lower in this age group due to lower MAP and high renovascular resistance, with GFR maintained by postglomerular efferent arteriolar vasoconstriction that is dependent on high levels of angiotensin II activity. It is for this reason that the angiotensin-converting enzyme inhibitors are used in these patients with extreme caution [111].

Preventive and treatment strategies aim to maintain systemic oxygen delivery, maintain perfusion pressure to vital organs, and prevent any further deterioration in function. Thus in the preoperative phase careful attention must be paid to balancing pulmonary and systemic perfusion (Qp : Qs). As is well described, soon after birth the pulmonary resistance begins to fall and thus, in patients with ductal-dependent systemic flow, pulmonary blood flow may increase. This potential increase in pulmonary blood flow results in a concomitant decrease in systemic flow with resultant decreased perfusion of vital organs. Management at this time will therefore include prostaglandin infusion to maintain ductal dependent flow, low fraction of inspired oxygen (FiO_2), support of cardiac function, and early corrective or palliative surgery. Intraoperative aims include many of the factors that are discussed elsewhere in this chapter including dampening the inflammatory response, decreasing DHCA time, the effects of nonpulsatile versus pulsatile CPB, decreasing circuit size, and limiting the exposure to blood products. After the completion of CPB the aims of preventative management include decreasing total body water and inflammatory mediators by means of modified ultrafiltration; ensuring that there are no residual lesions that may affect Qp : Qs or directly affect cardiac function; and ensuring appropriate and ongoing cardiac support in the form of inotropic drugs, vasopressors, vasodilators, and diuretics.

The incidence of AKI varies dependent on surgical procedure with a range of 0.7% for short, uncomplicated surgeries (e.g., ASD closure), increasing up to 59% for longer, more complicated operations (e.g., arterial switch). Across the entire spectrum of procedures the incidence is in the range of 6–17%; however, renal replacement therapy is required in 2.3–11.5% [112–114]. Mortality in this subgroup of patients may be as high as 79% [113]. Table 10.6 describes the risk factors associated with the development of AKI in the immediate post-CPB period. Although this has been collated from data collected over the last 10–15 years it seems that the incidence of acute post-CPB renal failure is decreasing [113]. It is unknown whether this can be ascribed to improved perfusion techniques, improved surgical technique, improved drug therapies, or an improved understanding and management in the ICU. The development of AKI has been associated with a risk factor for mortality as well as prolonged hospital stay and associated increase in-hospital costs. Despite these alarming numbers the diagnosis may prove difficult as consensus as to the definition is not clear. In a small meta-analysis performed by Zappitelli and colleagues, definitions varied and included serum creatinine (SCr) doubling from baseline, SCr tripling from baseline, and the need for dialysis [114]. Another diagnostic marker is the use of the p-RIFLE (pediatric – risk, injury, failure, loss, and end-stage renal disease), which estimates the decrease in Cr clearance and thus renal dysfunction [115]. In a novel approach, investigators identified the gene for neutrophil gelatinase-associated lipocalin (NGAL) as one of the most up-regulated genes expressed in the kidney not only after ischemic injury but also during sepsis and post-transplantation. NGAL functions as a bacteriostatic by blocking the use of iron by microbial systems; more importantly in relation to renal injury it functions to limit renal damage, appearing rapidly in the urine and serum in response to injury [116]. Based on this, NGAL has been identified as an early predictor of AKI [117]. In the immediate post-CPB period it has been found that this marker increases in all patients, especially in those in whom prolonged CPB was necessary. In those patients in whom AKI occurred there was a marked sustained increase in NGAL. A grossly elevated level at 12 hours post-CPB correlated with mortality. Another biomarker that has been described is interleukin 18 (IL-18), which will rise between 4 and 6 hours after CPB, peaking at 12 hours and remaining elevated for 24–48 hours. It has been suggested that the combination of the two markers will identify patients who are at risk for AKI hours after CPB with treatment being insti-

Table 10.6 Risk factors for the development of acute renal failure.

Age ≤1 year
Elevated Aristotle/RACHS-1 (categories 4–6) surgical complexity scores
Long bypass time
Long cross-clamp time
Deep hypothermic circulatory arrest
Increased use of blood products
Low post-CPB cardiac output
Inotropic support (especially epinephrine and isuprel)
Low trough blood pressure on POD 1

tuted early rather than having to wait for 48–72 hours when SCr begins to rise [118]. By the time Cr begins to rise, as much as 50% of renal function has been lost.

Renal replacement therapy (RRT) is usually instituted in association with multiorgan failure, worsening renal function with increasing K^+, and total body fluid accumulation. Studies have shown that up to 20% of pediatric patients in multiorgan failure are associated with cardiac surgery and that the prevention of total body fluid accumulation is associated with improved survival [111]. Two forms of RRT are used, namely peritoneal dialysis (PD) and continuous renal replacement therapy (CRRT). PD is managed by placing a catheter into the peritoneal cavity, instilling solute into the cavity, and then removing it after a suitable length of time. It has advantages in that it requires no intravascular access, does not need heparinization, is well tolerated even during hemodynamically unstable periods, and may even remove proinflammatory mediators if used immediately after CPB [111]. Disadvantages of PD are the occurrence of peritonitis and that the removal of solution or electrolytes is a slow process. Advantages of CRRT include rapid removal of excess body fluid, treatment of life-threatening hyperkalemia, and ease in which the circuit can be placed in parallel with an ECMO circuit. In this setting CRRT is usually achieved by a venovenous circuit with the utilization of the internal jugular, subclavian, or femoral veins. In one study the results of this approach showed that in patients alive to discharge, up to 90% were discharged with normal renal function [112].

Endocrine Response to CPB

Patients undergoing cardiac surgery within the range of temperatures from normothermia all the way to deep hypothermia generate a significant hormonal stress response that involves both the sympathoadrenal pathway as well as the hypothalamic–pituitary–adrenal (HPA) axis. The interpretation of this release is problematic as there is considerable variability depending on age, nature of the surgery, and anesthetic technique [119]. In a study of 22 infants ranging in age from 2 days to 18 months with a mix of both cyanotic and acyanotic conditions who all underwent repair utilizing DHCA, the authors found that there was an increase in both epinephrine and norepinephrine. This increase persisted from the cooling phase through the warming phase and up to the end of the study, which unfortunately ended with chest closure. These findings led the authors to conclude that there is considerable sympathoadrenal stress associated with CPB and DHCA despite what appeared to be adequate anesthesia and analgesia. The nonlinear relationship between duration of arrest and the postarrest values possibly indicated that the tissues were beginning to become hypoxic, thus trending these values could suggest a safe time for DHCA [120]. Similar findings were found in both a clinical as well as an experimental study. In these investigations there was a small rise in levels with induction and surface cooling followed by a rise at the time of sternotomy. The levels had returned to near baseline at the time of DHCA with the same spike as seen in the aforementioned study with the onset of rewarming. The conclusions were also similar in that this rise could be related to either washout of products of metabolism indicating ongoing cellular metabolism or the onset of ischemia, or simply the washout of catecholamines produced during arrest [121,122]. It was found experimentally that epinephrine was released only from the adrenal whilst norepinephrine was released from the adrenal as well as from peripheral sources. Clinically, however, these elevations in catecholamines are of questionable significance.

The endpoint of the HPA axis (i.e., the secretion of glucocorticoids) is important in the setting of cardiac surgery as studies suggest that the effect of these glucocorticoids include: 1) enhanced vascular sensitivity to catecholamines; 2) increased myocardial β adrenergic receptors; 3) increased rennin substrate and calcium availability; and 4) inhibited vasodilation and catecholamine degradation. The end result of these factors may be that glucocorticoids enhance myocardial and vascular responsiveness to catecholamines. In studies performed on critically ill neonates, infants, and children with hypotension refractory to volume resuscitation as well as inotropic support, adrenal insufficiency was found with clinical improvement on administration of corticosteroids [123]. In an early study by Pollock and colleagues, the authors studied 20 acyanotic patients ranging in age from 1–16 years who presented for repair of lesions including ASD, VSD, canal defects, anomalous venous return, and aortic valve surgery. They divided the patients into two equal and comparative groups. The two groups were then exposed to either pulsatile or nonpulsatile flow, respectively, as the authors postulated that pulsatile flow would show a superior hormone response. However, this was shown not to be the case as both groups demonstrated normal corticosteroid responses. Although the initial focus of the study was on comparing the two forms of CPB and the effect on hormonal secretion, it could be concluded that despite the physiologic aberrancy of CPB the function of this axis remained intact [124]. In a recent study Gajarski and colleagues postulated that postcardiotomy infants with high vasopressor requirements would demonstrate adrenal insufficiency that would be proportional to CPB or DHCA times and vasopressors requirements. Although the results of the study did not demonstrate a difference between bypass techniques, a subgroup of patients was identified which demonstrated an apparent adrenal insufficiency. This subgroup, which was representative of both regular CPB and DHCA, demonstrated higher inotropic requirements, prolonged intubation, and prolonged ICU

stay. The authors concluded that despite the effects of CPB with or without DHCA, including the surgical stress, hemodilution associated with CPB, and lastly the concentrating effects of ultrafiltration, it appeared that in the majority of cases the HPA axis was intact [123]. Similar findings have been shown in other studies [125,126]. It appears that, at least in a subset of patients, the use of perioperative steroids would be of clinical benefit; however, the use of steroids in pediatric CPB is not routine and has indeed been questioned [127]. The literature shows that the question in to the use of peri-CPB steroids remains unsolved as there does not appear to be a consensus amongst different institutions into dosing, timing, or even whether or not to use these drugs [128–131].

Thyroid hormone levels have been found to become suppressed after critical illness and surgical procedures. This has the potential to cause a number of problems in the post-CPB period including prolonged ventilation, increased inotropic requirements, and increased need for diuretic therapy [132]. Several mechanisms have been proposed for this decrease. The stress of surgery itself may lead to a suppression of hypothalamic–pituitary axis. The effects of CPB, which include hemodilution, hypothermia, and the use of inotropic support, also lead to a decline. The release of endogenous mediators inclusive of glucocorticoids, tumor necrosis factor, and IL-6 are released in response to CPB and lead to low postoperative tri-iodothyronine (T3). Interestingly there is an initial surge of free hormone after the institution of CPB followed by low total and free T3/T4 levels. The nadir of this effect occurs between 12 and 48 hours after bypass and lasts up to 5 days [132,133]. At a cellular level the effect of thyroid hormone is to influence the entry and extrusion of calcium from the cardiac myocyte via the sarcoplasmic reticulum and cell membrane. Thus, the effect of low T3 is profound on myocardial function and may be manifest by both systolic and diastolic dysfunction and increased vascular resistance, which collectively are seen clinically as a low cardiac output state [133]. Treatment with T3 either as repeated bolus therapy or infusion in the immediate postoperative period has been shown to improve systolic, mean arterial blood pressure, and cardiac output, which in turn leads to improved renal perfusion and negative fluid balance [134,135].

The concentration of growth hormone (GH) has also been shown to increase secondary to CPB; however, there is no matching elevation in insulin-like growth factor 1 (IGF-1) or insulin-like growth factor binding protein 3 (IGFBP-3). The latter two proteins are the effector proteins for GH function. These findings indicate that, although GH secretion is appropriately elevated secondary to a stress response, the lack of effector protein elevation indicates an ongoing catabolic state that continues into the postoperative and recovery phases [136].

Hyperglycemia in the critically ill, adult patient is known to be associated with higher morbidity and mortality [137–139]. Hyperglycemia is a normal response to stress and with this is coupled the secretion of insulin, which aids the uptake of glucose into muscle where it is used for the ongoing production of energy. Surgery, with its associated stress response, results in an increase in counter-regulatory hormones (epinephrine, glucagon, growth hormone, and cortisol) as well as inflammatory cytokines (e.g., tumor necrosis factor and interleukins). The result is increased hepatic glucose mobilization, impaired peripheral glucose utilization, relative insulin deficiency, and, thus, hyperglycemia [139]. This is complicated by insulin resistance found in cardiac surgery patients. It has been found that during hypothermia glucose levels increase and insulin decreases. On rewarming glucose levels continue to rise with an associated rise in insulin as well as the previously described increase in catecholamine, cortisol, and growth hormone levels. These combined with increased inflammatory cytokines lead to the insulin resistance seen. In addition to these etiologic factors, the administration of corticosteroids and inotropes also plays a role. In three retrospective studies in the pediatric population, one of which was performed specifically in the cardiac population, the second in a general pediatric ICU (PICU), including postoperative cardiac patients, and the third in a large, tertiary care, general PICU, the conclusion appears to be similar to the adult studies – namely that hyperglycemia was associated with increased morbidity and mortality [140–142]. The differences, however, were that unlike in the adult experience where initial glucose level was associated with mortality, in the pediatric group it was the peak level as well as continued elevation that was associated with complications. The morbidities described in these studies included prolonged ventilation, prolonged ICU stay, and increased rates of infection. The unanswered question is what to do about the hyperglycemia, particularly in the immediate perioperative phase. The real concern amongst clinicians is for prolonged hypoglycemia and its effects on the brain. In an interesting study by Ballweg and colleagues, early postoperative hyperglycemia was not associated with worse neurodevelopmental outcomes at 1 year of age [143].

Systemic Inflammation

The perioperative period is a potentially deleterious time as the combination of anesthesia, the stress of surgery, and the immune-stimulating effects of the CPB circuit combine to result in a systemic inflammatory response. Indeed it has been found that certain patients, including those with single-ventricle physiology, may have an activated inflammatory response prior even to the commencement of CPB [144]. Possible etiologic factors responsible include: 1) cel-

lular activation with contact of blood products with the surface of the bypass circuit; 2) mechanical shear stress as the blood passes through suction systems and filters; 3) tissue ischemia and reperfusion; 4) hypotension and hemodilution; 5) administration of blood products; and 6) hypothermia (mild, moderate, and deep hypothermia) [104]. These factors will result in the activation of both humoral and cellular immune responses, which generate the activation of the complement, coagulation, and fibrinolytic pathways. Collectively these pathways result in endothelial damage, capillary leak, and organ dysfunction. In the literature, up to 50% of children have pulmonary and cardiovascular dysfunction attributable to this proinflammatory response in the post-CPB period [145]. The pediatric population may be at increased risk compared with the adult population as the body surface area to circuit size is greater.

Figure 10.7 demonstrates the effects of surgical trauma and CPB [145]. Complement activation occurs by both the alternative (contact with foreign surfaces, i.e., bypass circuitry) and classical pathways (protamine related). These two pathways result in the elevation of C3a and C5a; and C4a with additional C3a respectively. Elevations of C3a and C5a lead to activation and degranulation of neutrophils, release of histamine from mast cells and basophils, and platelet aggregation. These elevations have been associated with poor outcomes with severe organ dysfunction, prolonged mechanical ventilation and poor outcome [104,146]. Contact activation of clotting factor XII results in the eventual activation of kallikrein and bradykinin. The effect of increased kallikrein is the positive feedback on the activation of more factor XII whilst the increased bradykinin results in the stimulation of B1 and B2 receptors. The effects of their stimulation is the production of nitric oxide, free radicals, eicosanoids, and cytokines. This will result in vasodilation and increased capillary permeability which in turn may lead to organ dysfunction [144,147]. B2 receptors have also been found in the brain and this may play a role in the genesis of ischemia–reperfusion injury [104]. Cytokines are produced by a wide range of cells including monocytes, macrophages, lymphocytes, and endothelial cells. These factors are either proinflammatory in the form of IL-6, IL-8, and tumor necrosis factor α (TNFα) or anti-inflammatory in IL-10 and IL-1 receptor antagonist (IL-1ra). An increase in TNFα has been demonstrated to be associated with increased capillary leak [147]; however, other studies have failed to show any significant increase [145,148]. Elevations in IL-6 and IL-8 have been shown to correlate with compromised post-bypass cardiopulmonary function with increased inotropic requirements, severe capillary leak syndrome, and an increase in mortality [104,144,145,148]. The balance therefore between the proinflammatory and anti-inflammatory responses may thus be altered in those who demonstrate an aggressive systemic inflammatory response. In uncomplicated cases the systemic inflammatory response is self-limited and is only of a few days' duration [145].

The question that now begs answering therefore is what can be done to prevent initiation of this inflammatory process. Several therapeutic maneuvers have been proposed

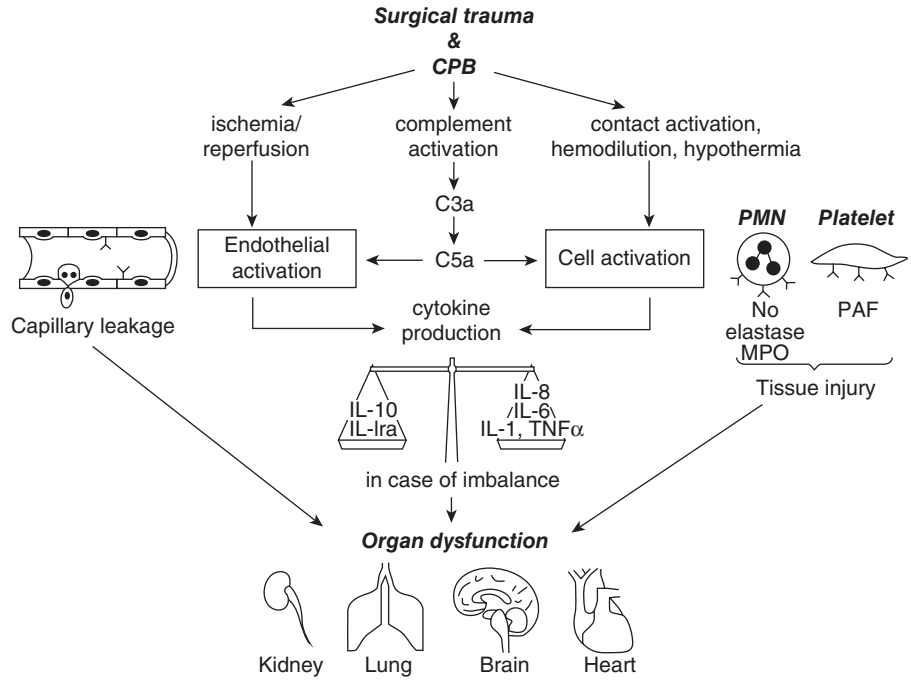

Figure 10.7 Illustration of effects of surgical trauma and CPB. Schematic representation of important mediators of the inflammatory response to surgical trauma and cardiopulmonary bypass (CPB). The different processes have a synergistic effect and may lead to organ dysfunction. (Reproduced with permission from Brix-Christensen [145].)

including the addition of steroids into the pump prime, the use of indomethacin, aprotinin, heparin-coated CPB circuitry, and the use of ultrafiltration [131]. The administration of steroids into the pump prime seems a logical therapeutic measure; however, data supporting this were derived from adult patients undergoing coronary artery bypass grafting [127]. Studies in the pediatric population have demonstrated variable results and indeed there does not appear to be agreement into timing or dosing of steroids, which may indicate the lack of data looking at dose, timing of dose, and clinically significant improvements after administration [129]. In one study there were measurable differences in the degree of inflammatory markers found between the 15 test subjects and the 14 controls. Although the age at the time of surgery, the CPB times, and the aortic cross-clamp times were similar in this study they did not reach statistical significance. The authors found that in the steroid group there was a decrease in the concentration of IL-6 and TNFα. They noted, however, that these decreases were after the initiation of bypass and before MUF in the TNFα group and after the removal of the cross-clamp in the IL-6 group. The concentration of C3a, however, was no different in both groups. In terms of clinical effect the steroid-treated group had lower alveolar arterial oxygen differences, lower temperatures (due to lower cytokine levels), required less supplemental fluid in the first 24 hours, had better renal function, and had less ICU time [149]. A further study looking into the effects of administration of preoperative steroids (methylprednisolone 30 mg/kg) 4 hours before surgery as well as intraoperatively compared with a cohort that received only intraoperative steroids found that the group who received two doses were at a laboratory (in the form of reduced levels of IL-6 and IL-10) as well as a clinical advantage as outlined in the first study [150]. Results of other studies have not, however, shown positive results. In a study that included patients ≥3 months of age but weighing ≤7 kg, 24 patients were given steroids while 26 were not. The strengths of this study included comparable age and surgical matching and the fact that all patients given steroids were operated on at one hospital while those who did not receive steroids were at another hospital. An obvious weakness of the study was that the dose and timing of the steroids were not mentioned in the study. Despite these factors the investigators found no differences in the inflammatory or clinical markers between the groups [127]. Possible explanations included that the patients had shorter CPB times, less surgical trauma, and dose and timing of the steroids. As has been indicated elsewhere in this discussion a large, randomized, prospective study is essential to properly elucidate this question.

Aprotinin, a serine protease inhibitor, was reported to be efficacious in the preservation of platelet function, to decrease bleeding diatheses associated not only with CPB but also other surgeries including spinal surgery, and also to have anti-inflammatory effects. Studies concluded that its use had beneficial effects on post-CPB organ function and improved hemodynamic stability. However, after published data in the adult literature suggested that there was a risk of thrombosis and renal failure with its use, the drug was voluntarily removed in November 2007 [151,152]. In the pediatric literature safety studies looking at these effects failed to concur with the adult studies [153,154]. As with many clinical questions in the literature some studies even questioned the drug's efficacy [155,156]. Aprotinin is, however, not available for clinical use.

As has been mentioned it is widely understood that the bypass circuit itself is probably the main culprit in inciting the inflammatory cascade. Following on this, two strategies have been used: miniaturization of bypass circuits (which will be discussed later) and the coating of the circuit in an attempt to make it more biocompatible. Other strategies that have been used by clinicians in an attempt to minimize the inflammatory effects include the use of aprotinin (which is no longer available for clinical use), ultrafiltration, the use of biocompatible circuits, and the use of smaller circuits. The latter three strategies will be discussed in greater detail in later sections. The conclusion that can be drawn from this discussion, however, is that it appears that a multimodal strategy is essential to decrease the deleterious effects of the multisystem inflammatory cascade that is incited during CPB.

Management of Cardiopulmonary Bypass

The trend in modern pediatric bypass equipment is to reduce the size of the extracorporeal circuit to reduce the prime volume. The priming volume may actually exceed the blood volume of the neonate by as much as 200–300%. This is in contrast to the adult CPB patient where the priming volume accounts for only 25–33% of the patient's blood volume. The effects of CPB have led surgeons to perform operations without the use of CPB and for interventional cardiologists to close ASDs and VSDs in the catheterization laboratory [157–162]. Indeed some undertake a hybrid approach for closure of VSDs, and other procedures such as stenting of the pulmonary arteries, in which the surgeon will obtain direct access to the heart and the procedure is performed using transcatheter techniques, often in conjunction with an interventional cardiologist [163].

Hemodilution

Research into the effects of CPB on the inflammatory cascade and organ dysfunction that occurs in the post-bypass period have also found that the use of blood products play a significant role in the inflammatory cascade.

These effects include an elevation in complement and inflammatory cytokines [164]. The use of blood in the pump prime, especially in neonates, infants and patients who will undergo DHCA and hypothermic low-flow bypass, is based on earlier published data that suggested that a hematocrit (HCT) of between 20 and 25 was associated with acute and long-term sequelae [165]. Acutely there appeared to be lower minimum cardiac index in the post-CPB phase, higher serum lactate levels at 60 minutes post-CPB, and a greater increase in total body water in the first postoperative day. At 1 year of age this same group tested lower in absolute number on the Psychomotor Development Index; a greater number of subjects also tested 2 standard deviations from the population mean. These authors concluded that an HCT diluted down to 20% was associated with the inferior results shown above; the optimal HCT above 25 could not be identified. In a further study of a cohort of patients undergoing two-ventricle and nonaortic arch surgery by the same group of researchers from Boston Children's Hospital, there appeared to be a point at an HCT of 23.5% where the 1-year psychomotor outcome was better than that below 23.5%. The authors noted that it was not possible to conclude, however, that there was an absolute safe HCT owing to the presence of confounding variables between subjects, for example age at operation, diagnosis, etc. [166]. A further study comparing HCT of 25% to HCT of 35% was also undertaken. Apart from a greater intraoperative fluid accumulation with lower HCT there were no reported differences between groups both in the early postoperative as well as at 1-year neurodevelopmental follow-up periods [167]. Thus, a conclusion that may be drawn is that an HCT of ≥25 may be adequate. At our institution we keep the HCT ≥30 in patients ≤1 year and ≥25 in those ≥1 year, irrespective of congenital abnormality. Based on this, blood is added into the prime volume so as to maintain the HCT at these levels that appear to be associated with improved outcomes.

Circuit Miniaturization

The desire to maintain HCT at these levels and also the previously mentioned discrepancy between patient size and circuit has lead researchers to attempt to miniaturize circuits, even for use in neonates. This has the advantage of not only decreasing the total surface area to which the patient will come into contact but also raising the possibility of bloodless prime. Methods that may be used to achieve this include using biocompatible coated circuitry and oxygenators, the use of vacuum-assisted venous drainage, the ability to decrease circuit length by bringing the pump as close to the patient as possible, and, finally, the exclusion of certain circuit components, for example arterial line filters and in-line cardioplegia [168].

Table 10.7 Properties of the ideal circuit. (Reproduced with permission from Janvier *et al.* [169].)

Inability to initiate thrombogenesis
Inability to initiate hemolysis
No complement activation
No toxicity of products extracted from the circuit by the blood
Chemical inertness so that no toxic metabolites generated

Biocompatible Circuits

As mentioned elsewhere the initiation of CPB will result in the activation of the five proteolytic plasma systems (coagulation, fibrinolysis, complement activation, kallikrein–kinin, and contact systems) and the cellular components (leukocytes, platelets, and endothelial cells). Thus, the theoretical ideal is to use surface modification of a circuit and thus dampen the response. Table 10.7 describes the ideal biocompatible circuit [169]. Surface modification can be achieved by four techniques: coating, chemical modification, attachment of macromolecules, and by blending of polymers [170].

The coating method will coat the surface of the circuit with another polymer thus attempting to reduce protein adsorption. The chemical modification technique uses a selected chemical group on the surface of the circuit to replace with another. In the blending method the surface polymers are altered to create hydrophilic/hydrophobic or natural/synthetic polymer combinations.

Polymethoxyethylacrylate (PMEA) (Terumo Medical Corporation, Somerset, NJ) consists of a hydrophobic polyethylene backbone with hydrophilic methoxyethyl pendant groups that have no chemically functioning attachments. Theoretically PMEA will not react with platelets and clotting factors, thus maintaining their number and function and reducing adsorption of proteins to the circuit surface, thus decreasing the inflammatory cascade. In two studies in the pediatric population there were some advantages to the PMEA-coated circuits with respect to a decreased activation of the inflammatory cascade as measured by neutrophil elastase activity and a decrease in the coagulation activation as measured by thrombin-antithrombin complexes [171]. Both of these studies interestingly found that there was no significant difference in the platelet number between the study and control group. This may indicate that these circuit alterations are ineffective with respect to platelet protection or that in the pediatric population factors other than contact activation are important. These factors may include platelet interactions with inflammatory mediators such as complement, leukotrienes, and collagenases. Limitations to these studies, however, included their small number of patients and that they tested the effects of these circuits alone and not in concert with antifibrinolytics, steroids, or modified ultrafiltration [171,172].

Phosphorycholine is used as a coating over the existing tubing material. It is marketed by Avant, Dideco, Mirandola, Italy, as Phisio and also incorporated into the SMART circuit, which is a combination of phosphorycholine coating and polycaprolactone–polydimethylsiloxilane additives to the base polymer resin of COBE (Cardiovascular, Inc., Arvada, Colorado). The mechanism of action of this coating is to mimic the surface of cell membranes within the vascular wall. The result is to attempt to decrease the thrombogenic and inflammatory responses as well as microbial adhesion to the surface of the circuit. An in vitro study performed by Hoel and colleagues comparing uncoated and Phisio-coated circuits showed no apparent differences in their effects on inflammation but there was a trend toward a lesser decrease on the platelet count in the coated group [173]. In another study the authors noted that the prime volume was large and that the hemodilution may have overshadowed any improvement in platelet number or function [172]. In this study the authors compared uncoated versus PMEA and phosphorylcholine circuits; they found no differences related to platelet count or function and also importantly no improvement in postoperative outcomes, suggesting that these circuits may not have had any effect on the inflammatory cascade either.

Heparin has been used as a component of the circuit in both adult and pediatric circuitry. Two examples of this are the biopassive surface from Medtronic, Minneapolis, Minnesota, and a heparin plus polymer coating from Gish Biomedical, Inc., Rancho Santa Margarita, California. The former consists of a polymer priming layer that is bonded to the surface of the circuit with the second polymer comprising a sulphate/sulphonate group and heparin. In the latter example a hydrophilic biopolymer binds to the circuit to which in turn heparin is bound. The use of this coating has been studied widely and appears to have some beneficial effect on the inflammatory response in children on CPB as measured by inflammatory markers directly as well as clinically by increased urine output and less time postoperatively requiring mechanical ventilation [174,175]. In both of these studies there was no mention of the use of any further methods to decrease the inflammatory response (i.e., antifibrinolytics, steroids, or the use of modified ultrafiltration). In a further study where heparin-coated circuits were compared with phosphorylcholine-coated circuits the results showed that there was a comparable decrease in inflammatory markers in both. In this study patients were divided into three groups. The first group had a 750-mL prime volume within a heparin-coated circuit whilst the other two groups used phosphorylcholine-coated circuits with 450-mL and 750-mL priming volumes, respectively. The authors noted that despite randomization the 750-mL phosphorylcholine group were a younger group of patients and displayed worse clinical outcome with respect to capillary leak, prolonged ventilation, and inotropic support. Once again the care did not include antifibrinolytics or modified ultrafiltration [176]. Clearly future studies need to be directed at the use of small volume prime and anti-inflammatory adjuncts.

Circuit Design

The use of smaller circuit size and thus prime volume is aimed at decreasing hemodilution, which in theory will result in lower numbers of transfusions, decreased severity of the inflammatory response, and thus reduced hospital costs related to improved outcomes [177]. Techniques that investigators have used to create these smaller circuits have included: low prime volume oxygenators, reservoirs, and arterial filters; shorter extracorporeal circuitry, remote pump heads, use of venous vacuum (which can in turn result in the use of smaller venous tubing), and in certain configurations removal of parts of the classic circuit, most frequently the arterial line filter [164,177–182]. These investigators have demonstrated safety even in the neonatal population with priming volumes as low as 110 mL. In the descriptions of these configurations the bypass circuit is placed at the operating room table with the surgeon and assistants almost straddling the circuitry (Figure 10.8) [179].The use of this technology clearly needs total team acceptance and understanding.

Surgeries performed in these case series range from relatively simple procedures (e.g., VSD or ASD closure) to cor-

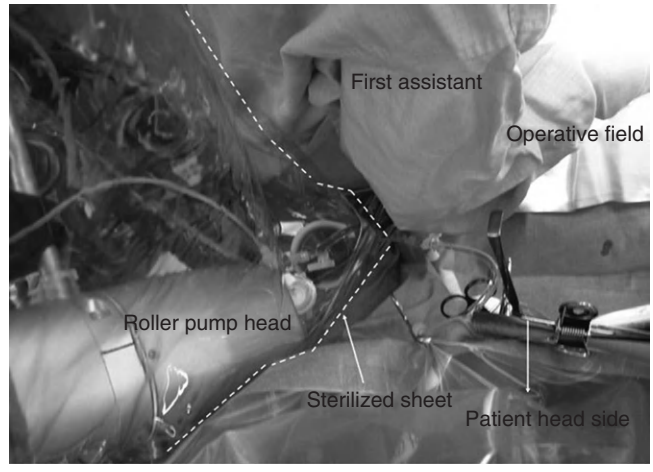

Figure 10.8 Operating field in cardiopulmonary bypass. Arrangement of the operating room and the sterilized polyvinyl chloride sheet is close to the first assistant's right elbow and functions as a protective barrier between the patient and the unsterilized CPB unit. The arterial, venous, and suction circuits are attached to the sheet. (Reproduced with permission from Miyaji *et al.* [179].)

rection of transposition of the great vessels, aortic arch hypoplasia, and even stage 1 Norwood procedures. In one of the studies there were descriptions of patients undergoing arterial switch, hypoplastic arch reconstructions, and interrupted aortic arch with VSD repairs without blood transfusions. Possibly the most startling fact of all was that one of the babies that underwent arterial switch operation weighed only 1.7 kg. These strategies clearly will lead to a degree of hemodilution, which is counter to what has been described earlier in this discussion. The patients were, however, monitored by using hemoglobin concentration, mixed venous saturation, regional cerebral oxygenation, and on-pump plasma lactate. Values of <7 g/dL, <70%, <50%, and >4 mmol/L, respectively, were used as transfusion triggers [179,181].

Laboratory experiments using neonatal piglets have demonstrated improved cardiopulmonary function post-deep hypothermia using miniaturized circuitry with asanguineous prime. The investigators found decreased TNFα, and the effect of primed neutrophils present in donor blood were of course absent. It has been found that these neutrophils are key factors in the genesis of the CPB-induced inflammatory cascade and capillary leak leading to organ dysfunction. Further analysis found improved right ventricular cardiac index, improved pulmonary vascular resistance index, and improved dynamic pulmonary compliance. The authors concluded that these could be attributed to a decrease in total lung water associated in turn with decreased inflammation [183]. In a separate study by the same group of investigators they were able to demonstrate improved CBF in a group of piglets that underwent CPB with the miniaturized circuit configuration. They demonstrated that the use of an asanguineous prime was associated with a decrease in the no-reflow phenomenon discussed earlier in the chapter. They further postulated that this may result in improved neurologic outcome [184].

Oxygenators

In the pediatric population, oxygenators must provide efficient gas exchange over a wide range of temperatures (10–40 °C), pump flow rates (0–200 mL/kg/min), hematocrit as low as 15%, line pressures, and gas flow rates. Both bubble and membrane oxygenators can achieve effective gas exchange under these diverse conditions. Historically three different types of oxygenators have been used, namely the film type, bubble type, and membrane type. In the film type a thin blood film is created with gas exchange taking place on the surface of the film. In this method there is no mechanical introduction of gas into the blood and thus trauma to red blood cells is minimal; however, a large surface area is necessary with a large priming volume. The bubble oxygenator uses bubbles introduced directly into the blood. It has advantages in that the effective surface area for gas exchange is large due to the surface area of the bubbles. The obvious disadvantage, however, is that the introduction of the bubbles causes red blood cell trauma. In addition to this the bubbles must clearly be removed from the circuit and this requires a settling chamber, which may in turn require added volume in the circuit. The final oxygenator is the one that is most widely used today. In this technique the blood is exposed to oxygen through a gas-permeable membrane and thus, because there is no direct contact between gas and blood, trauma is minimal [14]. Refinements in early membrane oxygenator design occurred in the 1980s with the introduction of microporous hollow fibers with blood flowing over the outside of the fiber and gas flowing down the fiber lumen. This increased the efficiency of gas exchange and at the same time decreased manufacturing costs in line with the cheaper bubble oxygenators [185].

Common to all CPB circuits are the presence of gaseous micro-emboli that have their genesis secondary to the following: pulsatile bypass, low venous reservoir levels, vacuum-assisted venous drainage, venous line air, field suckers, drug administration, and blood sampling. Perfusionists may use a number of methods to decrease this, ranging from filtration at the time of circuit set up, to ensuring adequate volumes within the venous reservoir and the placement of arterial line filters. Unfortunately, as has been mentioned before, the arterial line filter may add significant volume to the circuit. The use of arterial line filters has been reported in up to 96% of North American centers, whereas in Europe it has not been commonplace for a number of years [186]. The appropriate sizing of oxygenator for the pediatric population has been a focus in recent years as reducing the dimensions of this integral part of the CPB circuit will lead to significant reductions in prime volume. The first oxygenator designed specifically for the use in the neonatal population was the Dideco Kids D100 Neonatal Oxygenator (The Sorlin Group, Mirandola, Italy), which was initially evaluated in the USA at Duke University. The initial group of babies totaled six: two undergoing Norwood stage 1 palliations, two truncus arteriosus repairs, and two arterial switch operations. The investigators noted that the total priming volume for the oxygenator was only 31 mL and this enabled the priming volume of the circuit to be decreased by 12.5%. The change to this oxygenator did not compromise oxygenation and apart from the 1 unit of packed red blood cells (PRBC) and fresh frozen plasma (FFP) originally added as the prime no further blood products were used to maintain a hematocrit >35% [187]. As described above, the prime volume associated with the arterial line filter is significant adding between 20–40% in volume [186]. The Terumo Medical Corporation, Tokyo, Japan, have manufactured a miniature oxygenator, the CAPIOX® RX05 Baby RX™ Oxygenator, which has a prime volume of 43 mL with an added advantage of having

an integrated arterial line filter. The group investigating it found that it was easy to use, decreased the number of gaseous emboli, and did not increase prime volume in their miniature circuit set up when compared to their regular oxygenator [186]. It can thus be appreciated that newer-generation neonatal oxygenators have an advantage in that they are specifically designed for this patient population, are easy to use, and have the benefit of small prime volumes that enable teams to attempt to achieve the goal of asanguineous prime.

Initiation of Cardiopulmonary Bypass

Before the initiation of surgery and CPB the entire team must plan strategy for the safe undertaking of the planned procedure. The surgical team ensures that the proper instrumentation is available, that the lines that will be used for the bypass are appropriately sized and that they are cut to appropriate length under the direction of the surgeon. In addition to this the surgical team assembles the appropriate mechanical or tissue valves and thaws homograft tissue patches that may be required by the surgeon for specific repairs (e.g., pulmonary artery patches or aortic augmentation). From the anesthetic perspective, apart from ensuring the patient transitions smoothly from spontaneous to controlled ventilation, the patient will be intubated for the procedure. The question of whether the patient is to be intubated orally or nasally is practitioner and institution dependent. In addition the anesthesia team will place peripheral intravenous lines, and invasive monitoring in the form of an arterial line with or without central venous line. Central venous catheters are also institution dependent with some groups avoiding them in favor of direct intracardiac lines being placed by the surgeon before termination of CPB. The reasoning is to avoid any thrombosis to the central veins, particularly in single-ventricle patients whose venous drainage from the head and neck is integral to survival. Other preparations include the placement of Foley catheters, the adjustment of the temperature of under body cooling blankets, the placement of topical cooling in the form of ice bags to the head (in those undergoing DHCA) and the placement of further monitoring (e.g., EEG, cerebral oximeters, or transcranial Doppler).

The surgeon must plan a strategy that will best enable repair of the given defect. Factors that need be considered include the potential for the use of DHCA, accessing defects through the right side of the heart, whether or not an aortic cross-clamp will be necessary, and if the size of the child being operated on will influence cannulation strategy. Options available to the surgeon include dual caval cannulation for patients having repairs of ASD, VSD, atrioventricular canal defects, tetralogy of Fallot, and transposition of the great vessels with VSD; single venous cannulation for mainly those cases in which DHCA will be employed including augmentation of the aortic arch, Norwood stage 1 palliation, cavopulmonary anastomosis, and Fontan completion to name a few. In these cases CPB is used as a method to effectively decrease patient temperature. Once this has been achieved circulation is shut down and the cannulae are removed so that the repair may take place in a bloodless field. Importantly to this population group is meticulous de-airing of the circuit to avoid cerebral air embolus, keeping in mind that air may cross any of the intracardiac shunts.

As with the institution of CPB in the adult population, it is essential to check that the cannulae are appropriately positioned before going on to CPB. This will include the correlation of the pressure in the aorta with the invasive arterial line and that the venous cannulae are in the correct direction and that they are not potentially abutting the wall of either vena cava or right atrium. Once the patient is placed on to CPB, ventilation will cease and it is thus important to observe the oxygenation difference between the venous and the arterial cannulae as well as the SvO_2, which is measured from the bypass circuit. Table 10.8 lists both direct and indirect measures of adequate perfusion. Based on this list of measures there is a number of management strategies that may be employed should there be indicators of decreased perfusion. The perfusionist will ensure that the cardiac index is adequate based on the patient's weight or will increase MAP with the use of vasopressors agents. In the event that the cerebral saturations or SjO_2 decrease it is imperative that the surgeon check for correct placement of both arterial and venous cannulae. The arterial cannula may be directing blood away from the head vessels and the venous cannula may be positioned that it is causing obstruction to venous drainage from the head and thus decreasing cerebral perfusion pressure (CPP), which is calculated by CPP = MAP − ICP (or jugular venous pressure). Thus we see that alterations of either the arterial inflow or obstruction of outflow may result in a decrease in perfusion pressure. Other important factors that must be assessed are adequacy of hemoglobin concentration/hematocrit and oxygenation.

Anticoagulation

At birth concentrations of the vitamin K-dependent clotting factors (II, VII, IX, X); contact factors (XI and XII); and the anticoagulant and inhibitory factors (antithrombin III, protein C, protein S, CI esterase inhibitor, and plasminogen) are all reduced. The mechanisms may include decreased hepatic synthesis or increased clearance secondary to increased metabolic rate [156,188]. Despite these apparent abnormalities normal neonates have preserved coagulation function. The same cannot be said, however, for patients with cyanotic heart disease. This patient group is known to have impaired coagulation before surgery on the basis of polycythemia, abnormal platelet count and function, decreased factor concentration (V, VII, and VIII), and increased fibrinolysis [188,189]. Table 10.9 lists factors that are associated with coagulopathy in neonates and infants presenting for surgery with CPB [188].

As has been mentioned, the institution of CPB will result in activation of the clotting cascade; thus therapeutic anticoagulation is vital to prevent the formation of clot within the circuit and the disastrous effects of possible thromboembolism into the arterial tree. The anticoagulant universally used in both adult and pediatric CPB is heparin. At the Children's Hospital of Philadelphia the patient is given 200 IU/kg either by the surgeon as a direct injection into the right atrium or by the anesthesiologist into a peripheral intravenous site. Other institutions use between 300 and 400 IU/kg. The goal activated clotting time (ACT) is ≥480 seconds. This is based on early work by Bull and colleagues who formulated a heparin-protamine dose-response curve in the attempt to avert the use of either excess heparin or protamine [190]. Heparin works by binding to antithrombin III (ATIII) resulting in a conformational change in the enzyme and enhancing its activity. Under normal conditions there is a continuous balance between coagulation and anticoagulation within the body.

Procedure-independent factors	Procedure-dependant factors
Ductal dependent flow	Hemodilution
Cyanosis	Hypothermia
Prematurity	DHCA
Low cardiac output	Redo surgery
Neurologic injury	Prolonged CPB
Sepsis	Use of prosthetic material
Malnutrition	Low cardiac output

ATIII functions to inactivate thrombin and other proteases, most notably Factor Xa, thus preventing ongoing propagation of the clotting cascade. The effect of heparin on ATIII is to increase its efficacy by a factor of a thousand. As mentioned earlier the level of ATIII is decreased in neonates and only will reach adult levels by 3–6 months. Patients in this age group may be at risk for inadequate anticoagulation. However, it has been found that there are two other thrombin inhibitors, namely heparin-cofactor II and α-2-macroglobulin, and indeed the concentration of α-2-macroglobulin in neonates and infants is twice as high as that of ATIII. Guzzetta and colleagues tested a group of patients with ages from the neonatal to more than 10 years of age. Interestingly they found that despite these concerns, statistically significant prolongation in the ACT and the heparin dose–response relationship occurred in the neonatal group. The authors postulated that this could be on the basis that either neonates generate less thrombin or that ACT is a poor indicator of anticoagulation in this age group. This could be explained by the fact that these neonates already have in place umbilical or central lines and many have had interventions performed in the cardiac catheterization laboratory that triggered hemostatic activation. It would thus seem unlikely that thrombin production is lower in this age group. The ACT as an indicator may play an important role for a number of reasons. Firstly the ACT value does not correlate with the heparin concentration on CPB, secondly hypothermia and hemodilution may cause inaccuracy, and thirdly the decreased levels of contact activation factors (factors XII and XI, prekallikrein, and high-molecular-weight kininogen) may complicate the interpretation of prolonged ACT [191]. Studies have shown that despite an adequate ACT and a lack of visible clot there may indeed be thrombin generation at a cellular level, which may lead to increased platelet binding and also decreased levels of factor VIII. Based on these factors investigators have suggested that a protocol based on heparin concentration may be more effective [192,193]. In a separate study Guzzetta and colleagues found that with the heparin concentration technique there was decreased thrombin generation as well as preserved factor VIII levels, suggesting improved anticoagulation. The authors did, however, indicate that this higher heparin concentration method lead to increased blood requirements [192].

A concern in patients who present for repeat cardiac surgery is the incidence of heparin-induced thrombocytopenia (HIT) in the pediatric population. There are two forms of HIT. HIT-1 is characterized by a transient early onset of a nonimmune-mediated decrease in platelet count that does not require the discontinuation of heparin. HIT-2 is characterized by an immune-mediated decrease in platelet count by >50% [194]. In the adult cardiac experience the quoted incidence of this phenomenon post CPB is 1–3% with a thrombotic morbidity of between 38% and 81% and

a mortality of 28% [195]. The syndrome itself is an immune-mediated syndrome of platelet activation resulting in thrombocytopenia and diffuse venous and even arterial thrombosis. Thrombocytopenia will occur some days after the exposure to unfractionated heparin with platelet counts dropping to between 20 and 100×10^9/L. It is important, however, to be mindful of any drop in the platelet count as a drop in the count by 50%, even if the count is still in the normal range, is considered to be of significance. The antibodies are formed against platelet factor 4 (PF4) that is found on the surface of activated platelets as well as on endothelial cell surfaces secondary to heparin exposure. The presence of these antibodies occurs in up to 50% of adult cardiac surgery patients but only the quoted 1–3% will go onto develop the syndrome [195]. This seems to suggest that, although the platelet antibody is itself common after CPB, this in and of itself does not infer increased risk. It should, however, be noted that a positive antibody with thrombocytopenia places the patient at increased risk of developing HIT. In the adult population it seems that in those with a positive antibody the incidence of developing HIT is <10% [196]. The older pediatric population shows an incidence of a 50% positive antibody screen at the 10-day mark postoperatively [196]. In a case series of neonates, infants, and young children there were 10 cases of HIT with associated thrombotic complications [197]. These authors concluded that based on their experience, the incidence of HIT was equal to that in the adult population being 1.3%. In a separate study patients undergoing second surgeries were screened for presence of PF4 antibodies. The results once again echoed the prior studies in that there were 2/144 patients or 1.38% [198].

What are the alternatives to the use of heparin in a pediatric patient with a history of HIT or indeed HIT with associated thrombosis? In this regard three possible alternatives are available: 1) the use of an alternative anticoagulant with the complete avoidance of all heparin both intra- and postoperatively; 2) standard heparin anticoagulation with a platelet antagonist; and 3) waiting until the disappearance of HIT antibodies and proceeding with heparin anticoagulation [199]. A number of drugs are available for anticoagulation and are listed in Table 10.10. Of these aforementioned drugs it appears that only lepirudin and argatroban have been used to any degree. As they are both direct thrombin inhibitors they both work by directly and reversibly binding to the catalytic site of thrombin thus inhibiting the conversion of fibrinogen to fibrin. Successful use of both of these agents has been described in the literature in a wide range of procedures and ages. The advantage of the use of argatroban is that it is metabolized in the liver and can thus be used in patients with renal failure (lepirudin is renally excreted), can be monitored by ACT and has a half-life of <60 minutes. As HIT is a significant clinical problem but with a relatively low occurrence large clinical studies have not as yet been performed and thus dosing protocols are not standardized. Argatroban is used as an infusion with initial rates varying between 2 and 65 μg/kg/min. The use of an initial bolus was used inconsistently with a range of 35–750 μg/kg in divided doses. To maintain the ACT in the appropriate range further bolus doses of 20 μg/kg were used. The major adverse events related to these nonstandardized regimens were abnormally prolonged ACT and bleeding. There is no reversal drug as with heparin-protamine and thus the patient would require transfusions and even the use of factor VII [194,200,201]. Lepirudin has also been used for CPB although it may be more difficult to use based on its longer half life of 40–80 minutes, the need for ecarin clotting time (ECT) and renal excretion. It is also possible to monitor lepirudin with the activated partial thromboplastin time (aPTT) but this test would take too long in the setting of CPB. Just like with argatroban there is no reversal agent. Dosing of this agent follows the adult dosing of a bolus of 0.25 mg/kg and 0.2 mg/kg into the CPB circuit although a single group suggested increasing these doses due to a greater volume of distribution [198,202,203].

At the termination of CPB and as the cannulae are being removed protamine will be administered to reverse the anticoagulation owing to heparin. As with many areas in practice there is a range of dosing used in the clinical arena. As mentioned at the Children's Hospital of Philadelphia the heparin dosing is 200 IU/kg and for reversal the protamine dosing is 4 mg/kg with a maximum of 100 mg. This works out to be a ratio of protamine to heparin of 2:1 based on 1 mg of protamine to 100 IU (sometimes referred to as 1 mg) of heparin. In a survey of units within Great Britain and Ireland there was a reported ratio of 0.3:1 to 2:1 after a uniform heparin dose of 300 IU/kg. In adult cardiac surgery adverse reactions to the administration of protamine are well known and include anaphylactic and anaphylactoid reactions as well as pulmonary hypertensive events. The clinical result is a range from minor hypotensive events to fatal cardiovascular collapse. Although cata-

strophic events are rare, adverse events occur in up to 2.6% of adult patients [204]. Risk factors for adults include the use of protamine-containing insulin, previous drug reaction or exposure, vasectomy, rate of infusion, and allergy to protamine or fish. Pediatric patients, however, have different risks as they have less frequent or shorter exposures to cross-reacting antigens and lesser sensitivity to pulmonary intravascular macrophages to heparin–protamine complexes [205]. A study looking at the incidence in the pediatric population ≤16 years of age found that in a series of 1249 anesthetics the incidence of hypotension that persisted for >5 minutes was in the order of 1.76%. The authors noted that this might have included causes other than a protamine reaction due to the proximity to termination of CPB. Of interest in this study were the associated risk factors for hypotension namely: female sex, large dose of protamine, and a small heparin dose. The reason for the female sex being a risk could not be explained [205]. In a case report describing severe pulmonary hypertension, hypoxemia, and cardiovascular collapse after heparin reversal it appears that large protamine dosing of 10.7 mg/kg after an initial event and a subsequent 5.8 mg/kg after a second event were the etiological factors. Also of note was the female sex of the patient. This patient required inotropic support, jet ventilation, intravenous prostacyclin, and inhaled nitric oxide, but subsequently made a complete recovery [206]. In summary in relation to this reaction vigilance when giving any patient any drug cannot be overemphasized.

Termination of Bypass

In termination of CPB a number of important criteria need to be met. These will need to be identified and treated concomitantly at a time when the patient's clinical condition may be extremely tenuous.

General Principles

Before the termination of CPB an adequate cardiac rhythm must be established and if the native rhythm is inadequate either by rate or rhythm itself the heart will need external stimuli in the form of atrial and/or ventricular epicardial pacing. The use of inotropic support will obviously depend on the case, the presence of preexisting myocardial dysfunction, and the duration of CPB. In the pediatric setting this may take the form of dopamine, epinephrine, and milrinone but under certain circumstances vasopressin may be necessary. Concomitant with this will be the re-expansion of the lungs and resumption of ventilation. It is important that the lungs are fully re-expanded as atelectasis will lead to not only hypoxemia but also direct compression of the pulmonary bed. The combination of these two factors will lead to an increase in pulmonary artery pressure. In the neonate who already has an extremely reactive pulmonary bed this may lead to a spiral of increasing hypoxia, worsening pulmonary artery pressure, and subsequent right ventricular failure, which may necessitate placing the patient back onto CPB or even ECMO. The principles of preventing this phenomenon include adequate ventilation as eluded to above, ensuring adequate oxygenation, avoiding hypothermia, avoiding acidosis, the use of the phosphodiesterase inhibitor milrinone, and, as a last resort, using inhaled nitric oxide as a direct pulmonary artery vasodilator.

Hypothermia

If the procedure was performed at anything but normothermia the patient needs to be rewarmed to normal. Hypothermia may result in a wide range of abnormalities. Experimental evidence suggests that hypothermia will result in a negative inotropic effect at the atrial level, an effect that may be detrimental at the termination of CPB as normal atrial function is an important contributor of ventricular preload [207]. Hypothermic effects on ventricular function include bradycardia, heart block, reduction of fibrillation threshold, and an increase in pacing threshold. These effects may occur even at moderate hypothermia [205]. Termination of CPB necessitates adequate heart rate that may require external pacing and thus normothermia is vital. Another important problem related to hypothermia in the cardiac surgery patient is the effect that it has on bleeding. It appears that hypothermia will affect both platelet function as well as the coagulation cascade. The defect in platelet function is related to an impaired release of thromboxane A2, which is necessary for the formation of the platelet plug. The coagulation is affected by a temperature-dependent decrease in enzyme function. These effects may occur at even 1–2 °C below normal [208,209]. Even if patients are normothermic on termination of CPB, for obvious reasons it is imperative to keep patients warm thereafter as temperature may drift downwards soon after resumption of spontaneous circulation placing them at risk once again.

Bleeding

The origins of the ongoing coagulopathy upon termination of bypass are multifactorial and include cascade activation due to CPB, therapeutic hypothermia as part of CPB, dilutional, consumptive, and due to ongoing bleeding from the surgical site. Obviously strategies at preventing blood loss must start at the beginning of CPB. These attempts focus on limiting hemodilution, the use of antifibrinolytic agents, and use of fresh whole blood in the prime volume. We have already discussed at length the effects of hemodilution and thus it will not be discussed again.

The antifibrinolytics in use are the serine protease inhibitor aprotinin and the lysine analogs ε-aminocaproic acid and tranexamic acid. Aprotinin inhibits kallikrein and

plasmin with resultant decrease in hemostatic activation, inhibition of fibrinolysis, inhibition of the inflammatory cascade, and the preservation of platelet function. It is eliminated via the kidneys and then reabsorbed via the proximal tubule and then enzymatically broken down in phagolysosomes. Attempts have been made to establish the overall effects of the drug but this has been difficult as published studies have included small groups of patients, nonheterogeneous groups, and inconsistent dosing. It does appear that there were trends toward less bleeding, improved transpulmonary pressure gradients suggesting decreased inflammation and capillary leak, improved myocardial function, and decreased postoperative ventilation [156]. As mentioned prior problems were identified in the adult cardiac world with respect to postoperative renal failure and thrombosis risk in patients who received the drug and, despite these theoretical advantages, the drug is no longer used even in pediatric cardiac surgery, despite pediatric data, which may suggest that there is no statistically significant renal failure, need for dialysis, worsened neurological outcome or mortality (early or late) in the pediatric group [153,154,210–212]. At this time there is no plan to reintroduce the drug to market. The role of the lysine analogs has also long been studied. The mechanism of action is to interfere with the binding of plasminogen to fibrin, which is necessary for the activation of plasminogen to plasmin. Both drugs are eliminated via the kidneys with terminal half-life of 2 hours. The apparent advantages in comparison to aprotinin include the lack of an immunologic response, low cost, suggestion of platelet protection, and similar efficacy to aprotinin with respect to bleeding. In a meta-analysis containing more than 1000 patients it was found that in both cyanotic as well as acyanotic patients there was decreased bleeding, transfusion requirements, decreased sternal closure time, and improved re-exploration rates with the use of the lysine analogs. In two of the reviewed articles there was no improvement in postoperative ventilation time suggesting that these drugs have no anti-inflammatory effect [156]. In a further meta-analysis containing all three of the aforementioned drugs, the effect on bleeding was found to be similar comparing aprotinin to tranexamic acid with insufficient data to draw conclusions with the use of ε-aminocaproic acid [213]. In a further randomized study the two lysine analogs were compared in a cohort of patients ranging in age from 2 months to 14 years all with cyanotic heart disease. The results showed that both drugs had similar efficacy in decreasing postoperative blood loss as well as the use of blood products [214].

Introduced into the adult world in the late 1980s with investigations in pediatrics in the early 1990s, the use of fresh whole blood in the priming volume (between 24 hours and 48 hours old) carried a theoretical advantage over stored blood or reconstituted blood (made of packed red cells, FFP, and platelets) in that the coagulation factors and platelets had little time to degrade due to cold storage thus improving post-bypass hemostasis. Other advantages sited by proponents are the decrease in systemic inflammation manifest as decreased edema and improved organ function [215]. An early study from the group at the Children's Hospital of Philadelphia followed three groups of patients all under 21 years of age and representing both cyanotic and acyanotic conditions. In this study one group received very fresh whole blood (<6 hours old), the second received fresh whole blood, whilst the third received reconstituted blood. All subjects who required blood in the prime solution received whole blood. Once the heparin was reversed any further bleeding and/or volume requirements were met with the assigned blood. It was found that patients who received the reconstituted blood had significantly more bleeding in comparison to the other two groups and that the most significant decrease in bleeding was in patients who were transfused fresh whole blood and were <2 years of age undergoing complex repairs. Another interesting finding from this was that despite theoretical advantages of the very fresh whole blood there was no significant difference in bleeding between the two whole blood groups [216]. Further study into the question of fresh whole blood has looked at comparing reconstituted fresh whole blood versus banked blood and also into reconstituted blood versus fresh whole blood [215,217]. A head-to-head comparison of fresh whole blood versus reconstituted blood (PRBC and FFP) in circuit prime had outcomes in favor of the reconstituted blood. Although there was no difference in chest tube output and requirements for transfusions between the two groups the fresh whole blood was associated with increased perioperative fluid overload, increased ventilation, and prolonged ICU stay. The authors concluded that, although the reconstituted blood group required more donor exposure by four donors as compared to 3.5 in the fresh whole blood group, in their opinion the clinical hazards of fresh whole blood outweighed the risk of increased exposure. Despite these findings there is ongoing debate and, as further research is performed into circuit size, this debate may be resolved by the use of asanguineous prime [217].

The question of ongoing bleeding despite the above strategies occurs in a multitude of cardiac surgeries including patients with cyanotic heart disease, patients having long bypass times, DHCA, and those with operations that involve multiple suture lines. In these patients it is useful to perform coagulation studies, platelet counts, and fibrinogen levels to better guide therapy. The problem, however, is that there are not many institutions that can perform these tests in a time period where the results are still clinically relevant. Ongoing bleeding is treated with packed red cells or fresh whole blood with component therapy transfused as needed in the form of cryoprecipitate, platelets, or even FFP. Desmopressin acetate (DDAVP) has been used due to the characteristic of

the drug that it will decrease platelet dysfunction after CPB. DDAVP will increase the release of von Willebrand factor (vWF) multimers and factor VIII from endothelial storage sites. Factor VIII levels will increase immediately and that of vWF will peak in 30–60 minutes. The net effect of this is to augment platelet adhesion and aggregation [218]. Although the use of DDAVP has found success in adult cardiac surgery patients, the same results have not been found in pediatric patients, with studies finding no improvement in coagulation in patients who have been given the medication as a prophylactic measure [218,219].

In patients who continue to bleed despite the attempts to correct coagulopathy with blood products the use of recombinant factor VII has become a significant part of the armamentarium. The drug has been used clinically once coagulation factors, fibrinogen, and platelets have been administered and all attempts to correct surgical bleeding have failed; in some instances it has been used as a prophylactic measure in those surgeries which have seen long CPB times with a multitude of suture lines. Unfortunately, like with many drugs, pediatric dosing is extrapolated from adults. The dose thus is between 90 and 120 μg/kg, which is given every 2–3 hours. Studies have demonstrated that the half-life of fFactor VII in pediatrics may be half of that in the adult and that clearance is faster, possibly indicating a higher dose requirement [220]. It has also been suggested that transfusion of coagulation factors, fibrinogen, and platelets prior to the administration of factor VII may also affect the dosing regimen [220]. The pediatric experience thus far in the history of the drug has suggested it to be extremely efficacious but with some limitations and potential complications. The cost is extremely high with a 1- to 2-mg vial costing around $1000, with some patients obviously requiring more than just the one vial. The other concerns surround clot formation and thrombosis. Case reports have described mediastinal clot formation that in some cases has required emergency evacuation [221]. The drug has been used also in patients with intractable bleeding whilst on ECMO with success. In this subgroup of patients there is obviously concern for circuit thrombosis that would have catastrophic consequences and it has been suggested that the dosing be reduced to 30–50 μg/kg [221]. Yet another study has demonstrated no complications using the standard dose of 90–120 μg/kg in a group of ECMO patients [222]. Despite its very important place in the management of the post-CPB patient, there is still much investigation around the use of this drug with respect to optimal dosing as well as administration interval.

Anatomical Considerations and the Use of Transesophageal Echocardiography

Essential to the termination of CPB is an anatomically sound repair. This is true from a simple repair such as a secundum atrial septal defect to the complexities of a stage 1 Norwood reconstruction for the single ventricle. The effects of CPB on the myocardium are well proved and the longer the bypass time the worse these effects may become due to failure to establish electrical quiescence, unequal myocardial cooling, and the ongoing inflammatory cascade. It thus stands to reason a myocardium recovering from these insults will not function well should there be residual outflow tract obstruction, abnormal coronary flow, or abnormal flow through intracardiac baffles. Intraoperative transesophageal echocardiography (TEE) can thus be vital in diagnosing these problems in patients who are difficult to wean from CPB or who are possibly more cyanotic than expected. The problem in the early days of TEE was that probe size limited use in small patients and neonates – precisely the group of patients undergoing the most complex of procedures. Fortunately in recent years there has been development of probes that can be used in patients down to approximately 2.5 kg [223]. The incidence of post-CPB residual defects diagnosed by TEE, which will go on to require a second CPB run is approximately 7–9.6% across reported series [224–226]. This is clearly a significant number of patients who would possibly have required later reoperation or even postoperative emergent ECMO cannulation due to acute cardiac failure. Complications associated with passage of the TEE probe include failure to pass the probe, esophageal trauma that includes laceration or even perforation, airway compression, and hemodynamic compromise. The hemodynamic issues are related to compression of structures, which include the ascending and descending aorta, left atrium, pulmonary artery and veins, and superior vena cava [226]. Despite these possible complications they remain rare. In a study of 22 patients between 2 and 5 kg who underwent TEE examination before and after CPB no differences in lung function or arterial blood gas were found. In two patients the probe was removed because of concerns about ventilation unrelated to the TEE probe. The aforementioned parameters did not change before or after the removal of the probe [227]. In another study performed by the same authors looking this time at hemodynamic parameters, they found that there was an incidence of compromise in 1.7% of patients [226]. Despite the theoretical concerns in the very smallest of patients TEE examinations can be performed safely.

Modified Ultrafiltration

The institution of CPB will set up a proinflammatory state that is coupled with varying degrees of hemodilution. The net effect of this will be capillary leak that results in an increase in total body water and edema. This phenomenon, although affecting the entire body, will be especially problematic for the lungs, myocardium, and brain. Pulmonary compliance will decrease and the end result of myocardial

edema is both systolic and diastolic dysfunction [108,228]. Strategies that have been employed include the use of steroids, coated CPB circuits, and miniaturized CPB circuits. First described in 1991 by Naik and colleagues, modified ultrafiltration (MUF) was formulated to improve the removal of this excess body fluid after the termination of CPB. These authors found that their new technique was better able to remove body water and elevate hematocrit when compared to conventional ultrafiltration that is employed whilst the patient is still on bypass [229]. The perfusionist employs a number of forms of filtration, all of which are aimed at limiting the inevitable increase in total body water, as well as removal of electrolytes and inflammatory mediators. Prime ultrafiltration (PUF) is used when packed red cells are added to the prime volume. The aim of this filtration technique is to remove any unfavorable electrolyte elevations associated with stored blood, increase the pH closer to physiological range, and also decrease the inflammatory response [230]. Conventional ultrafiltration (CUF) is employed throughout CPB with a common use being the removal of extra volume and electrolytes added to the circuit after the use of cardioplegia. In zero balance ultrafiltration (ZBUF) crystalloid is added to the circuit at the time of ultrafiltration. A complication of ultrafiltration is depletion of the venous reservoir volume and thus ZBUF is an attempt to counter this hypovolemia. Dilutional ultrafiltration is the last method of ultrafiltration used with the patient on CPB. The aim of this method is the dilution of a given electrolyte that is elevated. Dilution is achieved by the addition of hypotonic fluid (e.g., half normal saline) into the circuit at the time of the ultrafiltration. The common goal of these methods is removal of excess free water and inflammatory mediators and maintaining the hematocrit at a safe level whilst on CPB.

Studies have shown that MUF will improve both cardiac and pulmonary function, increase hematocrit, and remove inflammatory mediators and that these effects are improved over the other ultrafiltration techniques described. The technique of MUF includes the following modifications to the CPB circuit upon weaning from bypass. A clamp is applied which functionally disconnects the venous line from the venous reservoir. A line is then brought up to connect the ultrafilter directly onto the venous line (Figure 10.9) [228]. The direction of flow to the ultrafilter is then from the venous reservoir and from the arterial line. A roller pump is then interposed between the blood source and the filter to ensure blood moves toward the patient at a rate of approximately 200 mL/min. Suction is also applied to the filter at about -125 mmHg to achieve a filter rate of approximately 100–150 mL/min [228]. Saline is used to chase the blood still in the venous reservoir through the circuit and also to maintain right atrial filling pressure at the desired level. The endpoints are time of the MUF procedure (usually 15–20 minutes), the desired hematocrit of ≥40, replacement of the venous reservoir with crystalloid, or the patient's inability to tolerate the procedure.

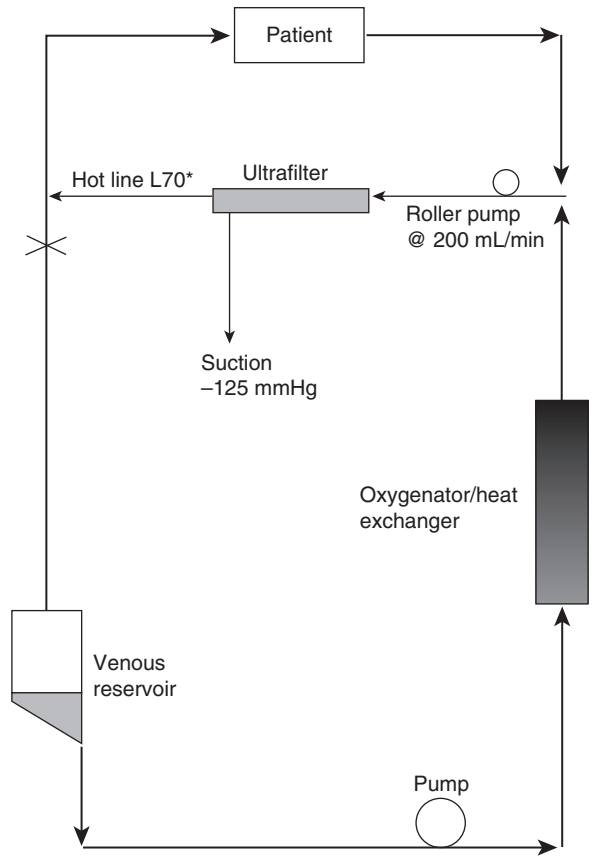

Figure 10.9 Set-up for modified ultrafiltration. (Reproduced with permission from Davies *et al*. [228].)

Table 10.11 shows the positive effects of MUF. The advantages of MUF with respect to cardiac function have been studied across the spectrum of patients [108,228,231,232]. The improvements in myocardial performance appear to be related to the decrease in myocardial edema that is seen after CPB. It has been shown that after MUF there is an increase in systolic function coupled with an increase in end-diastolic length and decrease in end-diastolic pressure. These improvements in diastolic function indicate improvement in left ventricular compliance [228]. In this study the myocardial dimensions were measured using intraoperative ultrasonic transducers. This was in agreement with earlier clinical observations made by Naik and his team in their original description. They observed that there was a universal rise in blood pressure and an apparent decrease in the myocardial dimension [230]. Overall MUF leads to improved left and right heart function. MUF has been shown to also improve pulmonary vascular resistance even in those patients who had elevated pulmonary pressure in the preoperative phase, an effect that lasts into the postoperative phase [108,231]. The patient

Table 10.11 Effects of modified ultrafiltration.

with single-ventricle physiology is potentially at risk during the process of MUF because blood is being drawn away from the aorta, which is thus taking blood from the coronaries as well as the pulmonary flow (in those patients with a modified Blalock–Taussig shunt). In a study by Gaynor and colleagues, however, this was shown to be a safe procedure in this group with similar improvements in myocardial function as noted earlier [232].

Improving pulmonary function is important for not only myocardial function but for ventilation–oxygenation and the resulting decrease in the need for postoperative mechanical ventilation. Pulmonary dysfunction after CPB is manifest as lowered compliance, increased pulmonary vascular resistance, and a decrease in gas exchange. The mechanisms associated are related to hemodilution that decreases plasma oncotic pressure resulting in an increase in interstitial fluid. This is coupled with the atelectasis that occurs secondary to no ventilation on CPB. Furthermore the lung is obviously ischemic during bypass, which leads to the production of oxygen free radicals once the lung is reperfused. Lastly other factors such as hypothermia and foreign body contact of blood with the CPB circuit result in the release of inflammatory mediators that may further worsen pulmonary damage [231]. The effects of MUF are thus secondary to a decrease in interstitial fluid that in turn leads to increased pulmonary compliance, improved oxygenation, and a decrease in pulmonary artery pressure. All these positive factors will also lead to improvement of right ventricular function [108,231]. From the studies already referenced an added benefit to these pulmonary improvements is decreased postoperative ventilation and, in turn, ICU stay.

MUF has also been shown to improve the coagulopathy associated with CPB as well as decrease the transfusion requirements. CPB leads to a hemodilutional state which effects hematocrit and coagulation factors as well as a separate effect on platelet number and function. The effect of MUF will lead to an increase in hematocrit (which in patients with single-ventricle physiology will improve oxygen saturation and oxygen-carrying capacity) and improvements in the level of coagulation factors by removing the aforementioned dilutional volume. This will in turn lead to improved coagulation, decreased bleeding, and decreased blood requirements. These effects have been shown in neonates and in those with prolonged CPB, two groups who are associated with increased bleeding. Despite these obvious advantages MUF has no effect on platelets [108,231,233,234].

Creation of a cavopulmonary anastomosis and Fontan completion will result in an increase in venous pressure. This is the primary etiologic association found in a subgroup of these patients who develop postoperative pulmonary or pericardial effusions. In an early study looking into the effect of MUF on associated morbidities it was found that there was a significant reduction in effusions. The difference was found to be most significant in the Fontan group where the incidence was 48.5% in the control group whereas in the MUF group this decreased to 10.5%. In those patients undergoing cavopulmonary anastomosis the control group showed 11.5% versus 4.9% [234]. The morbidity and mortality associated with ongoing effusions include chronic hypoxia and ongoing protein loss resulting in anasarca and immune suppression. These findings have been supported in other studies [108,235]. Clearly the use of MUF plays an important role in decreasing this morbidity and mortality. Recent advances have also included the creation of a fenestration in the Fontan baffle that serves as a pressure release from the now high pressure venous system into the atrial chamber.

The systemic inflammatory response that is generated with the onset of CPB can prove to be deleterious to organ function when attempts are made to wean from bypass. Inflammatory cytokines such as TNF, IL-6, IL-8, thromboxane B_2, and endothelin 1(ET-1) are released secondary to this inflammatory process. The first three of these are prominent in the systemic inflammatory response syndrome that occurs post CPB while the latter factors may contribute to the pulmonary vascular hyperactivity and pulmonary hypertension that occurs in certain individuals. As the use of MUF improves clinical outcomes, studies have attempted to show that it will lead to the decrease in these factors. Huang and colleagues showed that the use of continuous ultrafiltration and MUF will lead to a decrease in the concentration of IL-6 but had no effect on ET-1 [236]. Contrary to this study Bando and colleagues found that a combination of dilutional ultrafiltration with MUF will result in the decrease in ET-1, thus decreasing pulmonary/systemic pressure ratio and also lower ventilatory requirements [237]. In a third study the addition of a polysulfon ultrafilter to the MUF circuit for both

conventional ultrafiltration and MUF improved the removal of IL-6 and TNF [107].

Despite all these positive effects of MUF there are important safety concerns. These include: inadvertent cooling during the procedure; hypotension if too much blood is drawn off via the arterial line; and varying technical difficulties with the circuit, for example air cavitating out of solution in the arterial line, clotted MUF circuit, and exsanguination owing to unclamping of the oxygenator circuit.

The effect of hypoperfusion/reperfusion has the potential to cause a breakdown in the normal gastrointestinal mucosal barrier. The translocation of endotoxins into the bloodstream may result in hypotension, fever, hypermetabolism, tissue damage, and coagulopathy, all factors that can cause problems as patients are being weaned from CPB. Yngaard and colleagues found that the endotoxin load significantly increased during CPB, peaking at the end of CPB. The use of MUF significantly decreased the load from 24.2 ng at the peak to 9 ng after MUF with the majority of the load found in the ultrafiltrate. In a separate study quoted by these authors it was found that an endotoxin load >4 ng/kg may depress myocardial function. The conclusion of the study was that despite not removing the load, MUF may aid in the modification of the inflammatory response seen [238].

The use of MUF has become standard in the performance of congenital cardiac surgery with the benefits as listed above. In most centers patients undergo continuous ultrafiltration in one form or another during CPB with MUF being performed on weaning from bypass. The disadvantages are mainly of a technical nature that can be overcome with experience. When combined with the other modalities already discussed in this chapter the use of MUF is an important adjuvant in combating the deleterious effects of CPB.

Treatment of Post Cardiotomy and Acute Cardiac Failure

In some patients there is an apparent period of hemodynamic and ventilatory stability that is followed by instability of varying degrees upon sternal closure. This may necessitate that the sternum remain open for a period ranging from a few hours up to 2–3 days. This is achieved by placing a tube strut between the two sternal edges (a rigid tube, e.g., a 4- to 5-mm endotracheal tube may suffice) and then closing the skin with a Gore-Tex patch. Concerns for this technique are obviously the risk of infection, tamponade due to inadequate drainage, and the inability to perform cardiopulmonary resuscitation (CPR) in the face of cardiopulmonary arrest. Sternal closure can then be achieved either in the ICU or in the operating room. At the Children's Hospital of Philadelphia this is routinely performed in the ICU with good results.

Table 10.12 Differences between ECMO and VAD.

	ECMO	VAD
Acute resuscitation	+	–
Bleeding at insertion	+	+++
Thromboembolic risk	+	+
Long-term support	–	++
Pulmonary support	+	–
Awake patient	–/+	+++
Able to ambulate	–	+++
Pulsatile flow	–	+

Cardiac failure may occur in a wide range of settings and may require immediate or planned intervention. The two modalities used are extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VAD). Table 10.12 lists some of the differences between these two modalities.

ECMO has been used in a number of settings that include mechanical cardiac failure or oxygenation failure upon weaning from CPB, ECMO-CPR (E-CPR) in a wide array of clinical settings, and emergent elective ECMO (e.g., severe myocarditis with impending cardiac failure secondary to nonperfusing rhythm or low cardiac output or even preoperative). In the majority of cases ECMO is established by cannulating either the neck or directly through the open chest at the time of cardiac surgery. The neck is cannulated by using the internal jugular vein to access the central venous circulation and the carotid artery to access the aorta. The advantage of ECMO is the speed at which it can be deployed and hence the concept of E-CPR has been widely promoted, with many institutions having ECMO teams on call on a 24 hours a day basis. An added advantage to this is that cannulation can be performed by noncardiac surgeons. This clearly requires a large institutional commitment of both manpower and resources. In a 2007 review from the Extracorporeal Life Support Organization it was found that in 73% of cases (499/682) E-CPR was used primarily for children with primary cardiac disease with the survival to discharge quoted as 38% [239]. Later series have quoted survival rates of 39–44% [240,241]. This is in comparison to a series of only cardiac patients who underwent ECMO placement both after cardiac surgery and as part of management for low cardiac output not associated with surgery [242]. In this series the survival to 24 hours post decannulation was 58%; however, the overall survival was only 39%. In 2005 the American Heart Association made the following recommendations regarding E-CPR: 1) E-CPR is considered if initial resuscitation attempts fail and the condition leading to the arrest is reversible or amenable to heart transplant; 2) CPR is started no more than a few minutes after no

cardiac output; 3) ability to rapidly perform ECMO [243]. The survival rate in published series for patients treated only with CPR ranges from 16–34.5% [244–246]. These data include patients who underwent CPR for bradycardia with spontaneous but decreased perfusion. This group of patients will elevate the survival percentage; for patients who had an asystolic arrest the survival percentage was substantially less. At first glance this difference in survival does not appear to be that great but considering that a 10% difference between CPR and E-CPR translates to ten lives saved out of 100 this is undoubtedly a significant difference under the appropriate circumstances. Figure 10.10 shows a schematic representation of an ECMO circuit [247]. Although this drawing depicts cannulation through the chest, the same set-up is used for neck cannulation. In the group of patients who require cannulation as part of ongoing CPR or in the operating room where there is failure to wean from CPB either from a cardiac or pulmonary standpoint, the decision to proceed to ECMO cannulation is an obvious one. The decision, however, to "electively" cannulate a patient as part of ongoing management is a decision that is not taken lightly. The use of ECMO requires ongoing anticoagulation and just as with CPB an inflammatory cascade is started. The concerns with anticoagulation encompass both sides of the problem: undercoagulation with resultant circuit clot formation and the possibility of embolic phenomena to the brain, limbs or abdominal cavity; or overcoagulation with catastrophic cerebral hemorrhage as a devastating complication. Anticoagulation is achieved with the use of intravenous heparin with the target ACT of 180–220 seconds. There are those patients who may even go on to develop heparin-induced thrombocytopenia that will necessitate anticoagulation with an alternative anticoagulant. Other concerns include the development of infection, renal failure, pulmonary hemorrhage, lack of improvement of the original etiological factor, and the inability to bridge the patient to transplant in the case of a primary cardiac etiology.

In a series of patients looking at the outcomes of patients placed on ECMO prior to corrective surgery the investigators had a number of interesting findings. This series of patients had a median age of 0.12 months with a range of 0–193 months with 17 patients being neonates and a further six being younger than 1 year. The patients in this series were representative of both single and biventricular repairs. Hypoxia was the predisposing factor in 65% and all patients were operated on whilst on ECMO. In all there were 16 patients who survived to hospital discharge. Failure to wean from ECMO/CPB at the end of corrective/palliative surgery was the most significant risk factor. Other associations were weight less than 2 kg and neonatal patients. Although the nature of the postoperative circulation was not found to be a significant risk factor, patients who underwent complex repairs of single-ventricle physiology had higher mortality [248].

The most devastating complication associated with either E-CPR or ECMO is neurological injury caused by hypoxia at the time of arrest or embolic and hemorrhagic events on ECMO. It has been found that in patients undergoing E-CPR those patients with cardiac causes for

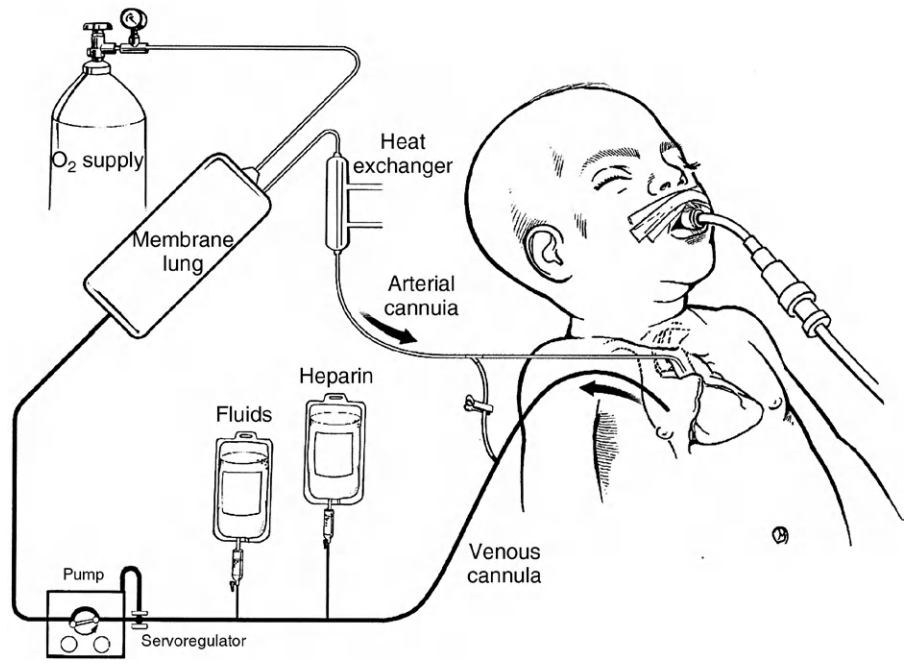

Figure 10.10 Schematic representation of ECMO circuit. (Reproduced with permission from Aharon *et al.* [247].)

requiring ECMO had improved neurological outcomes compared to those with pulmonary or metabolic etiologies. It has been postulated that this is due to the fact that postoperative cardiac patients are in ICU with continuous hemodynamic monitoring, vascular access, and, importantly, practitioners trained to rapidly deploy CPR and ECMO. Additionally patients who develop arrest secondary to respiratory causes are severely hypoxic at the time of arrest and thus are at increased risk of neurological damage [249]. The overall incidence of neurological complications was between 12% and 26%, which are indeed significant numbers [243,249,250]. Associated risk factors include severe metabolic acidosis at the time of going on ECMO, hypercarbia, venoarterial ECMO, ongoing inotrope and vasopressor requirement, and the need for further CPR whilst on ECMO. Location of cannulation was not found to be an independent risk factor for neurological outcome [249].

Assessing mortality risk factors is difficult in this patient subgroup. In the aforementioned cardiac ICU series the patients were divided into those post surgery and those not. In postoperative patients it appeared that age <1 month, male sex, and the development of renal and/or hepatic failure appeared to be risk factors. In the group who did not undergo surgery prior to going on ECMO there were no clearly significant factors, although male gender and renal/hepatic failure were nonstatistically significant associations. In this series the indication for ECMO (i.e., failure to separate from CPB or cardiac lesion such as single ventricle) was not found to be a predictor of mortality; similarly the duration of ECMO was no reason to withdraw support [242]. In an earlier series of 50 patients who required ECMO in the immediate post-CPB phase and ranging in age from 1 day to 11 years, it was found that those who had biventricular physiology had worse mortality than the single-ventricle patients in the same series. These findings were in contrast to earlier published data where it was found that patients undergoing the Norwood repair had the lowest survival rates amongst ECMO patients. These authors pointed to maintaining a balanced circulation for the single-ventricle patients as possible reasons for improved ECMO survival in this subgroup. Prolonged CPR and once again renal failure were associated with increased mortality; however, prolonged support worsened survival in this series [247].

In summary ECMO plays an important role in the management of patients with CHD and in those with acquired myocardial dysfunction due to myocarditis. It is used in the preoperative phase, as support in the immediate post-CPB period in those patients who cannot be weaned from CPB due to myocardial dysfunction or severe hypoxia, or in patients who undergo acute cardiopulmonary failure in the ICU after initially successful weaning from CPB. ECMO has also been used as support in patients who are being bridged to transplant or in those whose newly transplanted heart has failed. Although morbidity and mortality are high these figures would approach 100% without this life-saving modality.

The need for pediatric ventricular assist devices (VAD) has come about because of the increased rates of survival of patients with complex CHD but also because of improvements in medical therapy that has prolonged the life of patients with severe cardiomyopathy who may have otherwise succumbed to their disease years ago. Improvements in pediatric VAD therapy has lead to the development of miniaturized pumps and optimized cannulae appropriate for patients right down to neonatal size with stroke volumes of as little as 10 mL. In comparison to the adult population where VAD therapy is employed at the time of failed weaning from CPB this role is filled by ECMO in the pediatric population with VAD therapy being used in a patient where ongoing support is projected for weeks or months. In addition to this, advantages of VAD therapy include the ability to have the patient extubated, feeding enterally and, importantly, ambulating. The presence of respiratory failure, pulmonary hypertension, and residual intracardiac shunts are possible contraindications [251]. VAD therapy can be divided into paracorporeal (devices where the assist device is outside of the body) and intracorporeal (where the device is implantable within the patient). The paracorporeal systems include the Thoratec ventricular assist device (Thoratec Laboratories, Pleasanton, CA, USA), Abiomed BVS 5000 and Abiomed AB 5000 (Abiomed, Danvers, MA, USA), Berlin Heart EXCOR VAD (Berlin Heart AG, Berlin, Germany), and MEDOS HIA VAD (MEDOS, Medizintechnik AG, Stolberg, Germany). Intracorporeal (implantable) devices include the Micromed Debakey VAD (Micromed Technologies, Houston, Texas, USA), Jarvik 2000 Flowmaker (Jarvik Heart, Inc., New York, NY, USA), the Berlin Incor (Berlin Heart AG, Berlin, Germany), and the Thoratec Heartmate II VAD (Thoratec Laboratories, Pleasanton, California, USA). Of these VAD systems the following four are the most widely used: The Berlin Excor, MEDOS HIA VAD, and the Thoratec VAD are pulsatile paracorporeal systems whilst the Micromed DeBakey VAD is an intracorporeal axial flow device. The Berlin Heart Excor Pediatric VAD was the first system that was commercially available designed especially for the pediatric patient. It is paracorporeally placed and air driven with pumps of 10-, 12-, 15-, 25-, 30-, 50-, 60-, and 80-mL stroke volume. This will translate to the possibility of supporting a patient down to 2.5 kg. Figure 10.11 demonstrates a size comparison between pediatric and adult size as well as how the unit works [252]. The support configuration can be as LVAD, RVAD, or BiVAD. Overall survival is between 40% and 60%, and these statistics include patients who have been successfully weaned from support and those bridged to transplant [251,253]. The MEDOS HIA VAD is

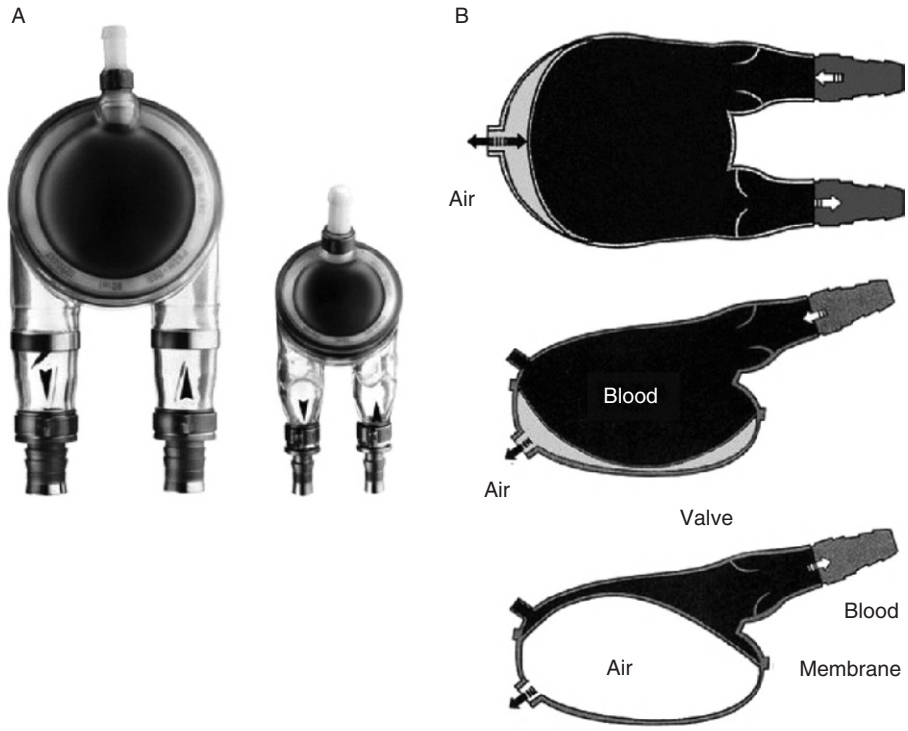

Figure 10.11 Adult versus pediatric Berlin heart chamber and pumping mechanism. **(A)** Adult (left) and pediatric (right) Berlin Excor® VADs. The adult pump has a stroke volume of 80 mL and tilting disc valves. The pediatric-sized pump is suitable for children with body weight of 3–9 kg. This pump has a stroke volume of 10 mL and polyurethane trileaflet valves. Pumps of all sizes are now available with polyurethane valves. **(B)** Cross-section of the Berlin heart pump with polyurethane valves. (Reproduced with permission from Potapov *et al.* [252].)

available in Europe in three sizes for the left ventricle (10, 25, and 60 mL) and three sizes for the right ventricle of (9, 22.5, and 54 mL). It can thus be used in RVAD, LVAD, or BiVAD formation. The Thoratec VAD has been used successfully worldwide in the pediatric population with a body surface area of 0.7–2.1 m^2. Multicenter experience has shown 60% survival to transplantation. Patients who required support for cardiomyopathy/myocarditis showed better survival than those presenting with CHD [254]. The Micromed DeBakey intracorporeal axial flow VAD is FDA approved for use in children 5–16 years of age with body surface areas between 0.7 and 1.5 m^2. Figure 10.12 shows the working parts of this system and its placement within the body [251]. Initially designed for use in adult patients by researchers at Baylor College of Medicine in Houston, Texas, and engineers at NASA, the first patient in the USA into whom this device was placed was a 10-year-old girl with a body surface area of 1.2 m^2 who presented with a dilated cardiomyopathy. She was successfully bridged to transplant after 84 days [255]. Disadvantages of this system include its availability only as an LVAD system, its size that precludes its use in patients with body surface area <0.7 m^2 and the requirement for normal pulmonary function.

Factors associated with morbidity and mortality in patients managed with VAD therapy are similar to the ECMO population. These include bleeding at the time of insertion and explantation, thrombosis with devastating embolic phenomena, infection, and organ failure. The bleeding experienced on insertion and explantation are secondary to the dissection that takes place with a large area of surgical trauma, the suture lines created in the major vessels and within the ventricular wall, and the coagulation cascade abnormalities associated with the blood–circuit interface. Although the major concern will be thrombosis in the circuit, later on this coagulopathy must be aggressively treated so as not to compromise VAD function due to hypovolemia. Therapy is similar to treatment of bleeding which accompanies separation from bypass including platelets, FFP, cryoprecipitate, blood or fresh whole blood, and the use of factor VII preparations. Keeping the use of indwelling catheters to a minimum and maintaining the skin area around the cannulae insertion clean can control infection. Long-term anticoagulation is one of those continuously evolving topics. It has been established that in these patients even viral infections that are otherwise well tolerated in healthy children are dangerous in this

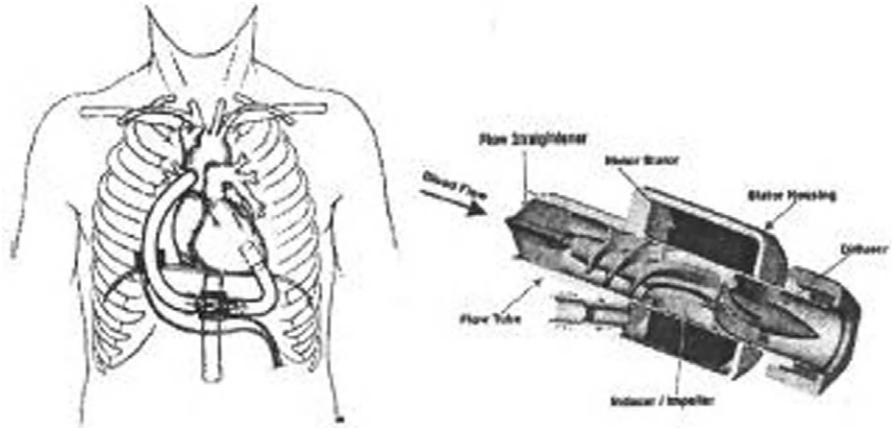

Figure 10.12 Mechanism of MicroMed DeBakey VAD. (Reproduced with permission from Fynn-Thompson *et al.* [251].)

population as the endogenous reactions to these infections may further activate the coagulation cascade and hence adjustments may be necessary at these times [253]. The strategy that is employed involves heparin-coated circuitry, frequent checks of the circuit by trained personnel, the use of heparin which is monitored by means of aPTT (60–80 seconds) and thromboelastography, monitoring antithrombin III with replacement if the level drops below 70%, and the use of antiplatelet drugs to prevent aggregation and adhesion. These drugs include aspirin and dipyridimole [253,255]. Platelet aggregation tests should be performed with target activation of 30%. Another possible improvement in the coagulation strategy has been the placement of the drainage cannula at the ventricular apex as apposed to the atrium. This may improve flow through the ventricle and outflow from the device [255].

This discussion would not be complete without comparison of survival between ECMO and VAD although this may be a case of comparing apples to oranges as ECMO plays a vital role in acute resuscitation, a role that VAD cannot. Despite the previously quoted studies a multicenter review by Blume and colleagues showed that in the current era the rate of patients successfully bridged to transplant was as high as 86% in the VAD population. Also of note was that the post-transplant survival in the VAD group was similar to those status 1 transplant patients not requiring support. This is in contrast to ECMO patients where 47–57% of patients survived to transplant [256]. Improvements in survival of VAD patients over earlier experience is related to improved surgical techniques; better timing of VAD placement (i.e., placement as function shows signs of deterioration versus waiting for end-organ damage); improved postoperative management with respect to myocardial support, earlier nutrition, earlier extubation, and better understanding of coagulation therapy; and improved patient selection [256]. Neurological outcome is a major morbidity in both groups. Early experience showed that in-hospital neurological complications occurred in 30% of ECMO patients and 10% of VAD patients [257]. The authors did however note that these patients, representative of both systems, improved with time with only 5 of 31 demonstrating ongoing severe disability. Despite the improved management outlined above there remains a 20% risk of stroke in VAD patients of which >50% prove fatal [254]. The worse outcome in the ECMO group may be associated with younger age at the time of support, this group has more complex disease, more cyanotic heart disease, that a large part of the ECMO group were neonates, and that greater anticoagulation was needed in the ECMO group. This higher anticoagulation translated into ACT of between 180 and 220 seconds that puts these neonates at higher risk for intracranial hemorrhage. In addition to these factors the ECMO circuit is more complex with the oxygenator and long tubing lengths increasing thromboembolic risk [257].

What then is the future of pediatric mechanical support? At this time only the MicroMed DeBakey VAD has FDA approval for use in the pediatric population with the aforementioned systems being given permission by the FDA on a case-by-case basis on compassionate grounds. In the spring of 2004 the National Heart, Lung and Blood Institute (NHLBI) awarded five companies sponsorship for basic and applied research into new circulatory assist devices and other systems exclusively for infants and children with congenital and acquired heart disease. The objective is to provide circulatory support for infants and children while minimizing the risks of bleeding, infection, and thromboembolism [252,258]. Unfortunately none of these devices has yet undergone clinical testing.

In conclusion the use of mechanical support in the pediatric population has improved vastly over the last two decades from a scaled-down adult machine to therapy dedicated

and researched exclusively for children. As outlined there is still a long way forward and we await the NHLBI projects.

Conclusions

The use of CPB has progressed greatly in the last 60–70 years with clinicians and researchers overcoming a large number of obstacles; for example giving surgeons, anesthesiologists, perfusionists, and critical care cardiologists the ability to palliate single-ventricle patients into their third and even fourth decade of life as opposed to the nearly 100% mortality this diagnosis carried as little as 30 years ago. One of our greatest challenges moving forward will be limiting the neurological damage that occurs in some of our patients and, failing that, giving us the ability to help these patients with the challenges that they will face in their lives.

As can be seen this is a field of medicine where a team approach is of extreme importance as each group of practitioners has a vital role in patient care. The management is multimodal with no single therapy outweighing the others in importance. This concept cannot be stressed enough. Many questions remain unanswered, but the most important principle to remember is that these patients require care specific to them and not anything that is simply made smaller from adult principles.

CHAPTER 11

Intraoperative Myocardial Protection

Paul J. Chai
All Children's Hospital, Saint Petersburg, FL, USA

Myocardial protection is a critical component of cardiac surgery. Without the use of myocardial protection techniques, permanent ischemic damage begins to occur in the heart after 20 minutes [1,2]. A complete understanding of the principles of myocardial protection is essential for the cardiac surgeon. A variety of myocardial protection techniques exists, and cardioplegia protocols can vary significantly from one center to another. Despite this variation in technique, these key principles of myocardial protection remain constant: the reduction of metabolic activity by hypothermia and the cessation of contractile and electrical activity of the heart. These principles remain important in the special circumstances of cardiac surgery in the neonate and infant.

Considerations for myocardial protection in pediatric cardiac surgery differ from those for adult cardiac surgery in a number of significant ways. The coronary arteries and myocardium are generally nondiseased in patients with congenital heart disease; therefore, in most cases the congenital heart surgeon does not need to worry about the uniform delivery of cardioplegia or deal with significantly scarred or impaired regional or global ventricular function. The congenital heart surgeon needs to deal with a heart in varying stages of maturity. This variation is significant because, as the myocardium matures, fundamental changes occur that directly influence the ability of the heart to withstand periods of ischemia and injury. The point of transition is not well known but likely occurs in the first year of life and potentially within the first 3 months of life.

It is generally believed that normal neonatal myocardium is more resistant to ischemia and reperfusion injury than mature adult myocardium [3,4]. It is important that this added resistance does not seem to be present in the hearts of cyanotic neonates and children or those with acute or chronic heart failure. These differences must be taken into account when considering the optimal strategy for myocardial protection during cardiac surgery of the neonate and infant. Myocardial protection techniques must be tailored to the age of the patient and complexity of the procedure in order to ensure the best outcomes.

Physiologic Differences Between Immature and Mature Myocardium

There are a number of specific physiologic differences between the immature myocardium of the infant and the mature myocardium of the adult that are important to understanding the greater tolerance to ischemia of the pediatric heart. These differences include a disparity in preferred substrate for metabolism, dissimilar levels of glycogen content, and differences in calcium and catecholamine sensitivities (Table 11.1) [5].

Substrate for Energy Production

Myocardium derives its energy production (adenosine triphosphate [ATP]) from the oxidation of fatty acids, glucose, lactate, ketone bodies, and amino acids. Additional energy production is also used from endogenous substrates such as glycogen and triglycerides. In the adult heart, long chain fatty acids are the main substrate for myocardial energy production. The adult myocardium gains as much as 90% of its ATP production from the oxidation of these fatty acids [6]. In contrast, the neonatal heart uses glucose as its main substrate. Energy production is supplemented by the use of fatty acids, ketones, and amino acids [7]. This shift in substrate preference from glucose to fatty acids occurs within the first few weeks of life and is caused by upregulation of 5′-adenosine monophosphate-activated protein kinase [8]. During this period of development, the neonatal myocardium has a diminished sensitivity to insulin [9] as well as a much greater capacity to store glycogen [10]. It is

generally accepted that the immature myocardium has a greater ability to use anaerobic metabolism.

The relevance of these physiologic differences between the neonatal and adult myocardium is not completely understood at this time. There may be some correlation between the neonatal heart's increased use of glucose with its increased tolerance to ischemia. For instance, Liu *et al*. found that after a period of ischemia in the adult heart, fatty acid oxidation rapidly normalized while glucose oxidation, as well as contractile function, remained depressed [11]. A positive correlation between return of contractile function and enhanced glucose uptake was demonstrated in patients undergoing coronary artery bypass operations [12]. In different experimental settings, activation of glucose oxidation enhanced functional recovery of cardiac muscle during or after ischemia [13,14].

Doenst proposed several explanations for these findings [5]. First, glucose is a more efficient substrate because it carries more of its own oxygen [6]. Second, more protons generated during ischemia are consumed when glucose is oxidized at the pyruvate dehydrogenase step [11,14]. Third, ATP generated from glycolysis supports the function of key ion pumps and calcium homeostasis [15]. Fourth, metabolism of glycogen may help with the maintenance of function of sarcoplasmic reticulum [16]. It is possible that some or all of the mechanisms responsible for these findings may be already present in hearts using glucose as a primary substrate (such as pediatric hearts) and may explain its prolonged tolerance to ischemia.

Calcium Metabolism

Pediatric myocardium is significantly more sensitive to extracellular calcium compared to adult myocardium. This may be because of the underdevelopment of the sarcoplasmic reticulum in pediatric myocardium, resulting in a reduction in storage capacity of calcium. The adult heart gets most of the calcium required for contraction from the sarcoplasmic reticulum [17,18]. In pediatric hearts, the reduced storage capacity of the sarcoplasmic reticulum forces much of the calcium to be provided by influx of calcium from the extracellular space [19]. The activity of sarcoplasmic Ca-ATPase (the enzyme necessary for calcium reuptake into the sarcoplasmic reticulum) is reduced in the pediatric heart. This reduction of sarcoplasmic Ca-ATPase activity results in a decreased ability to release calcium on stimulation of the ryanodine receptor, as well as a reduction in calcium reuptake into the sarcoplasmic reticulum. This biochemical variation found in the pediatric heart may explain why postischemic calcium overload may easily occur with the use of a perfusion medium containing high or normal levels of calcium. Several studies have described adverse effects using cardioplegic solutions containing high or normal concentrations of calcium during pediatric cardiac surgery and have recommended the use of subphysiologic levels of calcium in cardioplegia solutions [20–22]. As a result, most cardioplegic solutions in use today contain very low levels of calcium [23–25].

Enzyme Systems

Two enzyme systems seem to be relevant to the protection of the heart during periods of ischemia. The first of these systems is the antioxidant system, which includes the enzymes superoxide dismutase, catalase, and glutathione reductase. The activity of this enzyme system, which is important in the protection of the heart from free radicals, is reduced in immature myocardium [26]. Free radical generation is markedly elevated during reperfusion after a period of ischemia, and so a decreased defense mechanism would render the heart more susceptible to free radical injury. Children with tetralogy of Fallot are known to have a significant reduction in the activity of glutathione

reductase [26–28] and may be at even greater risk from free radical damage than others. Some groups have incorporated the use of leukocyte filtration in the cardiopulmonary bypass circuit in an attempt to reduce the amount of free radical generation. Studies have so far yielded mixed results [29–31].

The enzyme 5′-nucleotidase, which catalyzes the conversion of adenosine monophosphate (AMP) to adenosine, is the second enzyme system of potential importance. While AMP is unable to pass through the plasma membrane, adenosine easily passes through the plasma membrane and is subsequently lost. The adenine nucleotide pool can become depleted with the production of adenosine. The size of this adenine nucleotide pool is important for postischemic recovery of the heart [32–34]. If the pool is depleted more than 50%, immediate full recovery of contractile function is impossible. Some groups have demonstrated improved ischemic tolerance by inhibition of this enzyme system [35–37]. This enzyme system is also reduced in immature myocardium and may be an additional reason why immature myocardium is more tolerant to ischemia [24,35].

Catecholamine Sensitivity

The sensitivity to catecholamines is decreased in immature hearts. In vitro studies suggest that a decreased coupling of myocardial beta-adrenergic receptors to adenylate cyclase at birth is the cause [38]. In contrast, the kinetics of cyclic adenosine monophosphate hydrolysis and the inhibitory potential of phosphodiesterase inhibitors such as milrinone are not affected by age. This explains the wide use of phosphodiesterase inhibitors in the postoperative care of neonates and infants. The question of whether this decreased sensitivity in the immature heart contributes to its increased tolerance to ischemia is difficult to answer at this time.

Summary

The preference of the immature heart for the use of glucose, the large stores of glycogen, and the low activity of 5′-nucleotidase may contribute to the neonatal and infant heart's extended tolerance to ischemia. In contrast, however, the reduced activity of the free radical scavenger system, the increased sensitivity to calcium, and unknown factors related to the unique environment of the cyanotic heart may serve to reduce the heart's ischemia tolerance. These findings, in addition to the observation that the immature heart is less sensitive to the effects of catecholamines postoperatively, suggest an even more important need for optimal myocardial protection in patients with congenital heart disease. The most important strategies for pediatric myocardial protection compared with adult myocardial protection should include consideration of all of these findings.

Clinical Strategies for Myocardial Protection

There is no clear consensus concerning the optimal strategy for myocardial protection in the neonate and infant. Strategies vary significantly from center to center, as does the composition of cardioplegia used. Published studies often demonstrate conflicting results, which makes it difficult to recommend a "best" method of myocardial protection. Some of the mechanisms and principles behind myocardial protection strategies are discussed below.

Hypothermia

Hypothermia alone can provide a significant amount of myocardial protection and may be the single most important factor concerning myocardial protection in the neonate and infant. Some authors have suggested that under specific conditions, cardioplegia may in fact even be unnecessary [5,39]. This is demonstrated by a number of studies that have shown equivalent or better myocardial protection using hypothermia alone compared with the use of hypothermia with the addition of cardioplegia [40–43]. It should be noted, however, that these studies were performed at very low systemic temperatures of 15 °C or less. Studies at higher temperatures consistently demonstrate an advantage with the addition of cardioplegia [44–46].

Cooling of the human body to 32 °C reduces whole-body oxygen consumption by 45% [47]. At temperatures below 12 °C, oxygen consumption of the heart is below 1% of normal, and contractile function ceases [48]. In one study conducted in Siberia, because of the constraints of equipment availability, various forms of congenital heart disease were repaired using hypothermic circulatory arrest *without* cardiopulmonary bypass. Patients were packed in ice to achieve temperatures of 24–26 °C, and the repair was completed within 70 minutes. Results were remarkable, with mortality below 10% and neurologic complications at 13% [49].

Cardioplegia

Cardioplegia provides an additional level of protection during cardiac surgery. The essential use of cardioplegia is for cessation of all contractile and electrical activity of the heart. This results in a significant reduction of energy consumption, even at normothermia [24]. Almost all cardioplegic solutions exert their protective effects via depolarization or hyperpolarization of the membrane and mechanical arrest of the heart. The actual composition and method of delivery can vary significantly from institution

to institution because there is currently no consensus on the type of cardioplegia that should be used. This variation is reflected in the fact that more than 150 cardioplegia solutions are used clinically for cardiac transplantation in the United States [50]. Many studies attempt to address this issue; however, these studies are fairly contradictory in their conclusions [21,46,51–54]. The primary differences in the composition of cardioplegia solution seek to address the mechanisms involved in ischemia-reperfusion injury. These can include elevated osmotic pressure to prevent edema formation, addition of buffering agents to reduce acidosis, addition of free radical scavengers, or supplementation with substrates to improve energy production during rewarming and reperfusion [20,23,55–57]. Indeed, the neonatal heart may be more prone to problematic myocardial edema, which may lead to decreased ventricular compliance, increased ventricular stiffness, and diastolic dysfunction; therefore, cardioplegia with normal and possibly slightly elevated osmotic pressure may be beneficial.

Many studies have examined the efficacy of cardioplegia (Table 11.2) [5,21,39–46,49,51–54,58–67]. All of the studies demonstrate some protective benefit of using either hypothermia or cardioplegia or both. There is no clear conclusion as to whether the use of hypothermia or cardioplegia alone is superior. There is benefit from cardioplegia over the establishment of the same temperature by a noncardioplegic method (i.e., topical cooling, blood perfusion, etc) as a function of myocardial temperature during ischemia (Figure 11.1) [5]. The benefit of cardioplegia in the neonatal period appears to be directly related to myocardial temperature. Baker demonstrated in rabbits that the importance of cardioplegia in addition to hypothermia increases with age [58]. The maintenance of deep myocardial hypothermia, therefore, is of critical importance in the clinical setting. This can be difficult to maintain in the pediatric setting, considering the small size of neonatal and infant hearts. Multiple strategies, such as systemic hypothermia, cold ambient temperatures in the operating room, and the periodic reinfusion of cold cardioplegia, are therefore necessary. Since the main purpose of reinfusion of cold cardioplegia is to cool the heart, the potassium concentration is often lowered to avoid excessive hyperkalemia [20].

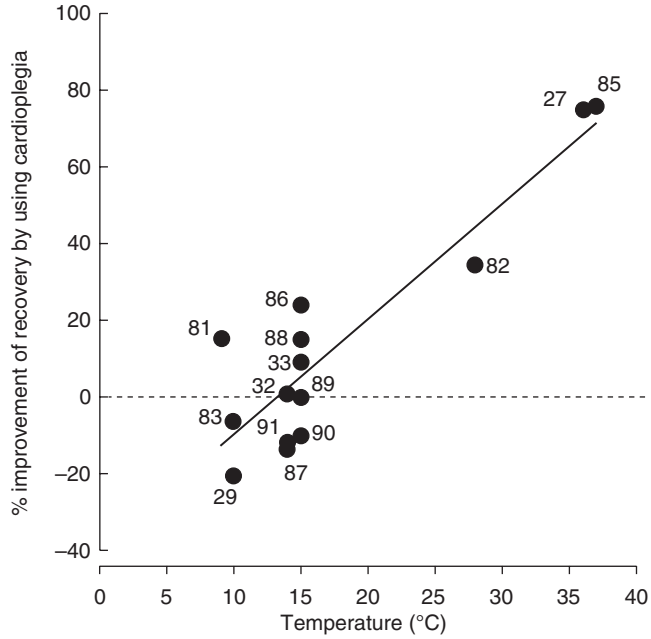

Figure 11.1 Benefit of cardioplegia over establishment of the same temperature by a noncardioplegic method (i.e., topical cooling, blood perfusion, perfusion with crystalloid buffer) as a function of myocardial temperature during ischemia. A positive value indicates that cardioplegia was better than the noncardioplegic method; a negative value indicates that the noncardioplegic method was better. (Reproduced with permission from Doenst *et al.* [5].)

Blood Versus Crystalloid Cardioplegia

The relative advantage of blood cardioplegia compared with crystalloid cardioplegia is still the subject of debate. Blood cardioplegia offers several theoretical advantages over crystalloid cardioplegia, such as the ability to carry oxygen and an excellent buffering capacity. Other theoretical advantages include a more similar electrolyte and osmotic composition and the potential to scavenge free radicals and minimize oxidative damage to the heart. In spite of these advantages, it has been difficult to demonstrate a clinical superiority of blood cardioplegia over crystalloid cardioplegia. The research literature remains inconclusive, and crystalloid cardioplegia remains in use at numerous centers.

In the field of pediatric heart surgery, only a few clinical investigations comparing blood and crystalloid cardioplegia have been reported [54,68–70]. One recent study demonstrated better preservation of myocardial metabolism and ventricular function in infants receiving blood cardioplegia [68]. In another study, no significant differences in clinical outcomes were demonstrated between the two cardioplegic methods; however, in cyanotic patients, cold blood cardioplegia followed by terminal warm blood cardioplegic reperfusion ("hot shot") significantly reduced the decrease in adenosine triphosphate, indicating better myocardial protection [70]. Researchers concluded that, for cyanotic patients, cold blood cardioplegia with a hot shot is the best method of myocardial protection.

Potassium Depolarization Arrest Versus Hyperpolarization Arrest

Potassium depolarization arrest via hyperkalemia has become a fundamental component of cardioplegia solutions

Table 11.2 Synopsis of comparative studies on protection of the pediatric heart during ischemia. 1991	Kofsky *et al.* [65]	Dogs	6–8 wk	Adult CP works well in children	4
1992	Hosseinzadeh *et al.* [42]	Pigs	1 wk	Hypo better than CCP; rapid cooling best	4
1993	Baker *et al.* [41]	Rabbits	1 wk	pH 6.8 better than hypo; hypo better than CCP	4
1993	Pearl *et al.* [53]	Pigs	1–2 d	CCP equal to BCP; normal Ca^{2+} better than low Ca^{2+}	4
1995	Baker *et al.* [58]	Rabbits	1–8 wk	Hypoxic hearts more ischemia tolerant. CP-protective effect increases with age	4
1996	Karck *et al.* [52]	Rats	4 wk	Hypo better than CP	4
1996	Bolling *et al.* [21]	Pigs	5–18 d	Normal Ca^{2+} detrimental in hypoxic hearts only	4
1997	Bolling *et al.* [59]	Pigs	Neonatal	BCP better than CCP in hypoxic states	4
1997	Young *et al.* [54]	Children	1–15 y	No difference between CCP and BCP	2
2001	Imura *et al.* [64]	Children	1 mo; 10 y	Hypoxic heart less ischemia tolerant	3

[a]Evidence-based medicine score is the modified American Heart Association/American College of Cardiology score.

today [71]. Depolarization arrest significantly reduces the metabolic energy demands of the myocyte. Studies indicate that normothermic arrest at 37 °C decreases the oxygen demands of the heart by 90% to 1 mL $O_2 \times 100$ g per minute [72]. Although depolarization arrest has become a fundamental component of cardioplegia, the merits of hyperpolarization arrest deserve some consideration. Certain energy-dependant processes, such as the sarcolemmal and sarcoplasmic reticular Ca2+-ATPases and Na-K-ATPase pumps, remain active during depolarization arrest. Some groups have argued that the energy requirements of these pumps may contribute to ischemic injury during potassium depolarization arrest through continued energy depletion and ionic imbalances [73]. A comparison of hyperpolarized cardioplegic arrest with a potassium ATP channel agent versus depolarization arrest with a traditional agent in rabbits found improved functional outcome in the hyperpolarized group [64]. These results are intriguing and merit further exploration into possible improvements to the traditional cardioplegic solutions in use today.

Warm Induction

A small subset of patients with left-ventricular dysfunction was found to have a reduced tolerance to aortic clamping. This poor tolerance to myocardial ischemia was thought to be because of depletion of myocardial energy stores. Rosenkranz *et al.* tested this hypothesis by depleting myocardial energy stores in dogs using 45 minutes of ischemia [33]. The dogs were then treated with either cold or warm induction of cardioplegia before receiving 2 hours of aortic cross-clamping with intermittent doses of cold cardioplegia. This group found that the dogs that had received warm induction had improved ventricular function and improved aerobic metabolism. Other groups have further demonstrated this finding as well [74].

Warm blood induction is felt to be beneficial in dysfunctional hearts because arrest at 37 °C without ischemia enhances metabolic repair by channeling aerobic ATP production to reparative processes. The use of a warm induction dose of cardioplegia may therefore add a further level of myocardial protection by replenishing energy stores of previously abnormal hearts during cardiac surgery. This technique may deserve serious consideration in patients who come to the operating room with energy-depleted hearts, such as patients with severe cyanosis, hemodynamic instability, or heart failure.

Substrate Enhancement

Further enhancements to cardioplegia solution include the addition of substrates such as aspartate and glutamate. Studies investigating amino acid use through anaerobic pathways found that infusion of three amino acids – aspartate, glutamate, and ornithine – during ischemia augmented recovery of contractile function in isolated rabbit hearts [75]. Glutamate directly enters the tricarboxylic acid cycle as alpha-ketoglutarate and provides for nonglycolytic generation of ATP. Aspartate use is via the malate-aspartate shuttle. Aspartate is converted to oxaloacetate and then to malate. Malate enters the mitochondria where it is converted back to oxaloacetate, which liberates the reducing equivalents needed for ATP synthesis.

Lazar *et al*. demonstrated the benefit of using glutamate-enriched cardioplegia solution [76]. That group found increased rates of contraction and relaxation, improved stroke work index, and improved recovery of ATP using glutamate-enriched cardioplegia. Engelman *et al.* found that the use of a glutamate and aspartate enriched solution during reperfusion resulted in a reduction in infarct size and improved levels of ATP and acetyl coenzyme A in swine model of ischemia-reperfusion injury [77]. Other experimental studies have also suggested that including glutamate and aspartate in the warm induction of cardioplegia and also in the reperfusate provides an additional level of myocardial protection and recovery [20,46,62,65,78].

Clinical Techniques

The clinical techniques used among institutions today vary widely. Cardiac surgery in the neonate and infant is a team approach, which makes it difficult to assess clinical outcomes of any one specific technique of myocardial protection from another. Differences in operative techniques, operative times, and quality of postoperative care can significantly camouflage any possible differences in myocardial protection. What may work well for one surgeon in a particular center may not work for another.

The lack of clear and consistent data makes it difficult to recommend a single strategy of myocardial protection, especially because primary myocardial failure after cardiac surgery is a rare cause of death today [79,80]. Although myocardial failure as a cause of death remains rare, a decrease in cardiac output after pediatric cardiac surgery is fairly common. This decrease in cardiac output is especially apparent between 6 and 18 hours postoperatively, as documented by multiple studies from Children's Hospital Boston [81–84]. This phenomenon would suggest that areas of improvement pertaining to myocardial management techniques remain. Still, it is unclear whether this decrease in cardiac output would be obviated by improved strategies of myocardial protection; in fact, this phenomenon may be independent of myocardial protective strategies and instead be related to any of a variety of alternative etiologies including a generalized post-cardiopulmonary bypass inflammatory response, cytokine activity, enzymatic activity, and hormonal variations [85,86].

The Boston group found that a residual volume or pressure load on the heart (i.e., an imperfect repair) was the most important cause of an excessive drop in postoperative cardiac output [79]. Other important factors included ventricular distention during surgery (from failure to vent the heart adequately), retraction and stretch injury to the myocardium (from excessive retraction on tissues for exposure), coronary artery injury, ventriculotomy, edema, perfusion factors, and reperfusion conditions [87].

Cardiac Distention

In contrast to the findings that the immature myocardium is significantly more resistant to ischemia compared with the adult heart, there is a general feeling among surgeons that immature myocardium is significantly more vulnerable to stretch injury. Stretch injury occurs mainly from overdistention of the left heart and excessive retraction on myocardial tissues. Overdistention of the left heart can have many detrimental consequences other than primary myocardial contractile dysfunction. Overdistention of the left ventricle also leads to distention of the left atrium and pulmonary veins, which eventually results in a high transcapillary pressure in the lungs. This elevated pulmonary transcapillary pressure eventually leads to significant pulmonary edema and pulmonary dysfunction.

The cardiac surgeon needs to be acutely aware of instances when distention of the left heart is occurring. Palpation of the left ventricle, or even the main pulmonary artery, should alert the surgeon when overdistention is present. Left-heart venting should be performed either through the right superior pulmonary vein or through an atrial septal defect to keep left-ventricular pressures low. The safest time to insert a left atrial vent is after the aortic cross-clamp is applied, to negate any chance that air could be introduced to the left side and embolize to the brain. Instant measures to reduce left-ventricular overdistention include having the perfusionist immediately drop the flow rate and/or temporarily releasing the aortic cross-clamp until the issue is resolved.

Cardioplegia Protocols

Clinical techniques vary from groups who advocate the use of single-dose cold cardioplegia in neonates and infants to groups who favor a more conventional approach adapted from use in adult cardiac surgery. The group at Children's Hospital Boston is one group that advocates the use of a single dose of cold cardioplegia in specific circumstances. Their practice is to use a single dose of cardioplegia infusion (20 mL/kg) combined with systemic deep hypothermia for neonatal procedures. In patients older than 2–3 months of age, periodic doses of cold cardioplegia are repeated at 20- to 30-minute intervals. Beyond 1 year of age, repeat doses of cardioplegia are administered every 20 minutes using an initial dose of 20 mL/kg followed by subsequent doses of 10 mL/kg [87].

Another cardioplegia protocol from Boston uses an innovative single-dose cardioplegia protocol for all patients, with usually no repeat doses. The formulation was based on animal studies done by McGowan *et al*. and Takeuchi *et al*. [56,88]. Occasionally, a repeat dose is given in larger patients with sick myocardium. Cardioplegia is a custom mix crystalloid cardioplegia with 1 part oxygenated pump blood and 4 parts crystalloid. Blood is added for its buffering capability. Components of the crystalloid solution include Plasmalyte A, sodium bicarbonate, mannitol (decreases myocardial edema and acts as a free radical scavenger), potassium (depolarization), lidocaine (maintains arrest in a hyperpolarized state), and magnesium (Table 11.3) [89].

The group at the Congenital Heart Institute of Florida currently uses a cardioplegia protocol that involves the administration of up to four distinct cardioplegia solutions, depending on the particular procedure being performed (Table 11.4).

For standard cases at mild to moderate levels of hypothermia, a warm-induction dose is given initially (10–20 mL/kg), followed immediately by a high K cold-induction dose (20–30 mL/kg). Total induction volume is 40 mL/kg. Subsequent maintenance cardioplegia doses are given at roughly 20-minute intervals using the low K maintenance solution at half-induction doses (10–20 mL/kg). Before removal of the cross-clamp, a hot-shot dose of physiologic K warm perfusion is administered (10–20 mL/kg), followed by warm oxygenated blood reperfusion for 2 minutes.

Patients undergoing procedures that require a period of circulatory arrest are cooled to systemic temperatures of 18 °C. For myocardial protection, only the high K cold-induction dose is given (40 mL/kg). The warm-induction dose is not administered for circulatory arrest cases.

For cardiac transplant patients, initial reperfusion of the recipient heart with an aspartate- and glutamate-enriched leukocyte-filtered solution is used [90].

Plasmalyte A	1000 mL
Mannitol 20%	16.30 mL
Magnesium sulfate 50%	4.0 mL
Sodium bicarbonate 1 mEq/mL	13.0 mL
Lidocaine 1%	13.0 mL
Potassium chloride 2 mEq/mL	13.0 mL

Table 11.4 Neonatal/pediatric cardioplegia composition at the Congenital Heart Institute of Florida. (D5W, 5% dextrose; NaCl, sodium chloride; THAM, tromeThamine.)

	High K+ cold induction	Low K+ maintenance	Warm induction	Physiologic K+ warm reperfusion
D5W/0.22 NaCl	165 mL	165 mL	165 mL	165 mL
THAM 0.3 M	60 mL	60 mL	60 mL	60 mL
Potassium chloride	15 mEq	6 mEq	15 mEq	1.5 mEq
Magnesium sulfate	5.6 mEq	5.2 mEq	15.6 mEq	14.3 mEq
Aspartate 3.92%/Glutamate 4.28%			75 mL	75 mL
Volume dispensed	233.9 mL	229.3 mL	311.4 mL	304.4 mL

Retrograde Cardioplegia

Retrograde cardioplegia is an effective technique for administering cardioplegia in selective cases. Retrograde cardioplegia is routinely used for cases involving an open aortic root and coronary artery transfers such as the arterial switch procedure and Ross procedure. Retrograde cardioplegia is also particularly helpful in cases where the ability to arrest the heart because of severe aortic insufficiency is in question.

The retrograde cardioplegia cannula is placed under direct vision into the coronary sinus and secured by either balloon insufflation or placement of a purse-string suture (6-0 Prolene) around the coronary sinus. For larger patients, the retrograde cannula can be placed "blindly" by feel through a small stab incision in the right atrium. A 6-Fr retrograde cannula (DLP®; Medtronic) is the preferred cannula for neonatal surgery. During infusion of retrograde cardioplegia, flow through the retrograde cannula is adjusted to result in a cardioplegia perfusion pressure no higher than 50 mmHg.

Disadvantages for the use of retrograde cardioplegia include the potential nonuniform distribution of cardioplegia away from portions of the right ventricle and right atrium. Using retrograde cardioplegia in patients with a left-sided superior vena cava draining into the coronary sinus may also cause problems. Placement of the retrograde cannula can be difficult in the neonate and may require a carefully placed purse-string suture around the coronary sinus to prevent dislodgement. Care must be taken in placement of the purse-string suture to avoid the conduction system and prevent complete heart block. Direct coronary ostial administration of cardioplegia is an alternative technique when retrograde cardioplegia is difficult or impossible.

Conclusion

Pediatric cardiac surgery is a unique process, with many differences from adult cardiac surgery. Techniques for myocardial protection must take into account a myriad of factors including the physical size of the heart and operating field as well as the physiologic differences of the immature heart.

Many different techniques and forms of cardioplegia are successfully used by multiple centers with excellent results. In 2004, Ungerleider published a review of practice patterns of congenital heart surgeons collected from surveys of the Congenital Heart Surgeon's Society and from audience response at the American Association for Thoracic Surgery (May 2003) and the Society of Thoracic Surgeons (January 2004) [91]. This review demonstrated that numerous practice patterns exist, with unanimity only in the recommended use of cardioplegia, although the delivery, type, and timing of doses varied.

It is difficult to effectively compare techniques used at one institution with another because multiple variables exist, including surgical technique, operative times, anesthetic management, and perfusion methods. What may give excellent results at one institution may truly be surgeon or center specific and may not translate well for use at another institution.

The fact that multiple protocols for cardioplegia exist suggests that we still have much to learn about the optimal methods for myocardial protection. Further investigations, specifically in the field of pediatric myocardial protection, will increase our understanding and continue to improve outcomes.

CHAPTER 12

Patent Ductus Arteriosus

Muhammad Ali Mumtaz,[1] Athar Qureshi,[2] Constantine Mavroudis,[3] and Carl L. Backer[4]

Introduction

The ductus arteriosus is an arterial connection between the pulmonary artery and the aorta. It is normally present in the fetus to direct the pulmonary arterial blood to the aorta. The ductus arteriosus closes shortly after birth, and the term *patent ductus arteriosus* (PDA) refers to the pathologic persistence of the ductal lumen after birth.

Patent ductus arteriosus was first ligated by Strieder [1] in Boston in 1937 in a patient with infective endocarditis. Although he achieved technical success, the patient died from aspiration in the postoperative period. The first successful ligation to a PDA is credited to Gross [2] in a 7-year-old girl in 1938. This ushered in a new era of cardiac surgery. Interestingly, treatment of PDA is also the lesion that was the substrate for closure by interventional cardiology methods when Porstmann [3] closed a PDA with a foam plug placed with a catheter. Furthermore, PDA happens to be the first anatomic lesion treated with pharmacologic manipulation [4]. This chapter discusses PDA occurring as an isolated lesion and not in association with other cardiac malformations.

Anatomy

The ductus arteriosus is a normal fetal structure connecting the pulmonary artery to the aorta. During the fourth week of embryonic development, the pharyngeal arches develop. Each arch has its own artery and nerve. The arteries join in the front with the truncus arteriosus and in the back with the dorsal aorta. The sixth aortic arch gives rise to the ductus and proximal branch pulmonary arteries. On the right side, the proximal aortic arch gives a branch toward the lung bud. The distal connection to the dorsal aorta disappears, and the proximal portion remains connected to the right lung and forms the right pulmonary artery. On the left side, the distal connection to the dorsal aorta persists as ductus arteriosus, and the proximal portion connects to the lung bud forming the left pulmonary artery. This results in the interesting relation between the recurrent laryngeal nerve and the ductus. The recurrent laryngeal nerve is the branch to the sixth pharyngeal arch. As the heart and great vessels descend into the thorax, the nerves are pulled into the thorax. Since on the right side the distal sixth arch disappears, the recurrent laryngeal nerve hooks around the derivative of the right fourth aortic arch (proximal subclavian artery), because there is no fifth aortic arch in humans. On the left side, the nerve hooks around the ductus because it is the persisting derivative of the sixth left aortic arch.

The pulmonic origin of the duct is typically at the pulmonary artery bifurcation, somewhat closer to the left pulmonary artery. It then gently curves posteriorly and inferiorly to be inserted into the descending aorta beyond the origin of the left subclavian artery. The angle between the superior edge of the ductus and the underside of the aorta is acute. It is occasionally "reversed" when this angle is greater than 90 degrees. Reversed ductus is commonly associated with pulmonary atresia and right ventricular outflow obstruction [5]. Ductus is occasionally inserted at the base of the subclavian artery. In the case of right aortic arch, it frequently inserts at the base of the left-sided innominate artery. It is typically absent in truncus arteriosus, pulmonary atresia/ventricular septal defect (VSD) with absent central pulmonary arteries, and in tetralogy of Fallot with absent pulmonary valve. It may occasionally be absent in tetralogy of Fallot. It is rarely bilateral or just right sided. The media of the ductus arteriosus is composed of longitudinally and spirally arranged layers of smooth muscle fibers within loose, concentric layers of elastic

tissue. The intima of the ductus arteriosus is thickened and irregular, with abundant mucoid material, sometimes referred to as intimal cushions. This is in contrast to the media of aorta and pulmonary artery, which have circumferentially arranged layers of elastic fibers [6].

Etiologic Factors

Prostaglandins

During fetal life, as the lungs are collapsed and fluid-filled, pulmonary vascular resistance is high, and ductal flow is right to left. The patency is maintained by low oxygen saturation and circulating prostaglandins. In mice, this effect appears to be mediated by cyclooxygenase-2 (COX-2) isoform. In a mouse fetus, ductal constriction can be achieved by selective COX-2 inhibitors but not selective COX-1 inhibitors [4]. The role of prostaglandins constitutes the rationale for the administration of nonsteroidal anti-inflammatory drugs in the treatment of PDA [7]. After birth, the increase in arterial oxygen results in inhibition of the prostaglandin synthase followed by a fall in the circulating prostaglandin level. This may be mediated via an oxygen-sensitive potassium channel [8]. This leads to ductal constriction and eventual closure.

Prematurity

A number of factors are responsible for the patency of the duct in the premature infant. Hypoxia and respiratory distress accompanying the lung disease of prematurity are the major factors. In neonatal lambs, respiratory distress results in elevation of prostaglandin levels that may lead to persistence of the PDA [9]. Similarly, cortisone increases the sensitivity of the ductal tissue to circulating prostaglandins, leading to earlier or premature closure [10].

Drugs

Various drugs, including angiotensin-converting enzyme (ACE) inhibitors, have been implicated in ductal patency.

Genetic Factors

Genetic factors also seem to play a role in persistence of PDA. Patients with trisomy-21 seem to have a higher incidence of PDA [11]. Siblings of patients with PDA had an increased incidence of up to 2–4% [12]. Char syndrome is an autosomal dominant trait characterized by PDA, facial dysmorphism, and hand anomalies. The mutation related to Char syndrome has been mapped to chromosome 6. Similarly, other mutations have been linked to PDA [13]. Others have found increased incidence in cases of parental consanguinity. Mutations on chromosome 12 have been linked to high incidence of PDA in children of consanguineous Iranian parents [14].

Congenital Infections

Infections such as rubella are associated with PDA. In addition, sepsis in premature babies frequently results in reopening of the PDA [15].

Pathophysiology

After birth, with the drop in pulmonary vascular resistance, there is increased blood flow from the aorta to the pulmonary artery through the PDA during both phases of the cardiac cycle. As a result, size-for-size, a PDA results in more pulmonary overcirculation than a VSD or an atrial septal defect (ASD). The resulting pulmonary congestion results in typical symptoms of congestive heart failure. Pulmonary hypertension from a persistent patent duct can develop earlier as well. The diastolic steal of systemic blood flow into the pulmonary circulation in neonates and premature babies is thought to be the mechanism for development of renal and gastrointestinal dysfunction. Because of velocity acceleration in a small or restrictive PDA, endothelial damage can occur. This may be a contributing factor for development of infective endocarditis.

Natural History

Recent studies have documented PDA to be present in 0.9% of full-term live births at 1 month of age [16]. One study reports an incidence of 4.5% in full-term normal babies at 2–6 months of age [17]. The incidence had previously been reported as much lower (1 in 2000) [18]. This discrepancy is probably related to the occurrence of "silent PDA" picked up by echocardiography. The incidence of PDA is around 30% in very low birthweight premature infants (<1500 g) [19] and decreases with age after birth. However, a very small percentage of PDAs close after 6 months of age. The mortality from untreated PDA is high, and 30% of patients born with an isolated PDA die within the first year. The most common mode of death is heart failure. Pulmonary hypertension, pulmonary hemorrhage, and infective endocarditis are other modes of death. Infective endocarditis has been reported in all age groups, including neonates [20]. Although the incidence of infective endocarditis in a patient with PDA has been debated, it is probably underreported [21,22].

Clinical Features

Clinical features of patients with PDAs vary depending on the resistances of the systemic and pulmonary circulations, the age of the patient, and the anatomy of the PDA. Preterm infants with PDAs may initially need their PDA as an obligatory shunt because of initial high pulmonary vascular resistance. With severe pulmonary hypertension,

the PDA serves as a mechanism to maintain cardiac output and prevent right heart failure. However, despite prematurity, many of these babies have significant left-to-right shunts through a PDA very early on in life and sometimes within hours of birth [23]. As pulmonary vascular resistance falls, if the PDA is significant, these babies develop signs of congestive heart failure, or "pulmonary overcirculation." This often manifests as an inability to wean from the ventilator or as an increase in ventilatory requirements. In extreme situations, poor systemic cardiac output may be seen with signs of poor peripheral perfusion and multiorgan failure. Although controversy still exists, the presence and hemodynamic consequence of a PDA may lead to chronic lung disease (bronchopulmonary dysplasia), necrotizing enterocolitis, intraventricular hemorrhage, and renal failure [24]. An uncommon and not often thought of consequence of a PDA is pulmonary hemorrhage, which can be catastrophic in some cases. Kluckow *et al.* found an incidence of 9.5% of pulmonary hemorrhage in premature newborns in a study where a ductus with a hemodynamically significant left-to-right shunt was seen in 92% of patients [25]. Left untreated, PDAs in premature babies are associated with increased mortality [26].

Infants with a significant left-to-right shunt present with signs of congestive heart failure (i.e., tachypnea, poor feeding, and poor growth). Children may present with symptoms of a left-to-right shunt, such as poor growth and fatigue, particularly with exertion, if the PDA is large. Infants and children can develop episodes of frequent upper respiratory tract infections or pneumonias. However, many children and adults are asymptomatic. Patients with large PDAs that are not treated have features of pulmonary hypertension and, in fact, may develop Eisenmenger syndrome [27,28]. Although rarely seen in the developed world, this is unfortunately still seen in developing nations.

Diagnosis

In patients with a significant left-to-right shunt through the ductus, a wide pulse pressure is present because of diastolic run off. The precordium is hyperactive, and a continuous, "machinery" murmur is audible in the left infraclavicular area and throughout the precordium (in small babies). In clinical practice, however, the diastolic component of this murmur is not always heard in premature babies. A diastolic rumble because of increased flow across the mitral valve is heard when the shunt is very large. Hepatomegaly is also present. Rales are not usually heard in congestive heart failure in babies and children. In patients who have significant pulmonary hypertension, the oxygen saturation in the lower extremities may be lower than in the upper extremities because of the predominant right-to-left shunt. An increased right ventricular impulse may be felt. A loud pulmonary component of the second heart sound is present. Often, no murmur is heard because of the elevated pulmonary vascular resistance. If, however, significant tricuspid regurgitation is present, a systolic regurgitant murmur is heard.

Elevations in plasma B-type natriuretic peptide levels have been found in preterm babies with symptomatic PDAs [29]. The electrocardiogram may support pulmonary hypertension (right-ventricular hypertrophy) or left-ventricular volume load depending on the presenting physiology. Chest roentograms show a normal-sized heart if pulmonary hypertension is present (may be enlarged if pulmonary hypertension is longstanding), and cardiomegaly with increased flow to the lungs is present if the left ventricle is volume loaded. Transthoracic echocardiography is the standard for diagnosis and defines the anatomy and hemodynamic significance of the shunt. In premature babies, defining a hemodynamically significant PDA on the basis of clinical grounds alone may be fraught with difficulty in the presence of other comorbidities. In these patients, echocardiographic parameters such as left-ventricular dilation, a left atrial to aortic root ratio of more than 1.3:1 or more than 1.5:1 (depending on hydration status), and diastolic flow reversal in the descending aorta are all indicators of a hemodynamically significant left-to-right shunt [30]. The left atrium may, however, not be significantly dilated in the presence of a significant atrial level shunt, which decompresses the left atrium. In preterm infants weighing less than 1500 g, an absolute PDA diameter of more than 1.5 mm at a mean age of 19 hours has been found to predict a hemodynamically significant PDA that would require treatment [31]. Details of the anatomy of the PDA, aortic arch, and brachiocephalic vessel branching pattern are extremely important, with obvious surgical implications. Transverse arch hypoplasia and typical juxtaductal coarctation should be ruled out (by careful ductal arch imaging and evaluation of the aortic isthmus). Cardiac catheterization is no longer used for diagnosis. However, in rare cases where pulmonary hypertension is present, diagnostic catheterization may be needed for hemodynamic purposes and to test the reactivity of the pulmonary vascular bed with pulmonary vasoactive agents.

Management

Medical treatment in children and adults who present with hemodynamically significant PDAs includes diuretics, digoxin, and afterload-reducing agents such as ACE inhibitors. Definitive treatment via interventional catheterization or surgery is relatively easily performed, and, in practice, few patients remain on medical therapy for congestive heart failure for prolonged periods of time. Antibiotic prophylaxis before potentially bacteremic procedures is no longer recommended per the recently revised American

Heart Association guidelines [32]. The management of a silent ductus is controversial, because there have been only few reports of silent PDAs as a source of endarteritis [33,34].

Management in Premature Infants

In the premature infant, PDAs can be challenging to manage and are a source of significant hemodynamic compromise. Medical and supportive treatment should target the hemodynamic effects of the left-to-right shunt. Optimizing the hematocrit, fluid restriction, and diuresis are all advantageous. Other measures include instituting intravenous inotropes (or oral digoxin) and ACE inhibitors.

Definitive treatment is either achieved by pharmacologic means or by surgery. In two separate reports in 1976, Friedman *et al.* and Heymann *et al.* reported the initial experience of closure of the ductus with indomethacin [4,35]. Indomethacin is a nonsteroidal anti-inflammatory agent (NSAID) that inhibits cyclo-oxygenase and, thus, prostaglandin synthesis [36]. Traditionally, intravenous indomethacin has been administered, and a variety of dosing regimens have been proposed. At our institution, we administer intravenous indomethacin at a dose of 0.2 mg/kg followed by 0.1 mg/kg for two additional doses at 12-hour intervals. If needed, this course is repeated at a dose of 0.2 mg/kg for three doses at 12-hour intervals. It is important to note, however, that indomethacin can effect platelet function (which can lead to necrotizing enterocolitis and intraventricular hemorrhage) and cause oliguria and renal toxicity. Recently, the use of intravenous ibuprofen has been shown to have similar closure rates (70% initial closure rate), with significantly decreased renal toxicity [37]. Moreover, oral ibuprofen has been shown to be as effective as intravenous ibuprofen with fewer adverse effects in very low birthweight infants [38].

If a hemodynamically significant PDA does not close or get significantly smaller despite medical therapy, surgical ligation is performed. Surgical ligation is also performed in these babies if there are contraindications to pharmacologic treatment with NSAIDs. Although there are reports of coil occlusion of the ductus in select preterm babies [39], we currently recommend surgical ligation in this group of patients. Prophylactic treatment of PDAs in preterm babies is controversial. It has been shown that it is possible to predict PDAs that are likely to become hemodynamically significant on the basis of early echocardiographic parameters [31]. Although this is advocated by some centers, in general this has not been our routine practice.

Surgical Repair of PDA

Isolated PDA can be repaired via thoracotomy or sternotomy or minimally invasive procedures.

Left Thoracotomy

Left thoracotomy is the more common approach for isolated PDA repair. Although anterolateral thoracotomy was used in the initial cases [1,2], muscle-sparing posterolateral thoracotomy is the more common approach at present. This can be done in any size patient. The alternate approach of transaxillary thoracotomy, which is really a modification of lateral thoracotomy, can also be used with good cosmetic results. The patient is placed in the right lateral position. An axillary roll of cushioned material is placed, and the left arm is secured appropriately. It is important to avoid pressure on skin and nerves while in this position (peroneal nerve, ankle, etc.). We prefer to use a rather small incision that is posterior to the midaxillary line and is about 1 cm or less below the tip of the scapula and to use a muscle-sparing approach to preserve the periosteum of the ribs. Entry is typically through the third or fourth intercostal space. Others have used an extrapleural approach [40], although transpleural is equally safe. The lung is gently retracted anteriorly using a small gauze sponge or a retractor.

Before dissection is begun, it is important to identify the complete anatomy, including the left recurrent and phrenic nerves, the left subclavian artery, the distal aortic arch, the descending aorta, and the PDA. It is important to stay as posterior as possible to the recurrent nerve. We typically do not identify the left pulmonary artery from this approach. We believe it is unnecessary and potentially hazardous to the recurrent laryngeal nerve. If the steps as noted above are followed, especially in that particular order, the anatomy can easily be understood, and ligation of the inappropriate vessel will not occur. The PDA is dissected at 1 or 2 mm from its aortic end, taking care not to injure it, especially in the window between its superior edge and the aortic arch. The duct can then be ligated or clipped. The technique of double ligation and excision ensures complete interruption and is the most reliable technique. It is our preferred technique in older children; however, it may be difficult in very small babies. Double ligation or double clipping is also used to ensure complete occlusion of the duct. A single chest tube is placed and can be removed after closure of the chest or 24 hours later as clinically indicated.

Median Sternotomy

Median sternotomy is rarely used for isolated PDA ligation. However, it is an option in cases where left lung compression is not possible (e.g., unilateral right lung diseases such as interstitial emphysema or bilobar right-sided pneumonia). Another situation requiring an anterior approach is for the window-like duct, which is short and wide. This may require cardiopulmonary bypass. In adults

with a calcified ductus, the anterior approach is preferred. A lower partial sternotomy or ministernotomy may be used if appropriate. The pericardium is incised longitudinally, and pericardial stays are applied. The PDA is dissected close to the pulmonary arterial location because the recurrent nerve is closer to the aorta. Furthermore, use of electrocautery should be very limited in dissection of the PDA, especially laterally to avoid thermal injury to the recurrent laryngeal nerve. It is critical to identify the right and left pulmonary arteries, especially in a small baby. Dissection can be facilitated using a fine-tipped clamp. The PDA can then be ligated with silk or braided polyester or clipped using metal clips. Alternatively, ligation and division ensures interruption of the PDA. A single pericardial or pleuropericardial drain is placed, while ensuring that it is not compressing the heart.

Minimally Invasive Techniques

Patent ductus arteriosus ligation has been accomplished using video-assisted techniques as well as robotic surgery [41–43]. Video-assisted surgery has gained more popularity, and some centers use this technique exclusively. Incidence of conversion to open technique is low, and in experienced hands, the surgical time is comparable. With the availability of 3 mm ports and camera, video-assisted techniques are feasible even in premature babies [42,44]. Lung retraction instead of lung collapse can be used. Costs and early morbidity of video-assisted techniques compared with the open technique are similar [45]; however, the long-term sequelae of thoracotomy are avoided. Robotic surgery is currently limited to children more than 12–15 kg. Operative times are long, and it is difficult to show any benefit over video-assisted technique at this time [46].

Special Considerations in Premature Infants

A premature baby presents significant challenges. The PDA may not be necessarily more fragile, but the small size of the baby creates technical issues. Airway and intravenous access are critically important. The endotracheal tube can easily be dislodged during positioning. Careful temperature management of the baby to avoid hypothermia is imperative. We perform the surgery in the neonatal intensive care unit. Our usual approach is a muscle sparing posterolateral left thoracotomy through the third intercostal space. The basic surgical steps are similar to those described earlier. The PDA can be singly ligated or clipped. It is important to identify the anatomy to avoid ligation of the incorrect vessel. We typically leave a single chest tube overnight, although others have been removed at the end of the case.

Special Consideration in Infants and Children

Children and infants can be in significant congestive heart failure because of a PDA. Whereas most of these patients will have PDA occlusion via percutaneous technique, those coming to surgery typically have a large and possibly shorter duct. They may come to surgery after a failed attempt at percutaneous occlusion, in which case the device or coil may still be deployed. If no device or coil is in place, left posterolateral thoracotomy is safe. A muscle sparing approach via the fourth intercostal space is our preferred approach. The duct should be doubly ligated and preferably divided to avoid any chance of residual shunt. In cases where the duct is very short and wide, it may best be addressed via median sternotomy with options for cardiopulmonary bypass. This situation is rather rare. If a PDA closure is required in a child with a failed device and the device is still in place, it is usually best to address this from the front with a full or partial median sternotomy because the device can be extracted from the pulmonary artery with or without the use of cardiopulmonary bypass [47].

Special Considerations in Adults

Surgical closure of PDA in adults is rarely required because of advances in percutaneous techniques. Patients requiring surgery are best addressed via a median sternotomy and preparation for cardiopulmonary bypass. This is because of frequent calcification of the duct. A calcified duct can be closed under circulatory arrest or regional cerebral perfusion. It is common to use a patch or primary closure through the pulmonary artery. Another excellent option avoids or limits the use of circulatory arrest by using a balloon-tipped catheter to occlude the duct [48,49]. This then allows the surgeon to sew a patch on the pulmonary arterial end from the inside of the pulmonary artery.

Surgical Outcomes

Excellent outcomes have been reported after surgical ligation of PDA with little or no surgical mortality and a low morbidity [45]. Recurrent laryngeal nerve injury has been reported, with a low incidence except for one study with 52% incidence [32]. Cases of chylous leaks are rare. Incidence of scoliosis after thoracotomy has been noted in 19–31% of patients [50–52]. By preserving the periosteum of the ribs and performing a posterolateral muscle sparing thoracotomy, there is potential to avoid some of the sequelae of thoracotomy. Video-assisted techniques further decrease the trauma of thoracotomy and its long-term sequelae. The incidence of residual PDA is low in some studies (3.1%); however, with ligation and division, the incidence is zero [53].

Percutaneous Closure of PDA

In 1967, Portsmann performed the first transcatheter PDA closure, which was a landmark event in the field of interventional cardiology [54]. His initial technique, however, required a large sheath and arterial cutdown [54,55]. Since his pioneering work, numerous devices have been used [56–58]. Over the years, modifications of the technique and devices used have resulted in smaller delivery systems and the ability to occlude even large PDAs safely in small patients.

Currently, the two most widely used methods of closing PDAs in the catheterization laboratory employ the use of coils or the Amplatzer® Duct Occluder (AGA Medical Corporation; Plymouth, Minnesota). Generally, coil occlusion is performed in PDAs less than 3 mm in diameter. There are numerous types of coils that can be used. The coils that are most often used are 0.038-inch Gianturco stainless steel coils (Cook, Inc; Bloomington, Indiana). Dacron fibers are present on the coils to promote thrombus formation and closure of the PDA. Coils can be deployed antegrade (from the venous side; Figure 12.1) or retrograde (from the arterial side). The diameter of coil chosen is about twice the size of the smallest dimension of the duct, with 1.5 loops or less of the coil deployed on the pulmonary artery side and the majority of loops deployed in the ampulla on the aortic side of the duct. Coils are advantageous in that they are cheaper than Amplatzer Duct Occluders. Coil occlusion in very small infants is often not feasible, particularly in large PDAs with little constriction at the pulmonary end. In a large cohort of patients from the European Coil Registry, 5% of patients had a residual leak 1 year after coil implant [59]. In our experience however, the vast majority of residual leaks are clinically insignificant.

The Amplatzer Duct Occluder has helped overcome many of the shortcomings of coils (i.e., occurrence of residual leaks and limitations in occlusion of large ducts). They are mainly used to occlude PDAs larger than 3 mm and are approved for use in infants more than 6 months of age and weighing more than 6 kg. The device consists of a pulmonary end and a larger aortic end with a retention disc. The device has memory and is made of nitinol, which is easily collapsed into the appropriate-sized delivery sheath. Polyester fabric is added to the device to promote thrombus formation. The size of the device chosen should have

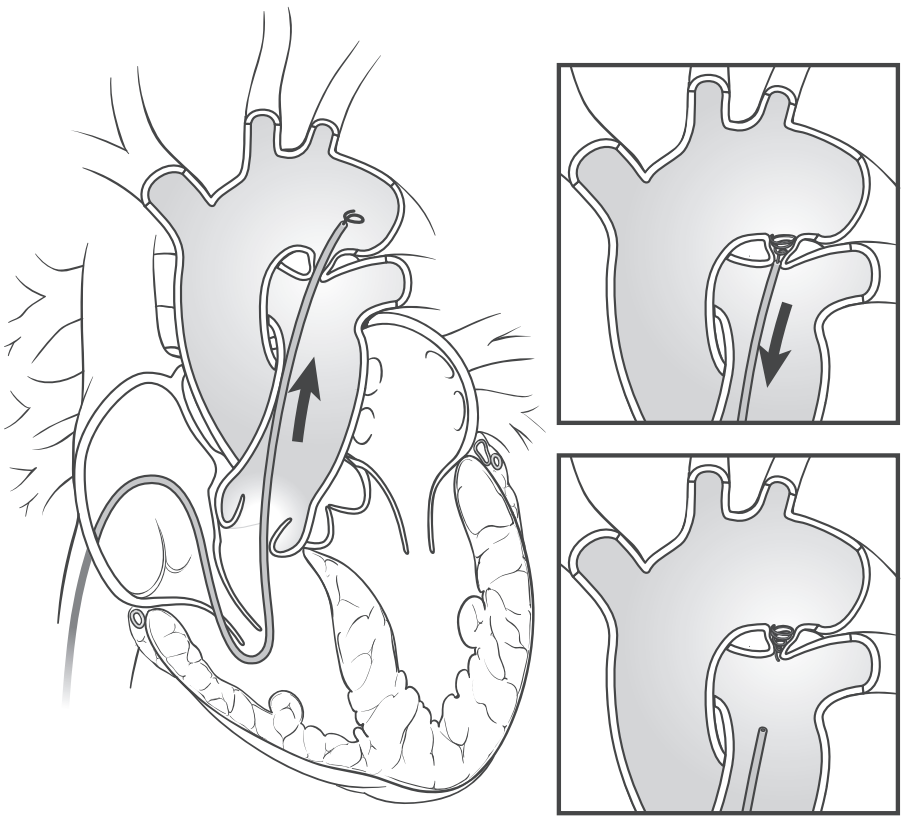

Figure 12.1 A coil being deployed antegrade (from the venous side) in a patent ductus arteriosus. Note that most of the loops of the coil are on the aortic side of the ductus (i.e., in the ampulla). (Reproduced with permission from the Cleveland Clinic Center for Medical Art & Photography. Copyright © 2009–2012. All rights reserved.)

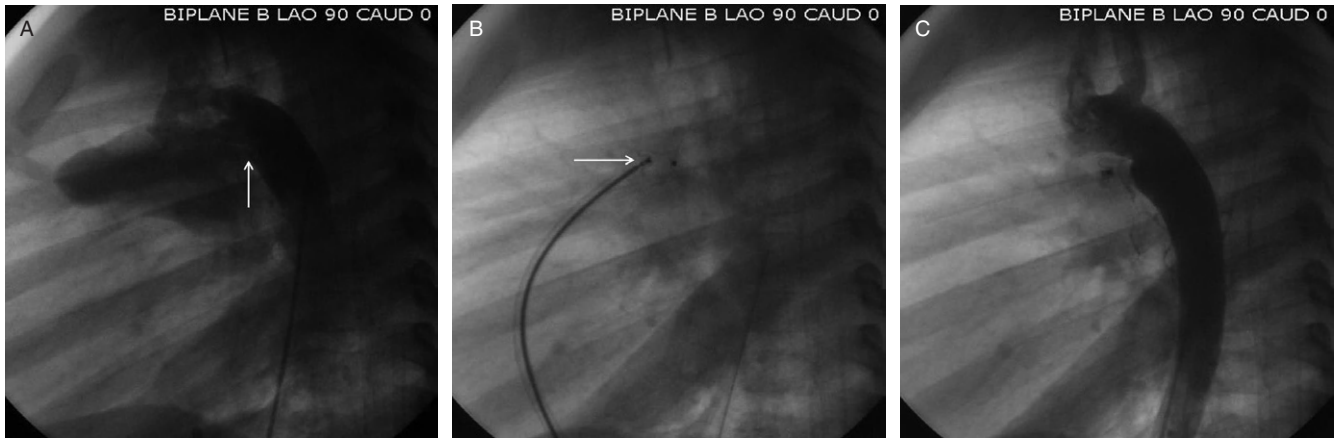

Figure 12.2 A, This straight lateral aortogram in a 2-year-old boy shows a moderate-sized PDA (arrow). **B,** An 8/6 Amplatzer Duct Occluder is advanced antegrade (from the venous side). The device has been deployed and the retension disc is seen opposing the aortic side of the ampulla, while the delivery cable (arrow) is still attached to the pulmonary end of the device. **C,** After release of the device, no residual shunt through the PDA is seen.

a pulmonary end diameter that is 1–2 mm larger than the narrowest dimension of the duct. These devices are available in sizes up to 14 mm in diameter (pulmonary end of the device). The device is always deployed antegrade to allow for the retention disc to appose the aortic side of the ampulla (Figure 12.2). An advantage of this device is that it can be fully retrieved before complete release into the delivery sheath (while still being attached to the delivery cable on the pulmonary end) if the device is not deemed appropriate or is in improper position. The experience with this device thus far has been promising, and the results of a multicenter trial using the Amplatzer Duct Occluder device showed complete closure rate of 98% up to 1 year after implantation [60]. Numerous other techniques, such as simultaneous deployment of multiple coils, have also been described for large PDAs [55,56,58].

The recent availability of a variety of coils and devices in the catheterization laboratory has limited suboptimal results and complications related to transcatheter closure of the ductus. A suboptimal outcome of transcatheter closure of PDAs was seen in patients from the European Coil Registry, which was defined as coil embolization, an abandoned procedure; persistent hemolysis; residual leak requiring a further procedure; flow impairment in adjacent structures (obstruction to left pulmonary artery or aortic flow); and duct recanalization [59]. Large PDAs and tubular PDAs were risk factors for a suboptimal outcome, and for those PDAs, the Amplatzer Duct Occluder is probably better suited. Serious and minor complication rates have been seen in 7.1% of patients undergoing closure with the Amplatzer Duct Occluder [60].

Many of the inadvertently embolized coils/devices can be safely retrieved in the catheterization laboratory, and important hemolysis can be treated by device/coil removal in the catheterization laboratory or by placement of another coil if needed. With newer technologies and smaller delivery sheaths, femoral arterial complications are now seen much less than in prior years. Infection is rare, but all patients undergoing PDA occlusion in the catheterization laboratory receive prophylactic antibiotics for 24 hours and should receive prophylactic antibiotics before potentially bacteremic procedures up to 6 months after the implant. Antibiotic prophylaxis is also recommended if residual shunts are present.

The overwhelming majority of PDAs (except those in very small infants) can be closed safely in the catheterization laboratory. In addition, catheter-based closure is as effective as and cheaper than surgical closure [61]. Surgical closure is generally performed in small infants with large ducts (less than 6 months of age or weighing less than 6 kg). Preterm babies whose ducts do not constrict after the administration of NSAIDs (or if there are contraindications to NSAID therapy) should also undergo surgical closure of their PDAs. Surgical closure of PDA is rarely performed in the older child or adult unless a concomitant surgical procedure is being performed.

Conclusion

We recommend occluding all hemodynamically significant or audible PDAs. For premature infants or symptomatic children weighing less than 6 kg, surgical PDA ligation via muscle sparing posterolateral thoracotomy is offered, though video-assisted PDA ligation may be a better long-term solution. For older children and adults, a percutaneous route is favored and surgery is reserved for cases where the percutaneous approach fails.

CHAPTER 13

Vascular Rings and Pulmonary Artery Sling

Carl L. Backer[1] and Constantine Mavroudis[2]

[1]Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Chicago, IL, USA
[2]Florida Hospital for Children, Orlando, FL, USA

Classification

The term "vascular ring" is used to describe vascular anomalies that result from abnormal development of the aortic arch complex and cause compression of the trachea, esophagus, or both. The first vascular ring described was a double aortic arch by Hommel in 1737 [1]. The phrase "vascular ring" was introduced to the surgical literature by Robert E Gross in 1945 [2]. At that time he reported the first successful division of a double aortic arch causing tracheal obstruction in a 1-year-old infant. "A ring of blood vessels was found encircling the intrathoracic portion of the esophagus and trachea." Most children with vascular rings present with symptoms in the first few months of life and require surgery within the first year of life [3]. Some of these anomalies are anatomically complete rings, or true vascular rings; others are anatomically incomplete, or partial vascular rings, but present similar symptoms because of the tracheoesophageal compression. In particular, a pulmonary artery sling is a rare vascular anomaly in which the left pulmonary artery originates from the right pulmonary artery and encircles the right mainstem bronchus and distal trachea before entering the hilum of the left lung. This anomaly was first reported by Glaevecke and Doehle in 1897 as a postmortem finding in a 7-month-old infant with severe respiratory distress [4]. The classification of vascular rings we have used at Children's Memorial Hospital in Chicago is based on anatomic and clinical features, particularly the location of the aortic arch(es). This classification scheme was recently endorsed by the Congenital Heart Surgery International Nomenclature and Database Project for the Society of Thoracic Surgeons database [5].

The history of vascular ring surgery began with the division of a double aortic arch by Gross at Boston Children's Hospital on 9 June 1945 [2]. Gross was also the first to suspend the innominate artery to the posterior sternum for innominate artery compression syndrome in 1948 [6]. The first repair of a pulmonary artery sling was by Willis J Potts at Children's Memorial Hospital in 1953 [7]. More recently, for the complex subset of patients with pulmonary artery sling who also have tracheal stenosis from complete tracheal rings, the pericardial patch tracheoplasty technique was first performed by Farouk S Idriss in 1982 [8]. The first tracheal autograft for tracheal stenosis also was performed at Children's Memorial Hospital [9]. Since Potts' first operation on an infant with double aortic arch at our institution on 27 July 1946 [10] we have operated on over 400 patients at the Children's Memorial Hospital with different types of vascular tracheoesophageal compression syndromes and this experience forms the basis for this chapter (Table 13.1).

Embryology and Pathology

In 1922 Congdon [11] reported his extensive experience with the study of the embryonic development of the human aortic arch system. Edwards [12] proposed a schematic model with a double aortic arch system and bilateral ductus arteriosus. More recently, Stewart and associates [13] summarized the pathologic, embryologic, and roentgenographic correlations of these lesions. In embryonic vascular development six pairs of aortic arches connect the two primitive ventral and dorsal aortae (Figure 13.1) [14]. The formation of a vascular ring depends on preservation or deletion of specific segments of the rudimentary embryonic aortic arch complex. Most portions of the first, second, and fifth arches regress. The third arches become the carotid arteries. A branch from the ventral bud of the sixth arch

meets the lung bud to form the pulmonary artery. On the right side the dorsal contribution to the sixth arch disappears; on the left it persists as the ductus arteriosus. The seventh intersegmental arteries arise from the dorsal aorta and form the subclavian arteries. Normally a portion of the right fourth arch involutes at 36–38 days in the 16 mm embryo, leaving the usual left aortic arch configuration (Figure 13.1) [14]. The apex of the aortic arch in this (normal) situation is to the left of the trachea.

Double Aortic Arch

If the right and left fourth arches both persist, a double aortic arch is formed (Figure 13.1) [14]. Two arches arise from the ascending aorta and pass on both sides of the trachea and esophagus, joining the descending aorta, producing a true ring. The right (posterior) arch gives origin to the right carotid and subclavian arteries. The left carotid and subclavian arteries arise from the usually smaller left (anterior) arch. In 70% of these infants, the right-sided arch is dominant, in 20% the left arch is dominant, and in 5% the arches are equal in size. The trachea and esophagus are encircled and compressed by the two arches.

Right Aortic Arch

If the left fourth arch involutes, a right aortic arch system is created (Figure 13.1) [14]. The apex of the aortic arch in these patients is to the right of the trachea. Depending on the exact site(s) of interruption of the left arch and the branching pattern to the left subclavian artery, left carotid artery, and ductus arteriosus, different configurations of right aortic arch are possible (Figure 13.2) [14]. The two common variations are retroesophageal left subclavian artery (65%) and mirror-image branching (35%) [15]. The right aortic arch with a retroesophageal left subclavian artery results from persistence of the right fourth arch and deletion of the left arch between the left carotid and subclavian arteries. The subclavian artery originates from the descending aorta and courses to the left behind the esophagus. The ligamentum extends from the descending aorta to the left pulmonary artery, completing the vascular ring (Figure 13.2A).

A right aortic arch with mirror-image branching and left ligamentum arteriosum results from persistence of the right fourth aortic arch and disappearance of the left arch between the subclavian artery and the dorsal descending aorta. When the ligamentum originates from the descending aorta, a complete vascular ring is formed (Figure 13.2B). If the ligamentum originates from the innominate artery, which is more common in this group, a vascular ring is not formed and the child is asymptomatic (Figure 13.2C). Although one third of patients with tetralogy of Fallot and truncus arteriosus have a right aortic arch [16], we did not find a reverse association with a specific cardiac defect when a vascular ring was formed by a right arch.

Pulmonary Artery Sling

The embryonic origin of pulmonary artery sling occurs when the developing left lung captures its arterial supply from derivatives of the right sixth arch through capillaries caudad rather than cephalad to the developing tracheobronchial tree [17]. The left pulmonary artery originates from the right pulmonary artery instead of the main pulmonary artery. The left pulmonary artery passes around the right main bronchus and courses between the trachea and esophagus, forming a "sling" that compresses the tracheobronchial tree (Figure 13.3) [14]. The airway may also be compromised by associated complete cartilage tracheal rings, the so-called "ring-sling" complex where the membranous portion of the trachea is absent and the tracheal cartilages are circumferential (Figure 13.3) [14,18].

Innominate Artery Compression

Innominate artery compression syndrome results from anterior compression of the trachea by the innominate artery. Why an innominate artery, which normally crosses in front of the trachea, should compress the trachea in some cases and not others is not well understood. The innominate artery appears to originate somewhat more posteriorly and leftward on the aortic arch than usual. As the artery courses to the right, upward, and posterior to reach the right thoracic outlet, it compresses the trachea anteriorly (Figure 13.4) [14,19].

Aberrant Right Subclavian Artery

A left aortic arch with aberrant right subclavian artery develops when the right fourth arch between the subclavian and carotid arteries regresses. The right subclavian artery (originating from the intersegmental artery) traverses

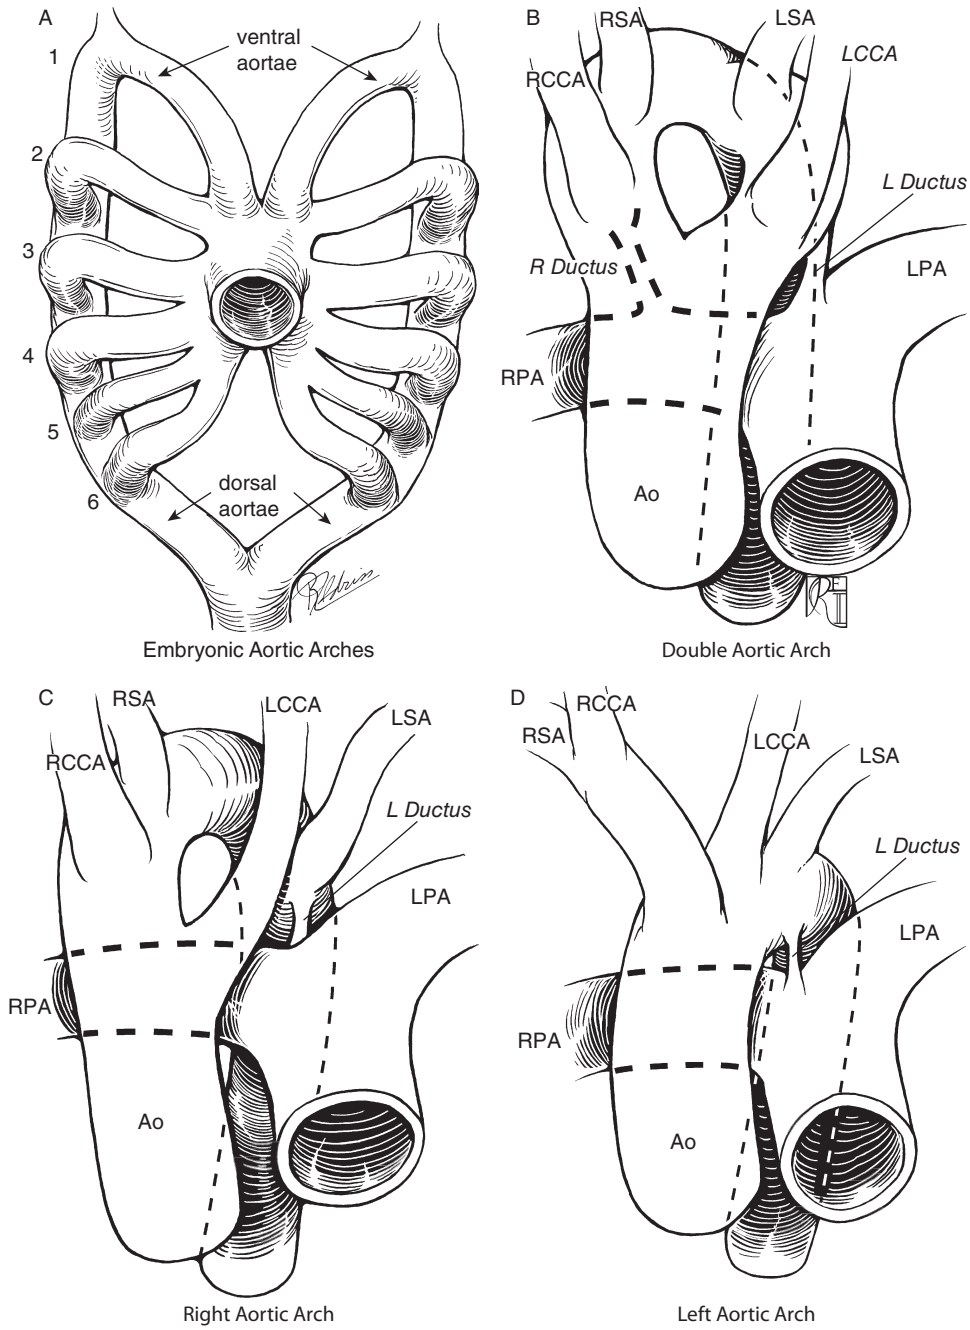

Figure 13.1 (A), Diagram of the embryonic aortic arches. Six pairs of aortic arches originally develop between the dorsal and ventral aorta. The first, second, and fifth arches regress. Preservation or deletion of different segments of the rudimentary arches results in either a double aortic arch **(B)**, a right aortic arch **(C)**, or the "normal" left aortic arch **(D)**. (Ao, aorta; CCA, common carotid artery; L, left; PA, pulmonary artery; R, right; SA, subclavian artery.)

the mediastinum and inserts on the descending aorta. The right subclavian artery then becomes a branch off the descending aorta and courses to the right, posterior to the esophagus. This produces an indentation of the esophagus, but does not form a complete vascular ring (Figure 13.5) [14]. In fact, this is the most common vascular anomaly of the aortic arch system (0.5% of humans) [20]. Because it is so common, it has been blamed in the past, mistakenly, for vague swallowing symptoms, earning the label "dysphagia lusoria," [21] or "difficulty in swallowing due to a trick of nature." The aberrant right subclavian is actually nearly always a "red herring," and not the true etiology of the child's symptoms [22]. We have not operated on a child with this diagnosis since 1973, although we are aware of some very rare cases where the aberrant right subclavian artery does compress the trachea causing symptoms.

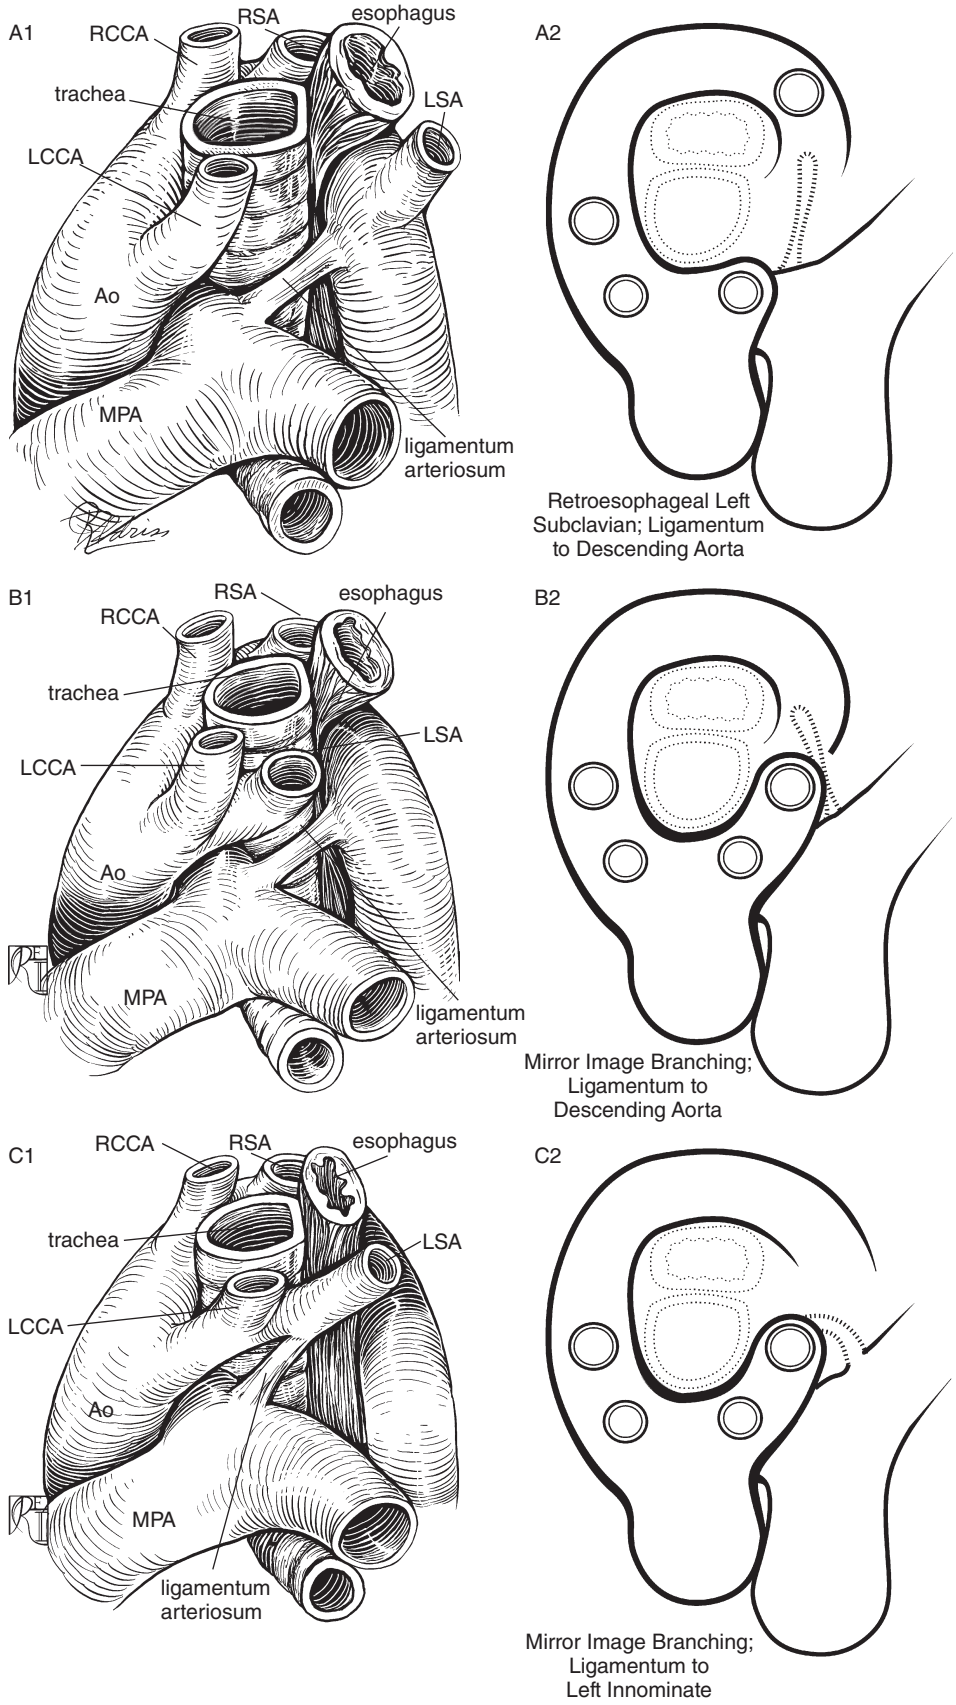

Figure 13.2 Right aortic arch types. **A,** Retroesophageal left subclavian artery, ligamentum to descending aorta. **B,** Mirror image branching, ligamentum to descending aorta. **C,** Mirror image branching, ligamentum to left innominate artery. Rare Vascular Rings

In the unusual combination of left aortic arch and right descending aorta, if there is a right patent ductus arteriosus or ligamentum arteriosum, a vascular ring is formed [23]. The left aortic arch in these cases is often a cervical arch, resulting from persistence of the third rather than the fourth embryonic aortic arch [24]. A large sweeping cervical arch may independently compress the trachea anteriorly, even in the absence of a right ductus. This combination is one of the very few vascular rings that are best approached with a right thoracotomy rather than a left thoracotomy [25]. These patients are very rare and often have associated cardiac anomalies [26]. Because we now obtain a computed tomographic (CT) or magnetic resonance image (MRI) on all vascular ring patients prior to an operation the exact anatomy and decision about the approach has become less of an "art" [27].

A single case report has described a ductus arteriosus traveling from the right pulmonary artery to the descending aorta between the trachea and esophagus with an aberrant right subclavian artery (ductus arteriosus sling) [28]. The ductus was compressing the trachea and right bronchus in a manner analogous to pulmonary artery sling. We reported a 5-month-old infant with a right aortic arch, right ligamentum, and absent left pulmonary artery who required division of the right ligamentum to relieve respiratory failure [29]. Robotin and colleagues [30] reported

three groups of unusual forms of tracheobronchial compression in a series of over 500 patients with vascular rings. Three patients had an encircling right aortic arch with a left-sided descending aorta and ligamentum ("circumflex aorta"), two patients had airway compression from a pincer effect between a malposed and enlarged ascending aorta and the descending aorta, and three patients had airway compression after an arterial switch. Van Son [31] recently reviewed two patients with a right cervical aortic arch and McElhinney [32] reviewed six patients with a cervical aortic arch. Another rare vascular ring occurs when a patient has situs inversus and has a left aortic arch with an aberrant right subclavian artery, with a right ligamentum. These patients (we have had one) require a right thoracotomy and ligation/division of the right ligamentum.

Clinical Presentation and Diagnosis

Most children with vascular rings present with symptoms within the first several weeks to months of life. The symptoms typically include some combination of the following: respiratory distress, stridor, the classic "seal bark" cough, apnea, dysphagia, and recurrent respiratory tract infections. (Table 13.2) [27]. Some older children will present only with symptoms of dysphagia or slow feeding where they tend to be the last child to leave the table because they have to chew their food carefully as a learned procedure. Infants may hold their head hyperextended to splint the trachea and lessen the obstruction, improving their breathing. Apnea or cyanosis may be precipitated by swallowing a bolus of solid food that presses on the soft posterior trachea within the restrictive confines of a ring. Most infants are well nourished, however, because they tolerate liquid formula well. When they are advanced to solid food, symptoms become more evident. The diagnosis of vascular rings requires a high index of suspicion because of the relative infrequency of this diagnosis compared with other conditions that cause respiratory distress in children such as asthma, reflux, and upper respiratory tract infection. Symptoms appear earlier and tend to be more severe in cases with a double aortic arch. A simple "cold" may precipitate severe respiratory difficulty. Children with innominate artery compression syndrome present with symptoms of tracheal compression, and nearly one half have had apneic episodes. It is of importance in these infants to rule out other causes of apneic spells. This includes a complete neurologic evaluation, investigation for gastroesophageal reflux, and sleep studies. Physical examination may reveal stridor, wheezing, tachypnea, a brassy cough, or noisy breathing. If the obstruction is severe, there may be obvious subcostal retractions, and nasal flaring. The number of patients presenting with various symptoms in our series of vascular ring patients is shown in Table 13.1.

Table 13.2 Symptoms leading to clinical presentation in patients with vascular rings*. (Reproduced with permission from Backer *et al.* [27].)

	Double aortic arch (n = 80)†	Right aortic arch (n = 78)†
Stridor	46 (57%)	18 (23%)
Recurrent upper respiratory tract infections	22 (27%)	18 (23%)
Cough	17 (21%)	8 (10%)
Dysphagia	12 (15%)	12 (15%)
Respiratory distress	8 (10%)	13 (17%)
Ventilator preoperatively	7 (9%)	3 (4%)

*More than one symptom occurred in many patients.
†Our records did not provide symptoms for the earlier patients in the series.

The diagnosis of a vascular ring starts with the plain chest radiograph. There is a myriad of other diagnostic procedures that may be employed. These include barium esophagogram, bronchoscopy, tracheograms, computed tomography, magnetic resonance imaging, echocardiography, and cardiac catheterization. The emphasis should be to arrive at a diagnosis with the most efficient use of the multiple tests available. Once the diagnosis has been made, further studies are not required and the clinician should resist the tendency to obtain more studies that simply continue to confirm the diagnosis in a slightly different way.

Chest Radiograph

The evaluation of a child with a possible vascular ring begins with anteroposterior and lateral chest radiography [33]. The mediastinum should be evaluated for a left aortic arch, right aortic arch, or double aortic arch as determined by the location of the aortic arch in relation to the trachea. When the location of the arch is not clear, a double aortic arch should be suspected. The lateral chest radiograph should be carefully evaluated for tracheal narrowing at the level of the aortic arch. High kilovoltage magnification technique is very helpful. If a right aortic arch or double aortic arch is suspected or narrowing of the trachea is seen on lateral images, further investigation for a vascular ring should be initiated. Unilateral hyperinflation of the right lung suggests a pulmonary artery sling. A completely normal chest radiograph is strong evidence against the presence of a vascular ring.

Barium Esophagogram

The barium esophagogram was historically the most widely used study for the diagnosis of vascular rings [34]. This is no longer the case and barium swallow has been supplanted by CT and MRI [27,35,36]. The impressions produced in the barium-filled esophagus by the anomalous aortic arch and/or branches often are quite characteristic for each lesion and may allow strong suspicion of the specific ring type present. A double aortic arch or right aortic arch with left ligamentum will appear as a deep persistent extrinsic indentation on the posterior aspect of the esophagus (Figure 13.6) [14]. Bilateral persistent compressions of the esophagus on the anteroposterior views are usually present with a double aortic arch (Figure 13.7) [3]. The dominant arch is usually on the right, higher, and more posterior than the lesser arch. A right aortic arch and retroesophageal left subclavian artery will produce an oblique indentation angled toward the left shoulder. A high posterior oblique indentation directed from left to right on the esophagogram is indicative of an aberrant right subclavian artery. A pulmonary artery sling is suggested by an anterior indentation of the esophagus (Figure 13.8) [14]. The diagnosis of a complete vascular ring can usually be established with some level of certainty with a barium esophagogram. However, determining the specific type of ring with a chest radiograph and esophagogram alone is not usually possible. Although historically surgeons would operate on these patients with only a barium swallow and a chest X-ray, we currently recommend CT or MRI on all vascular ring patients prior to surgical intervention [27].

Computed Tomography (CT)

CT scanning is very accurate in the identification of vascular anomalies of the aortic arch and great vessels and is our diagnostic method of choice [27,35]. A double aortic arch is diagnosed with certainty when both limbs are patent and enhanced with the intravenous administration of contrast material. However, in some cases the vascular ring may be completed by a nonenhanced segment, either the ligamentum arteriosum or an atretic portion of the lesser arch. In these cases the diagnosis of a complete ring depends on recognizing the arterial branching pattern, the side of the aortic arch, and focal narrowing of the airway. Three-dimensional reconstruction of the vascular structures establishes a very clear "road map" for the surgeon (Figure 13.9) [37].

One clue to an arch anomaly is the "four artery sign," which can be seen on sections obtained cephalad to the

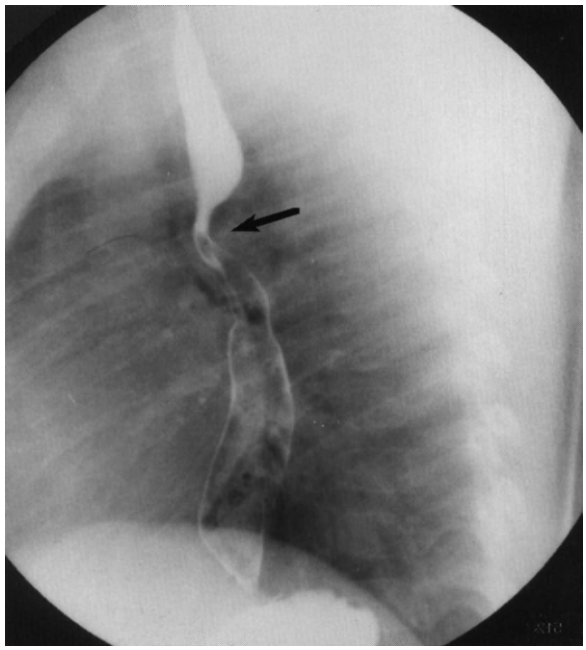

Figure 13.6 Lateral esophagogram of an 11-month-old boy with a double aortic arch, right arch dominant. Arrow points to the deep posterior indentation in the esophagus caused by the right arch.

Figure 13.7 Anteroposterior esophagogram of a 4-month-old boy who presented with stridor and was found to have a double aortic arch. (Reproduced with permission from Backer *et al.* [3].)

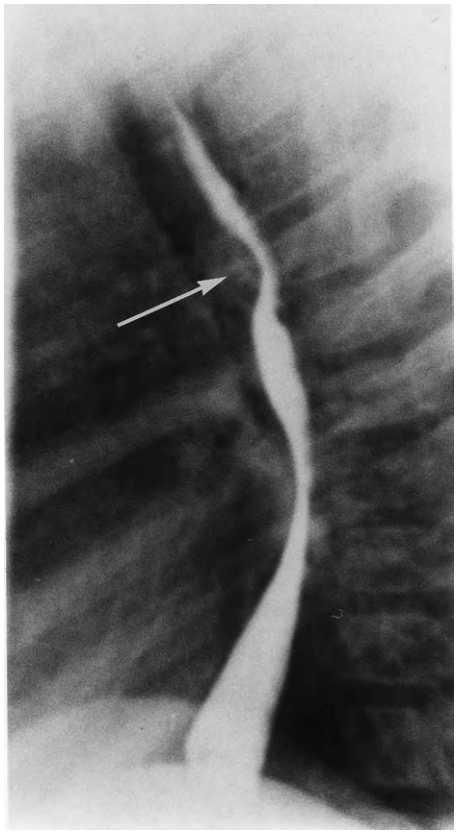

Figure 13.8 Lateral esophagogram of a 1½ -year-old girl with repeated episodes of stridor and respiratory tract infections. Arrow points to anterior indentation of esophagus caused by the anomalous left pulmonary artery.

Figure 13.9 Three-dimensional (3D) reconstruction of CT scan. A 5-month-old child with a double aortic arch, right arch dominant. The distal left arch can be clearly seen projecting like a thumb from the descending aorta. The vertical structure inside the "ring" is the nasogastric tube. The anterior portion of this left arch is atretic just distal to the left subclavian artery. The left aortic arch had eroded into the esophagus. (Reproduced with permission from Backer *et al.* [37].)

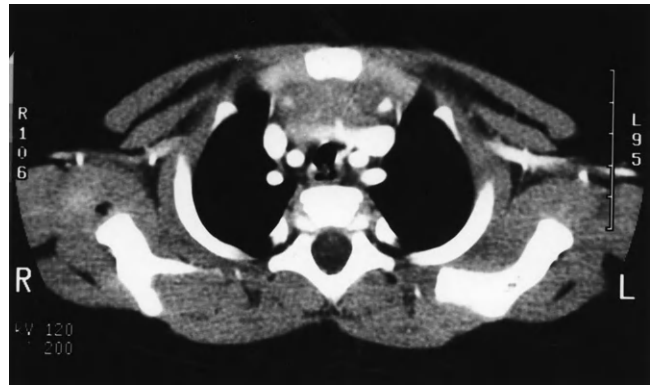

Figure 13.10 Computed tomographic scan of an 11-month-old boy with a right dominant double aortic arch. Note the four brachiocephalic vessels grouped symmetrically around the trachea.

aortic arch and consists of two dorsal subclavian arteries and two ventral carotid arteries evenly spaced around the trachea [38]. The sign is present when the two dorsal subclavian arteries arise directly from the aortic arch and not from a brachiocephalic artery. This occurs with double aortic arches and configurations with aberrant subclavian arteries (Figure 13.10) [14].

In patients with innominate artery compression syndrome, CT scan with contrast will show the anterior compression of the trachea by the innominate artery and helps to confirm the visual impression at the time of bronchoscopy (Figure 13.11) [14]. In children with a pulmonary artery sling, CT demonstrates the left pulmonary artery originating from the right pulmonary artery, encircling the trachea and coursing to the hilum of the left lung anterior to the esophagus and aorta (Figure 13.12) [37]. In addition, the presence of associated complete tracheal rings can be seen, and the extent of the tracheal narrowing can be used to plan the surgical approach.

Magnetic Resonance Imaging (MRI)

MRI is well suited for imaging vascular structures of the mediastinum (Figures 13.13 and 13.14) [3,39–42]. Axial images provide the same information as CT without ionizing radiation or the need for intravenously administered

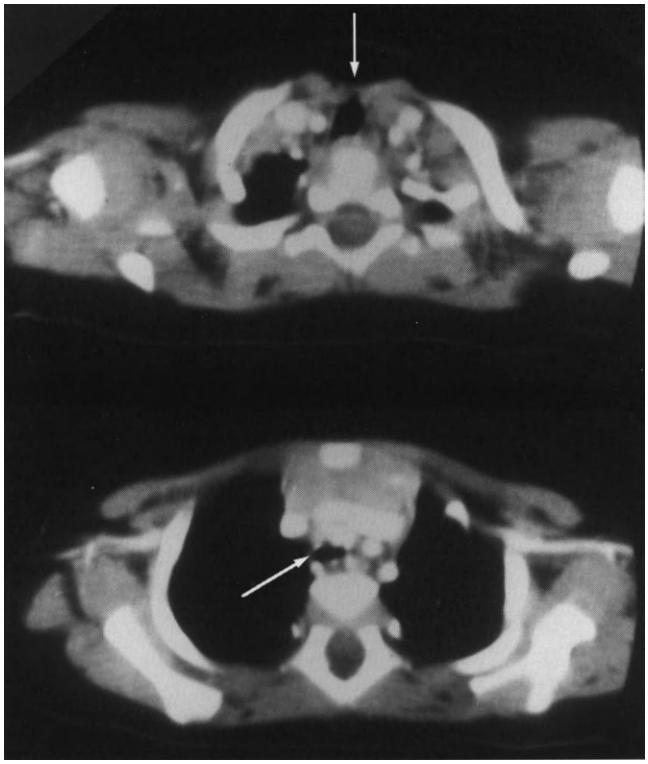

Figure 13.11 Computed tomographic scan with contrast of an infant with innominate artery compression syndrome. The superior cut shows a normal size trachea (arrow). The inferior cut shows the trachea (arrow) compressed by the innominate artery.

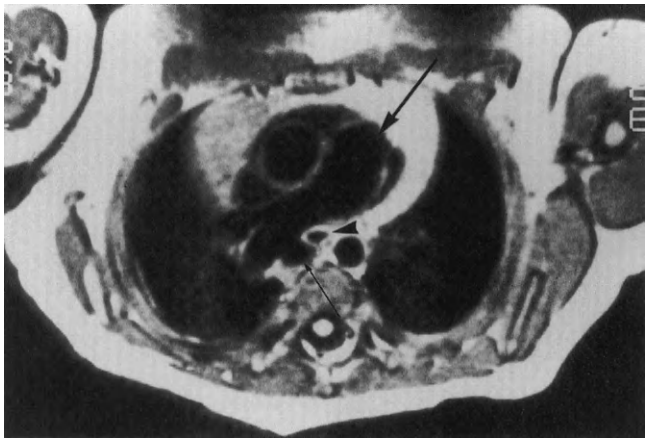

Figure 13.13 Magnetic resonance imaging in 7-month-old female infant with pulmonary artery sling and tracheal stenosis. Large arrow points to main pulmonary artery. Small arrow points to left pulmonary artery, which is curling around trachea. Trachea forms a complete ring easily visible on this study (arrowhead). (Reproduced with permission from Backer *et al.* [42].)

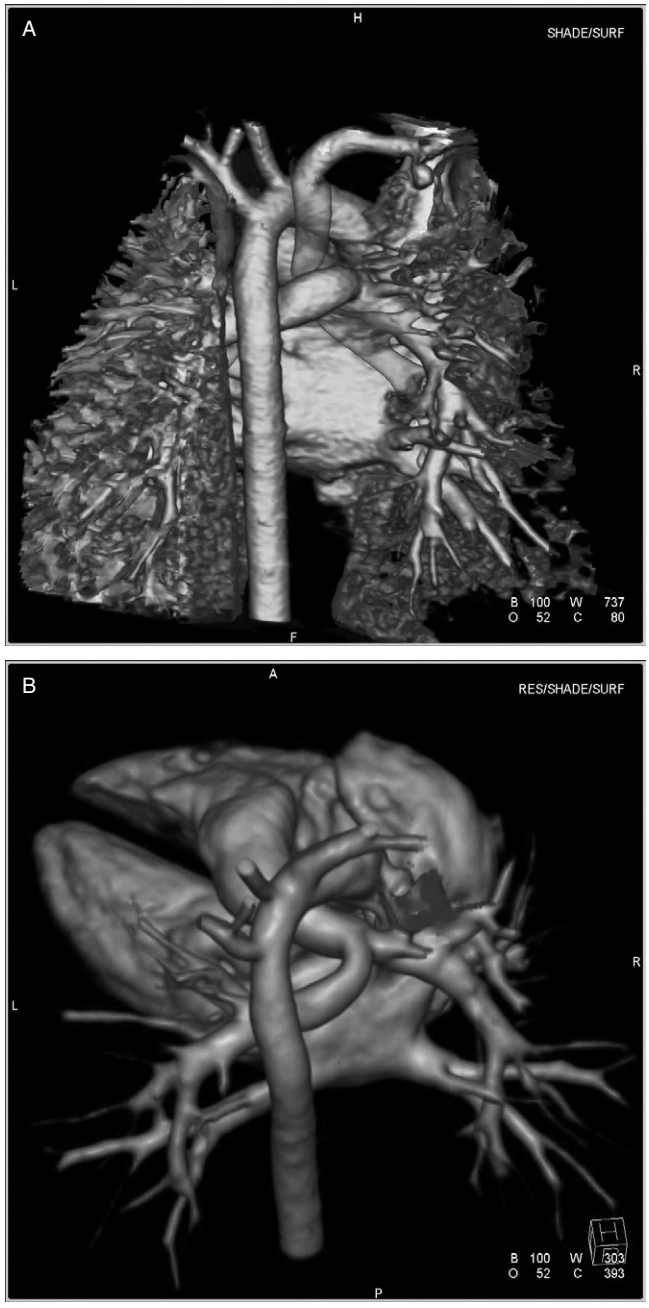

Figure 13.12 Three-dimensional (3D) reconstruction (pulmonary artery sling). **A,** This is a 3D reconstruction of a 2-month-old boy who had several apneic episodes requiring CPR. The child had a pulmonary artery sling causing significant tracheal compression. This posterior view shows the left pulmonary artery wrapping around and compressing the distal trachea and right bronchus. **B,** More cranial view of the same patient with the trachea removed to show the origin of the left pulmonary artery from the right pulmonary artery. The child had no further apneic spells after sling repair. (Reproduced with permission from Backer *et al.* [37].)

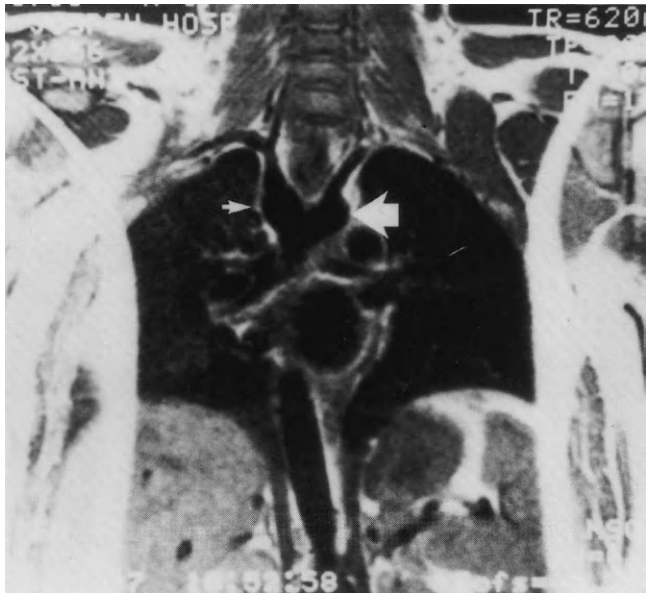

Figure 13.14 A 17-year-old patient with dysphagia. Magnetic resonance imaging shows a right aortic arch (small arrow) and a Kommerell diverticulum (large arrow) at the origin of the left subclavian artery. (Reproduced with permission from Backer *et al*. [3].)

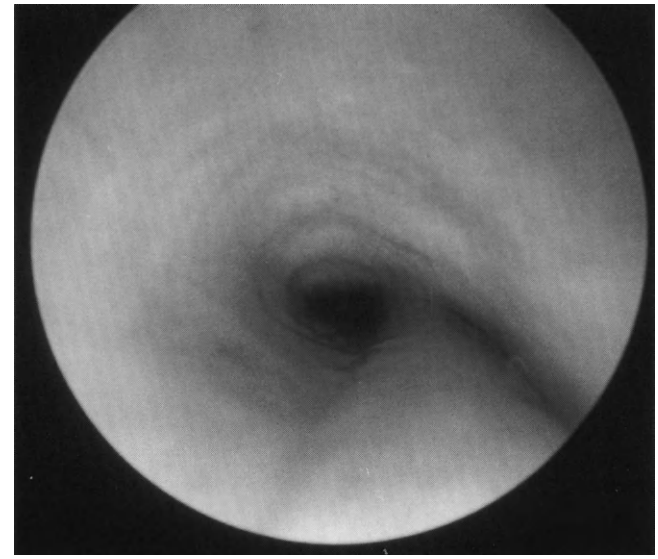

Figure 13.15 Bronchoscopic view of a 5-month-old boy with severe progressive stridor from innominate artery compression. Bronchoscopy shows the classic pulsatile anterior compression of the trachea extending from left to right.

contrast material. In addition, coronal and sagittal sections or images can be helpful in confusing cases. As with CT, the diagnosis of a vascular ring is based on the vascular branching pattern, the side of the aortic arch or arches, and narrowing of the airway. Unfortunately, like CT, MRI cannot reveal a small ligamentum or atretic segment. A disadvantage to MRI is the length of time required for the study necessitating sedation. When there is significant respiratory distress, sedation may not be safe. It seems that more often than not, the quality of MRI studies is poorer than CT scans because of patient movement. Sedation is not always necessary with CT since in a restrained infant dynamic scanning can be performed quickly. Because of these issues CT remains our imaging modality of choice. Both CT and MRI also can be helpful by revealing unsuspected mediastinal or tracheobronchial abnormalities.

Bronchoscopy

Bronchoscopy is often employed in children with respiratory distress who do not have a definite diagnosis [43]. External compression of the trachea just above the carina suggests either a double aortic arch or a right aortic arch with left ligamentum. The initial diagnosis of innominate artery compression is nearly always made with bronchoscopy. In these patients, bronchoscopy classically shows a pulsatile anterior compression of the trachea extending from left to right at a location closer to the vocal cords than true vascular rings (Figure 13.15) [14]. Indication of significant innominate artery compression occurs only when the extent of the compression is more than 70–80% of the lumen of the trachea. Anterior compression of this area with the tip of the bronchoscope while monitoring the right radial pulse is a useful diagnostic maneuver with resultant obliteration or weakening of the pulse. Bronchoscopy can also be used to rule out other causes of respiratory distress such as aspiration of a foreign body or subglottic stenosis. In cases of pulmonary artery sling, bronchoscopy is required to assess for associated complete tracheal rings. In all cases an extreme degree of caution is necessary during and after bronchoscopy as the tracheal lumen, already narrowed by the vascular compression, may be compromised further by edema from bronchoscopic manipulation We now obtain bronchoscopy in all patients with a vascular ring prior to surgical repair because of the 3–5% incidence of unsuspected tracheal pathology [27].

Tracheograms

Although tracheograms were used frequently in the era before CT/MRI studies, they are much less commonly performed currently. They should be obtained only with the utmost caution to avoid further ventilatory compromise. If excess contrast is used, the lung may be permanently damaged by the barium. CT scanning and MRI are proving to be good noninvasive alternatives to tracheograms for evaluating the tracheal anatomy. There are still occasional

difficult diagnostic cases, however, where a tracheogram can be quite useful [29].

Cardiac Catheterization

Cardiac catheterization formerly was used extensively to diagnose vascular rings in some institutions [44]. Because of the precision and noninvasive nature of CT and MRI, these tests have replaced angiography [42]. The only children for whom we now recommend cardiac catheterization are those with associated congenital cardiac anomalies. In particular, patients with a left aortic arch with right descending aorta and right ligamentum arteriosum often have associated cardiac disease and the diagnosis is often made by angiogram [28].

Echocardiography

Although echocardiography can detect aortic arch anomalies such as vascular rings, because of the limited windows it has not become a dominant diagnostic tool. The addition of Doppler color flow imaging is helpful in assessing for a ductus arteriosus and arch patency. Vascular ring segments without lumens cannot be displayed [45]. However, many patients with a vascular ring also have associated congenital heart disease. In our series of patients this occurred in 12% of the cases [27]. In Ruzmetov's series from Indiana, this occurred in 30% of the cases [46]. In our practice, if a child receives a diagnosis of complete tracheal rings, we use echocardiography as the procedure of choice to rule out an associated pulmonary artery sling if the child is too unstable for a CT scan [47].

Surgical Management

An operation is indicated in all symptomatic patients who have a vascular ring [48]. On close and pertinent questioning, nearly all patients with an anatomic vascular ring will be found to have significant airway symptoms. Initiation of early and appropriate surgical treatment is important to avoid serious complications that may arise after hypoxic or apneic spells. Delayed treatment may result in either sudden death or further tracheobronchial damage. Diagnostic errors may also lead to improper management of the respiratory obstruction with prolonged endotracheal intubation and occasional catastrophic erosion of the aortic arch into the trachea or esophagus [49–51]. Other reported complications of unrepaired vascular ring include aortic dissection and aneurysm formation [52]. The surgical approach varies depending on the specific vascular ring diagnosed (Table 13.3). A left posterolateral thoracotomy provides excellent exposure in almost all cases of the true vascular rings, i.e., double aortic arch and right aortic arch with left ligamentum. We use a right thoracotomy for the innominate artery compression syndrome, and a median sternotomy for pulmonary artery sling with or without complete tracheal rings.

Table 13.3 Surgical management of vascular rings.

Double aortic arch
1. Left thoracotomy (muscle sparing – 4th interspace)
2. Divide lesser of two arches at insertion with descending aorta
3. Preserve blood flow to carotid/radial arteries
4. Ligate and divide ligamentum arteriosum
5. Leave pleura open

Right aortic arch/left ligamentum
1. Left thoracotomy (muscle sparing – 4th interspace)
2. Ligate and divide ligamentum arteriosum
3. Resect Kommerell's diverticulum (if present) and transfer left subclavian artery to left carotid artery
4. Leave pleura open

Innominate artery compression syndrome
1. Right anterolateral thoracotomy (3rd interspace)
2. Resect right lobe of thymus
3. Suspend innominate artery to posterior sternum
4. Postoperative bronchoscopy

Pulmonary artery sling
1. Median sternotomy/extracorporeal circulation
2. Ligate/divide left pulmonary artery (PA)
3. Implant left PA into main PA anterior to the trachea
4. Slide Tracheoplasty for associated tracheal rings

Double Aortic Arch

Nearly all of these patients are best approached through a left thoracotomy. The exception is the patient with a dominanent left arch where the approach is best with a right thoracotomy. The left thoracotomy can be performed with a muscle-sparing technique, elevating the serratus and latissimus muscles and entering the thorax through the fourth intercostal space. The mediastinal pleura is widely opened. Careful dissection in the posterior mediastinum should be performed to clearly delineate the anatomic configuration of the vascular ring. In particular, the left subclavian artery, ligamentum arteriosum, and descending aorta should be identified (Figure 13.16A) [14]. Typically, the left (anterior) arch is the smaller of the two arches, and it may be atretic where it inserts into the descending aorta. In our series of patients the right arch (posterior arch) was dominant in 75% of the patients, the left arch (anterior arch) was dominant in 18%, and the arches were of equal size in 7%. With a dominant right arch segments of the left arch were atretic in 34% of the patients. With a dominant left arch segments of the right arch were atretic in 25% of the patients. The atretic area occurred most frequently at the posterior or distal end of

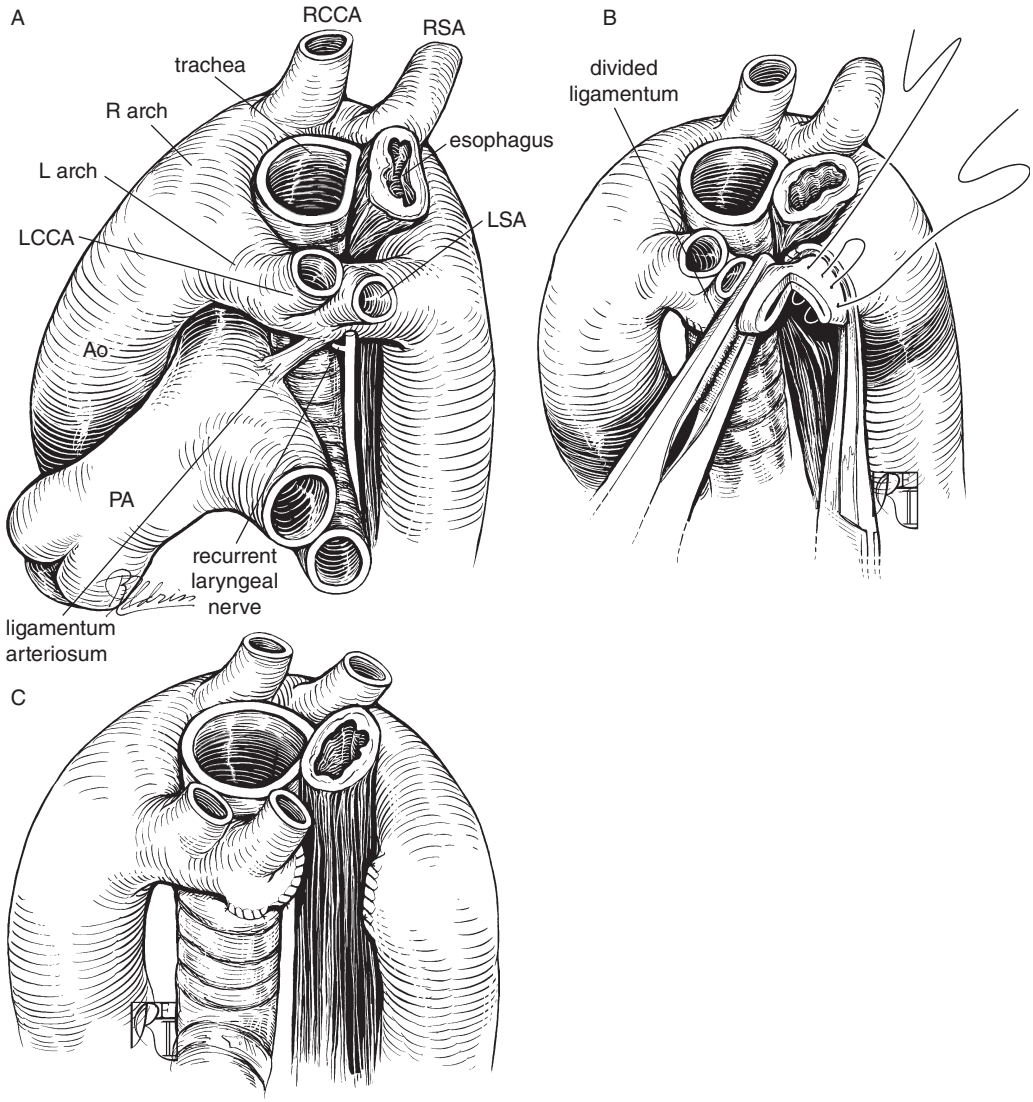

Figure 13.16 Double aortic arch division. **A,** Double aortic arch, right arch dominant. **B,** Dividing left aortic arch. **C,** Arch divided. (Ao, aorta; CA, carotid artery; L, left; LCCA, RCCA, left, right carotid artery; PA, pulmonary artery; R, right; SA, subclavian artery.)

the lesser arch. The vascular ring caused by the double aortic arch is released by dividing the lesser of the two arches, usually at the posterior insertion site into the descending aorta. The lesser arch is divided between clamps at a site selected to preserve brachiocephalic blood flow (Figure 13.16B) [14]. After applying the vascular clamps the anesthesiologist carefully checks the carotid and radial pulses on both the left and right sides. This ensures that the blood flow to these vessels is not interrupted. We place a pulse oximeter on both upper extremities and one lower extremity and that trace is also useful to watch for signs of vessel occlusion. Then the ring is divided and the two stumps are oversewn, each with a double layer of running polypropylene suture (Figure 13.16C) [14]. In addition, the ligamentum arteriosum is always ligated and divided and careful dissection performed around the esophagus and the trachea to lyse any residual adhesive bands. The recurrent laryngeal nerve and phrenic nerve are identified and protected throughout the case. The mediastinal pleura is left widely open to decrease the chance of recurrent stenosis in the area of ring division. This is quite important; I have noted that many of the patients with recurrent symptoms referred to our center from other institutions have had their pleura closed at the initial operation. The resultant scar tissue from this pleural closure can be quite dense.

Results of Double Aortic Arch Repair

Since the first case reported by Potts at Children's Memorial Hospital in 1946, 139 patients have had repair of

a double aortic arch at Children's Memorial Hospital. There has been no operative mortality from repair of an isolated double aortic arch since 1952. Two patients required reoperation for persistent symptoms arising from scar tissue at the divided posterior left arch. Nearly all patients were extubated in the operating room. We did not do routine postoperative bronchoscopy. In the past 15 years, we have only rarely used a tube thoracostomy [27]. The patients are monitored overnight in the cardiac intensive care unit, and discharged home on the second or third postoperative day. In most cases, it takes weeks to months for the barky cough to completely disappear, although it is nearly always significantly improved immediately postoperatively.

Right Aortic Arch with Left Ligamentum

For the patient with a right aortic arch and a left ligamentum, the same left thoracotomy muscle-sparing approach is used. After careful dissection and identification of the configuration of the aortic arch, the ligamentum arteriosum is identified. The ligamentum is either doubly ligated and divided or doubly clamped and divided with the two stumps oversewn (Figure 13.17) [14]. Any adhesive bands are lysed and the recurrent laryngeal nerve and phrenic nerve are carefully identified and protected. Patients with a right aortic arch and a left ligamentum may have a Kommerell's diverticulum at the origin of the left subclavian artery from the descending aorta [53]. This diverticulum is embryologically a remnant of the left fourth aortic arch. This diverticulum may enlarge to proportions that can independently compress the esophagus or trachea. Rupture of this aneurysm has also been reported [54]. We have become concerned about the size of this diverticulum when it is more than 1.5–2.0 times the diameter of the left subclavian artery. In this instance, the diverticulum or aneurysmal dilatation should be resected and the left subclavian artery transferred to the left carotid artery to prevent its independent compression of the trachea and esophagus (Figure 13.18) [55].

An unusual group of patients with a right aortic arch and left ligamentum have a left-sided descending aorta, the so-called "circumflex aorta." Robotin and associates [30] have described an aortic "uncrossing" operation for these rare patients (3 of 468 patients). This procedure is performed through a median sternotomy with cardiopulmonary bypass and hypothermic circulatory arrest. The aortic arch is mobilized, divided, and brought in front of the tracheobronchial tree, then reanastomosed end-to-side to the lateral aspect of the ascending aorta. All three patients described by Robotin had prior ligamentum division via left thoracotomy. We have performed this operation in two patients, one of whom had a dramatic improvement, the other a marginal improvement.

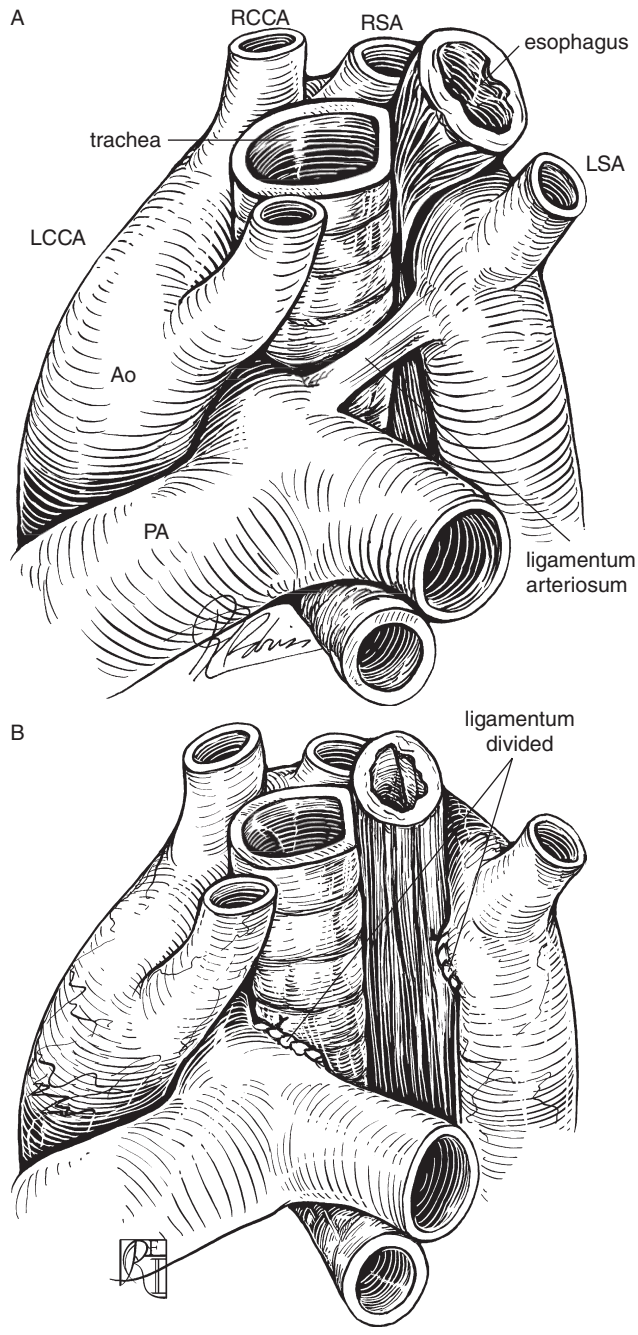

Figure 13.17 Right aortic arch – division and oversewing **(B)** of ligamentum arteriosum **(A)**. (Ao, aorta; CCA, common carotid artery; L, left; MPA, main pulmonary artery; R, right; SA, subclavian artery.)

Results of Right Aortic Arch with Left Ligamentum Division

One hundred and forty patients at Children's Memorial Hospital have had division of the ligamentum for a diagnosis of right aortic arch, retroesophageal left subclavian artery, and left ligamentum. There has been no operative mortality since 1959. No patient in our series has required

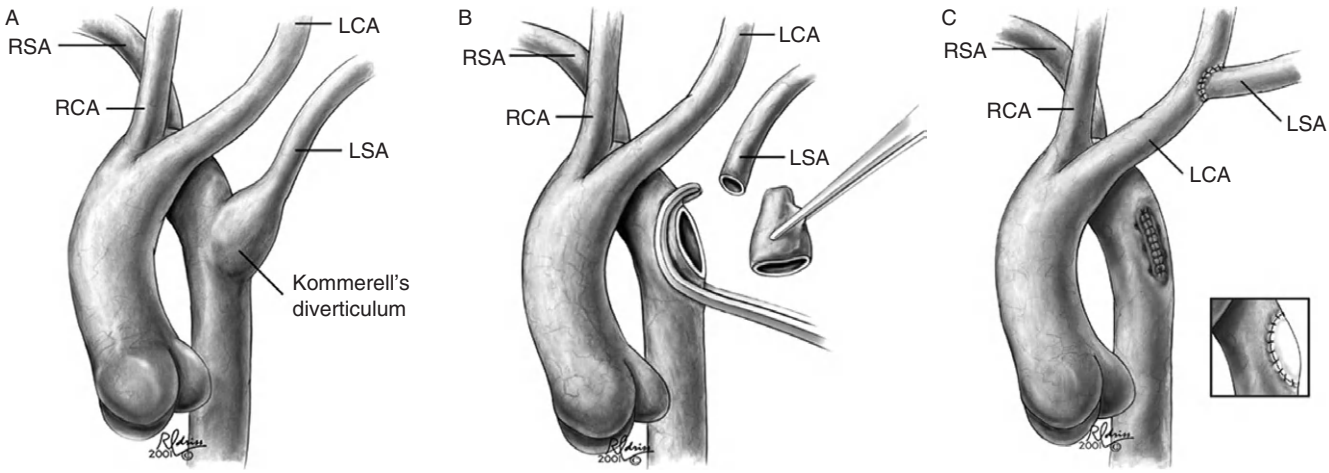

Figure 13.18 A, The typical anatomy of a patient with a right aortic arch, retroesophageal left subclavian artery, and large Kommerell's diverticulum. The Kommerell's diverticulum is an embryologic remnant of the left fourth aortic arch. (LCA/RCA, left/right carotid artery; LSA/RSA, left/right subclavian artery.) **B,** A schematic illustration of the resection of a Kommerell's diverticulum through a left thoracotomy. There is a vascular clamp partially occluding the descending thoracic aorta at the origin of the Kommerell's diverticulum. The Kommerell's diverticulum has been completely resected. The clamp on the distal left subclavian artery is not illustrated. **C,** The completed repair. The orifice where the Kommerell's diverticulum was resected is usually closed primarily, or, as shown in the inset, the orifice can be patched with polytetrafluoroethylene if necessary. The left subclavian artery has been implanted into the side of the left common carotid artery with fine running polypropylene suture. (Reproduced with permission from Backer *et al.* [55].)

a reoperation. In 66% of the patients a retroesophageal left subclavian artery was present. In 34% of patients there was a mirror image left innominate artery. In the past 10 years, 10 children who had recurrent symptoms after ligamentum division elsewhere underwent reoperation at our center. All had a large Kommerell's diverticulum compressing their esophagus and/or trachea that required resection. In these patients we resected the Kommerell's diverticulum and reimplanted the left subclavian artery into the left carotid artery, to relieve a sling-like effect of the right arch and left subclavian artery on the trachea. Eight patients have had diverticulum resection and left subclavian transfer done as a primary procedure. These 18 patients have all had dramatic relief of their symptoms, with no neurologic complications and all left subclavian arteries patent.

Innominate Artery Compression Syndrome

The management of compression of the trachea by the innominate artery has classically been with suspension of the innominate artery to the posterior aspect of the sternum [56]. This technique as originally described by Gross was performed through a left anterolateral thoracotomy [6], and at Boston Children's Hospital the left thoracotomy is still the approach of choice [57]. However, at our institution we have preferred a small right submammary anterolateral thoracotomy for these infants (Figure 13.19) [58]. The right lobe of the thymus is excised, taking care not to injure the right phrenic nerve. The innominate artery is secured with

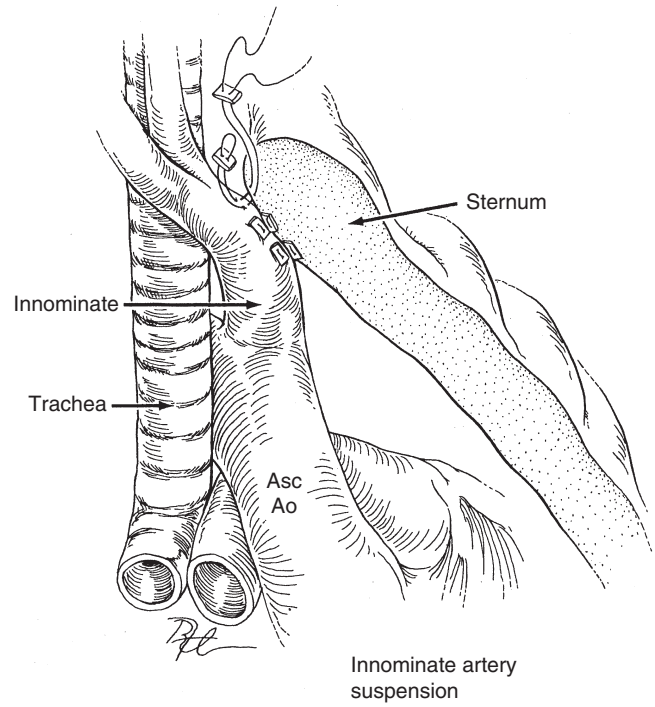

Figure 13.19 Innominate artery suspension. Exposure is through a right submammary thoracotomy. Fixing the adventitia of the innominate artery to the posterior table of the sternum with pledgeted sutures pulls the innominate artery anteriorly and actively pulls the tracheal wall forward and opens it. (Asc. Ao, ascending aorta.) (Reproduced with permission from Backer *et al.* [58].)

pledget-supported sutures to the posterior periosteum of the sternum to lift the innominate artery away from the trachea, simultaneously pulling the anterior tracheal wall open. Typically, three separate mattress sutures are used. The first is on the anterior surface of the aortic arch in line with the origin of the innominate artery, the second at the junction between the innominate artery and the aorta, and the third 0.5 cm distal to the origin of the innominate artery. Bronchoscopy is then performed after the suspension to confirm relief of the tracheal compression. Pre- and postoperative CT scans of a patient having innominate artery suspension are shown in Figure 13.20 [59]. Other authors have described using a median sternotomy with division of the innominate artery and reimplantation into the ascending aorta at a site more to the right and anterior to the native site [60]. This technique would seem to sacrifice the active suspending mechanism on the tracheal wall provided by the classical innominate artery suspension. In addition, there is some risk of cerebrovascular accident with the technique of division and reimplantation [59]. We and others [61] continue to recommend innominate artery suspension to the sternum through a right thoracotomy.

Figure 13.20 Computed tomographic scan before and after innominate artery suspension. **A,** Computed tomographic scan with contrast material preoperatively shows severe anterior compression of the trachea (large arrow) by the innominate artery (small arrowheads). In this instance the trachea is septated into two lumina by the severe compression. **B,** Computed tomographic scan with contrast material of the same child after innominate artery suspension shows a dramatic increase in the size of the tracheal lumen (large arrow). The innominate artery (small arrowheads) has been shifted anteriorly and to the right by the sutures fixed to the sternum. (Reproduced with permission from Backer *et al.* [59].)

Results of Innominate Artery Compression Syndrome Repair

Eighty-seven patients have had innominate arteriopexy at Children's Memorial Hospital. There have been no operative mortalities for isolated innominate artery suspension. Two patients have required reoperation for resuspension. The cessation of apneic spells is very reassuring to parents! However, it is our suspicion that this diagnosis was previously made too often, and the number of patients we have operated on for this diagnosis has decreased dramatically in the past 20 years (Figure 13.21) [62].

Pulmonary Artery Sling

The management of the infant with pulmonary artery sling has changed considerably since the original procedure by Potts at Children's Memorial Hospital in 1953 [7]. Potts operated on a patient without a precise preoperative diagnosis through a right thoracotomy. He doubly clamped and transected the left pulmonary artery, translocated it anterior to the trachea, and then reimplanted it into the original division site on the right pulmonary artery. The child survived the operation but on long-term follow-up has an occluded left pulmonary artery [63]. The next step in the evolution of surgical technique for this condition was to approach through a left thoracotomy with implantation of

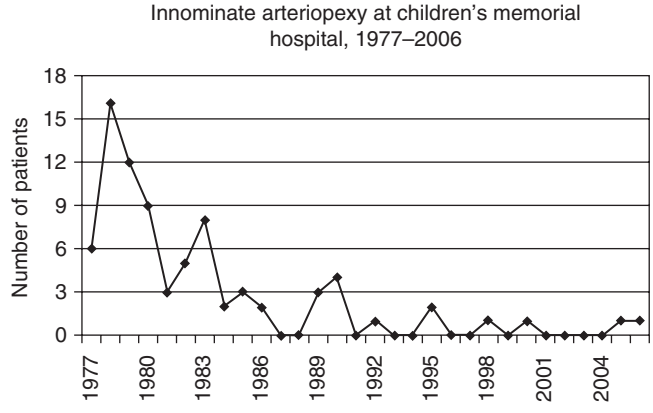

Figure 13.21 Innominate arteriopexy: Changing incidence of operative procedures at Children's Memorial Hospital from 1977 to 2006. (Reproduced with permission from Backer *et al.* [62].)

the left pulmonary artery into the main pulmonary artery at a site that approximated its normal origin from the main pulmonary artery [64]. This procedure initially had a high incidence of left pulmonary artery stenosis or occlusion, along with a high mortality [17]. Because between 50% and 65% of patients with pulmonary artery sling will have associated complete tracheal rings, the "ring-sling" complex [18], we have advocated an approach with median sternotomy and the use of extracorporeal circulation [42,65]. This allows accurate transection of the left pulmonary artery with implantation into the main pulmonary artery anterior to the trachea (Figure 13.22) [14]. The operation can be performed without respiratory compromise (patient is on cardiopulmonary bypass), and enough time and care can be taken to ensure patency of the left pulmonary artery. An alternative technique for pulmonary artery sling relief is to translocate the left pulmonary artery at the time of distal tracheal resection for tracheal stenosis [66]. We have only used this when the right pulmonary artery was severely hypoplastic or absent. Van Son and colleagues [67] compared the two techniques and demonstrated that the translocation technique had a higher incidence of residual left pulmonary artery stenosis.

Results of Pulmonary Artery Sling Repair

Between 1953 and 2008, 40 infants underwent repair of pulmonary artery sling at Children's Memorial Hospital, Chicago. Median age at repair was 4 months. One patient (the first) was approached through a right thoracotomy. Six patients were approached through a left thoracotomy (1972–1979). Thirty-three patients were repaired through a median sternotomy (1970, 1985–2008), and of these, 32 were repaired with the use of cardiopulmonary bypass. There has been no operative mortality. There were four late deaths, all from respiratory complications of simultaneous tracheoplasty. All left pulmonary arteries in patients repaired with the use of cardiopulmonary bypass are patent and blood flow to the left lung by nuclear scan ranges from 24% to 46% (mean 35 ± 9%). If there are associated complete tracheal rings, we previously used the pericardial tracheoplasty technique simultaneous with the pulmonary artery sling repair [8,68]. From 1996–2004 we used the tracheal autograft technique [9,69,70], and since 2004 we have used the slide tracheoplasty [71,72]. These techniques are discussed in depth in the next section.

Tracheal Stenosis

Infants born with complete cartilage tracheal rings often present with life-threatening respiratory distress in infancy [73]. There is absence of the normal membranous trachea, and at the site of the complete rings the tracheal lumen is often only 2–3 mm (Figure 13.23A) [14]. Medical management is associated with at least a 40% mortality [74]. Pericardial patch tracheoplasty as a surgical solution was first performed by Farouk S Idriss at Children's Memorial Hospital in 1982 [8]. These patients were operated on using cardiopulmonary bypass through a median sternotomy. The trachea was exposed and incised anteriorly through the extent of the complete tracheal rings. An autologous pericardial patch was sutured in place with interrupted polyglactin 910 (Vicryl™, Ethicon, Inc., Somerville, NJ) or polydioxanone (PDS™, Ethicon, Inc., Somerville, NJ) sutures (Figure 13.23B) [14]. The endotracheal tube was used to stent the trachea and patch for 1–2 weeks postoperatively. These patients survived, which was a major achievement, but had a high incidence of recurrent stenosis from patch tracheomalacia and granulation tissue [75].

The slide tracheoplasty is currently our procedure of choice for the patient with tracheal stenosis secondary to complete tracheal rings (Figure 13.24) [71,72,76–79]. The slide tracheoplasty is performed through a median sternotomy with extracorporeal circulation. We have used a collar incision in the neck like a "T" (at the top of the sternotomy incision) to adequately visualize the cervical portion of the trachea. If a pulmonary artery sling or cardiac anomaly is present, they are repaired first. After initiating cardiopulmonary bypass with an aortic and single atrial venous cannula, the trachea is divided in the midportion of the tracheal stenosis. This location is determined either by external visual inspection or fiberoptic bronchoscopy. The inferior portion of the trachea is incised anteriorly and the superior portion of the trachea is incised posteriorly. The corners of the tracheal openings are trimmed. An anastomosis is performed with running 5-0 or 6-0 PDS suture starting at the superior aspect and finishing by the carina. The patient then undergoes bronchoscopy to aspirate secretions and to ensure that the stenosis has been relieved. The repair is stented with an endotracheal tube for 3–5 days, and the child is kept on a ventilator. Follow-up bronchoscopy is performed to remove granulation tissue, clear secretions, and identify residual stenosis. The child is then weaned from the ventilator and extubated.

Between 1996 and 2004, we developed and used the tracheal autograft technique in 20 patients. The use of this method was sparked by successful reports using tracheal homograft [80], and our own initial marginal results with the slide tracheoplasty [76]. The autograft technique employs excision of the midportion of the stenotic trachea (this piece becomes the autograft), performance of an end-to-end anastomosis posteriorly, and then patching the trachea anteriorly with the autograft [9,69,70]. We have essentially abandoned this approach and now use the slide tracheoplasty. The other surgical alternative for complete tracheal rings is simple resection with end-to-end anastomosis for shorter segments [66,81–83]. We used this technique if the length of stenosis is less than 30% of the total tracheal length, usually less than seven rings.

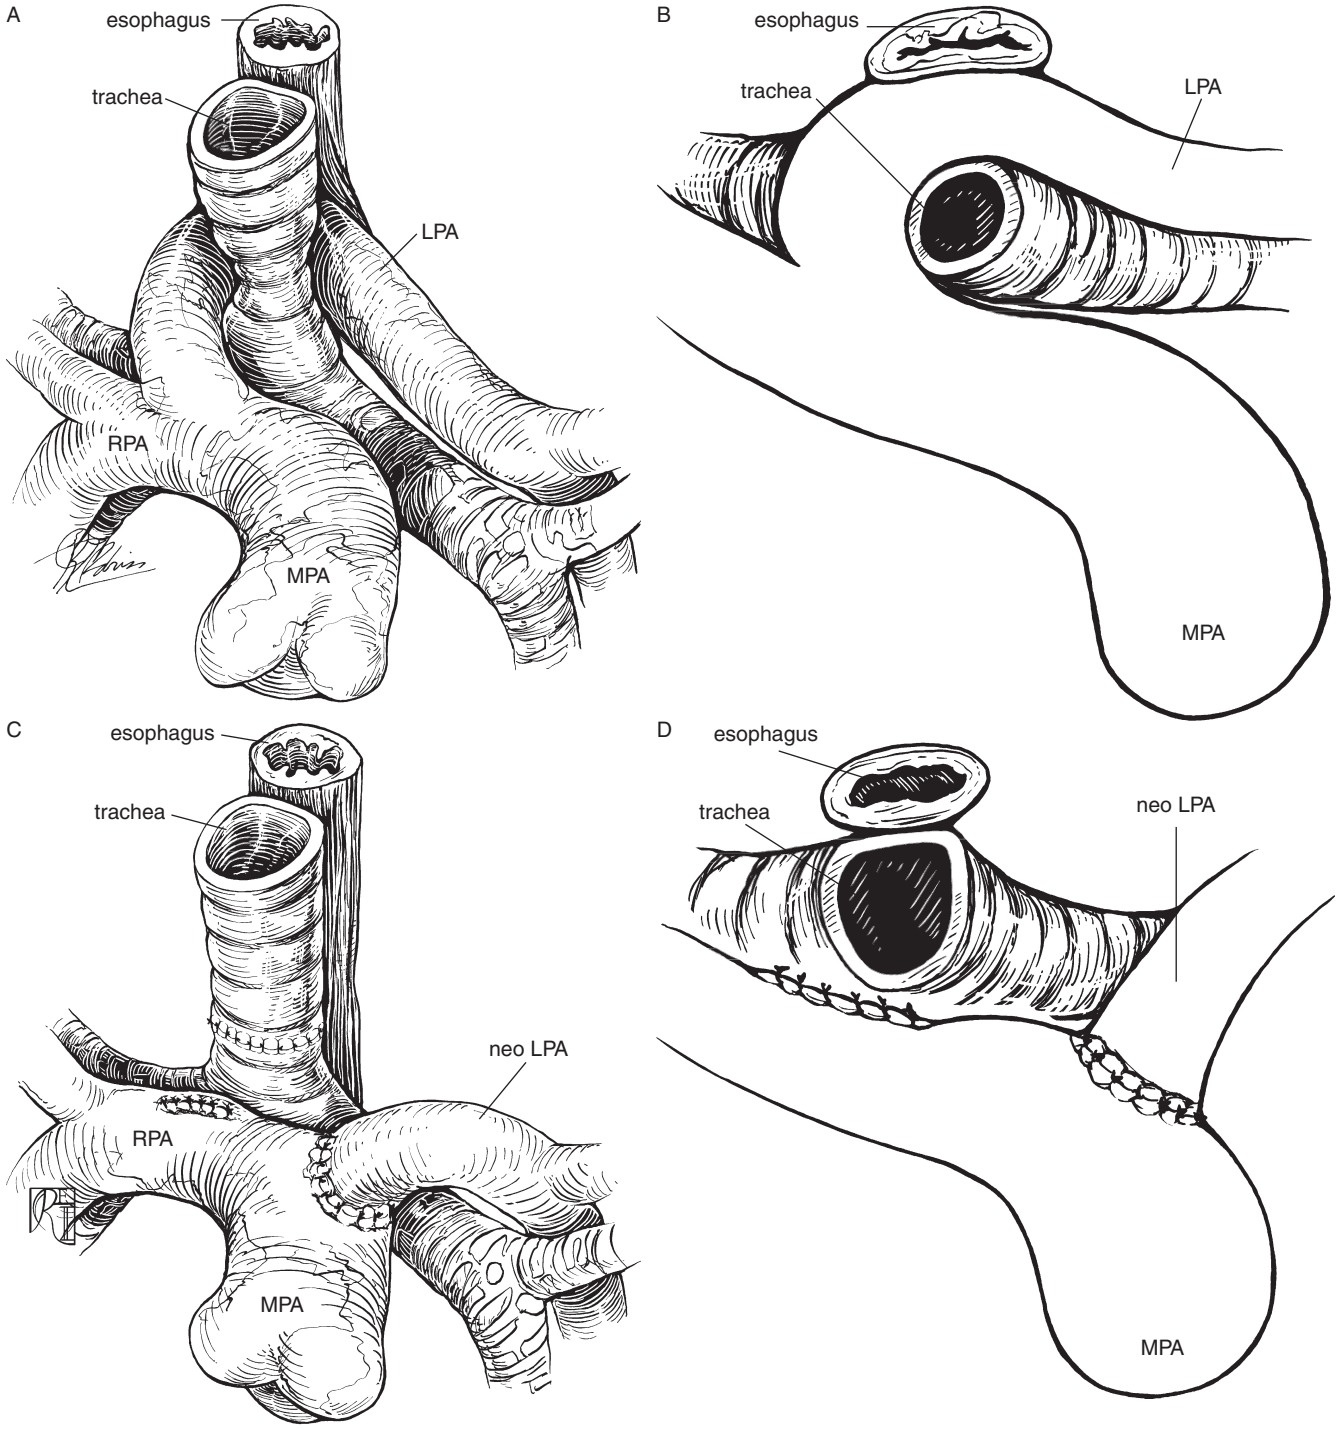

Figure 13.22 Illustration of operative technique for pulmonary artery sling repair with tracheal resection (performed with cardiopulmonary bypass). **A,** LPA encircles and compresses distal area of trachea and right main stem bronchus. **B,** Relationship of LPA to trachea and esophagus. **C,** Repair is by transecting LPA at its origin from RPA and anastomosing the LPA to the MPA at a site that approximates usual anatomic configuration. The tracheal stenosis has also been resected, and an end-to-end tracheal anastomosis is shown. **D,** Postoperative relationship of neo-LPA to MPA anastomosis shows the relatively long distance from the original LPA takeoff from the RPA. (LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery.)

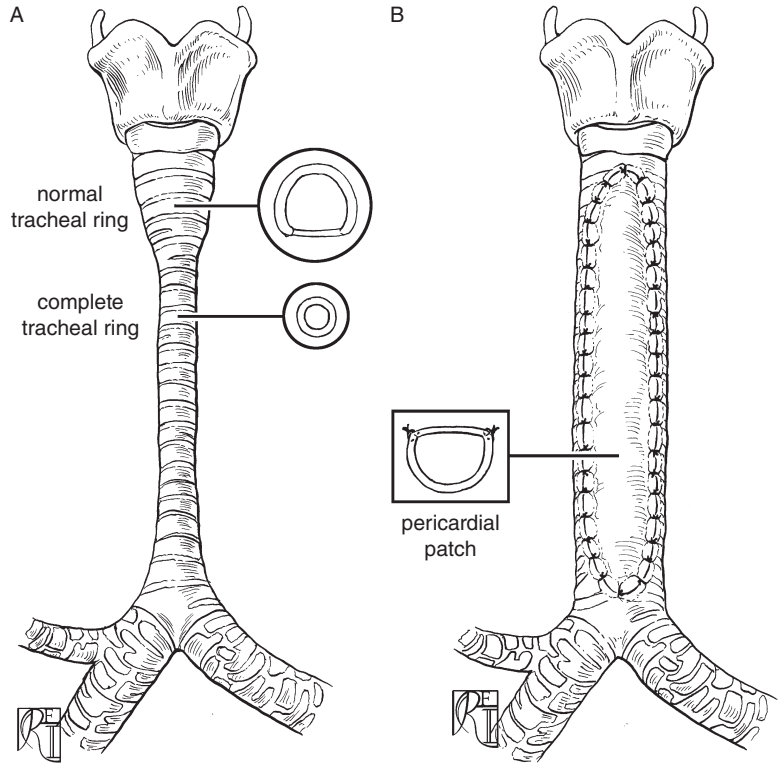

Figure 13.23 Pericardial patch tracheoplasty technique. **A,** Long segment tracheal stenosis with complete tracheal rings. The trachea is incised anteriorly through the extent of the complete tracheal rings. **B,** Completed repair with trachea patched anteriorly with autologous pericardial patch.

Results of Tracheal Stenosis Repair

Between 1982 and 2009, 75 patients have had repair of congenital tracheal stenosis at Children's Memorial Hospital. Median age at repair was 4 months. Techniques included pericardial patch tracheoplasty (n = 28), tracheal autograft (n = 20), tracheal resection (n = 13), and slide tracheoplasty (n = 14). Twenty-five of these patients (33%) had an associated pulmonary artery sling and 17 (23%) had an associated intracardiac anomaly. Twelve patients had unilateral lung agenesis or severe hypoplasia. Despite the increased severity of the pathology and more critical presentation, outcomes in patients with one lung physiology were not different from patients with two lungs [79]. There were seven early deaths (9%) and five late deaths (7%). Our current procedures of choice for infants with congenital tracheal stenosis are resection with end-to-end anastomosis for short-segment stenosis (up to six rings) and the slide tracheoplasty for long-segment stenosis. Associated pulmonary artery sling and intracardiac anomalies should be repaired simultaneously.

Postoperative Care

The postoperative care of all infants with vascular rings includes high humidity to loosen secretions, oxygen therapy when needed as monitored with pulse oximetry, and careful nasopharyngeal suctioning and chest physiotherapy. Early extubation is attempted for all patients except for those following tracheoplasty. Other helpful postoperative modalities include inhaled corticosteroids, albuteral treatments, and heliox. Most patients have a relatively uncomplicated course if no additional trauma is inflicted in the trachea and upper part of the airway. Antibiotic treatment of any associated pneumonitis is also indicated. Complete relief of symptoms may not be noted immediately after surgery, but most patients are generally significantly improved. A period of months to 1 year may be required before disappearance of the noisy respirations caused by tracheomalacia. This fact should be clearly explained to the parents preoperatively and also to the nurses to allay their fears regarding the residual noisy breathing.

Video-Assisted Thoracoscopic Surgery

An alternative to an open thoracotomy is video-assisted thoracoscopic surgery (VATS) for the division of vascular rings [84]. This has occurred as an extension of VATS use for patent ductus arteriosus ligation [85]. Burke [86] reported VATS use for eight patients with vascular rings. Anatomy of the rings included double aortic arch with an

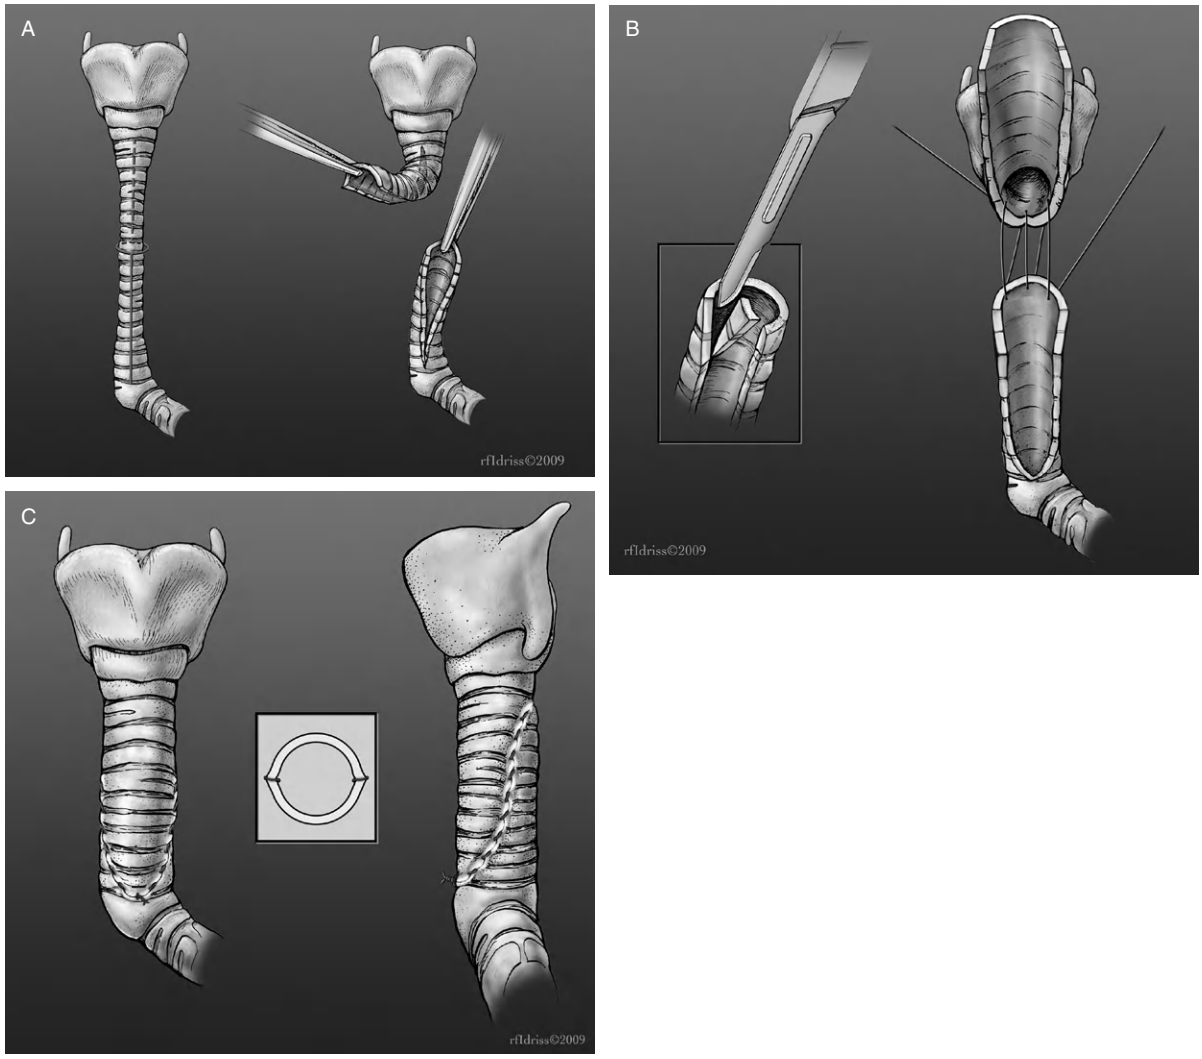

Figure 13.24 Slide tracheoplasty; absent right lung. **A,** The patient has been placed on cardiopulmonary bypass with mild hypothermia to 32°C. The trachea is transected in the midportion of the tracheal stenosis. This site is determined by either external examination or by internal bronchoscopic findings. The inferior portion of the trachea is incised anteriorly and the superior portion of the trachea is incised posteriorly. **B,** The ends of the trachea are beveled as shown in the small inset. The anastomosis is performed with running 6.0 polydioxanone suture. The suture line is started superiorly (parachute technique) and finished inferiorly just above the carina. **C,** Completed slide tracheoplasty. The everting running suture line helps to avoid the "figure of 8" configuration problem after the completed repair. (Reproduced with permission from Backer *et al.* [79].)

atretic left arch (three patients) and right aortic arch, left ligamentum arteriosum (five patients). Three patients (37.5%) required a thoracotomy to complete the procedure. The median operating time was 4 hours; median hospital stay was 3 days. It is interesting to note there were no patients with a patent arch. A concern for the patient with a patent arch is that once the clips are applied and the ring divided, the two stumps retract because of the tension on the ring. The posterior stump often retracts into the mediastinum, and if the clip should slip off, the risk of hemorrhage is great. We are aware of anecdotal reports of this severe complication. It is not always possible to tell externally whether a segment of the ring is atretic or patent. Even quite recent series have yet to demonstrate a significant advantage to VATS over open repair [87].

Conclusion

The diagnosis of a vascular ring should be suspected in any infant or child who presents with symptoms of respiratory distress. The diagnosis is best established by CT or MRI which accurately delineate the anatomy of the ring. Echocardiography should be obtained in all patients to assess for congenital heart disease. Bronchoscopy should

be performed in all cases to assess for additional tracheal pathology and provide an assessment of tracheobronchomalacia. The surgical approach for both double aortic arch and right aortic arch is usually a left thoracotomy (muscle-sparing approach). Some rare vascular rings are best approached through a right thoracotomy. We have used a right thoracotomy for innominate artery suspension. A median sternotomy and the use of extracorporeal circulation is recommended for the repair of pulmonary artery sling and patients who have associated complete tracheal rings. Our current procedure of choice for long-segment tracheal stenosis is the slide tracheoplasty. Surgical intervention successfully provides relief of tracheoesophageal compression from vascular structures in over 95% of infants and children.

CHAPTER 14

Coarctation of the Aorta

Carl L. Backer,[1] Sunjay Kaushal,[2] and Constantine Mavroudis[3]

[3]Florida Hospital for Children, Orlando, FL, USA

The word coarctation originates from the Latin *coarctere*, to contract. A coarctation of the aorta is a congenital narrowing of the descending thoracic aorta usually (but not always) occurring just distal to the left subclavian artery adjacent to the site of insertion of the ductus arteriosus (ligamentum arteriosum). The occurrence rate is 0.2–0.6 per 1000 live births and coarctation of the aorta represents 5–8% of all cases of congenital heart disease [1,2]. Coarctation of the aorta is the eighth most common congenital heart defect. Coarctation is often associated with other congenital heart defects including patent ductus arteriosus, bicuspid aortic valve, ventricular septal defect, and mitral valve abnormalities [3]. The clinical presentation of coarctation varies from cardiovascular collapse in infancy after ductal closure to asymptomatic hypertension in an adult.

Robert Gross [4] experimented with repair of coarctation in animals in 1938, and documented the possible complications of severe hemorrhage and paraplegia. The first successful repair of coarctation of the aorta in a human was performed in Stockholm, Sweden in 1944 by Clarence Crafoord [5]. He resected a coarctation and performed an end-to-end anastomosis in a 12-year-old boy with severe hypertension. Crafoord's patient had relief of hypertension and normalization of lower extremity blood pressure. The surgical management of coarctation of the aorta has evolved over the years mainly in attempts to prevent recoarctation. Other techniques described, in historical order, include prosthetic patch aortoplasty [6], subclavian flap aortoplasty [7], and resection with *extended* end-to-end anastomosis [8,9]. There are many other techniques with subtle variations described for coarctation repair, including: subclavian flap aortoplasty with preservation of arterial blood flow to the left arm [10], subclavian free flap [11], subclavian flap with resection of ductal tissue [12], coarctation resection with radically extended end-to-end anastomosis [13], end-to-side anastomosis of the descending aorta to the proximal aortic arch [14], and pulmonary homograft patch aortoplasty [15]. This chapter will review the embryology, anatomy, pathophysiology, natural history, diagnostic techniques, surgical alternatives, and postoperative considerations for coarctation of the aorta.

Embryology and Anatomy

Coarctation of the aorta was first noted as an autopsy finding by Morgagni in 1760 [16]. He described a localized constriction of the descending aorta. In 1903, Bonnet [17] suggested dividing patients with coarctation of the aorta into two groups, infantile and adult. "Infantile" later became known as preductal, and "adult" as postductal. In the infantile group, the ductus arteriosus is open and there is a tubular narrowing of the isthmus of the aorta proximal to the ductus. The ductus supplies the blood flow to the descending aorta (Figure 14.1A) [18]. In the adult type of coarctation the ductus is closed and there is a shelf-like narrowing within the lumen of the aorta (Figure 14.1B) [18]. The key difference between these two types is the patent ductus arteriosus provides blood flow to the lower extremity in the preductal (infantile) group and the ductus arteriosus is closed in the postductal (adult) coarctation. The critical factors that determine the hemodynamic burden to the patient are whether the ductus is patent, the size of the transverse arch, and the degree of narrowing at the coarctation site. In surgical series, particularly for evaluating outcome, a classification system of three groups of coarctation patients has been widely used: group I, patients with

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

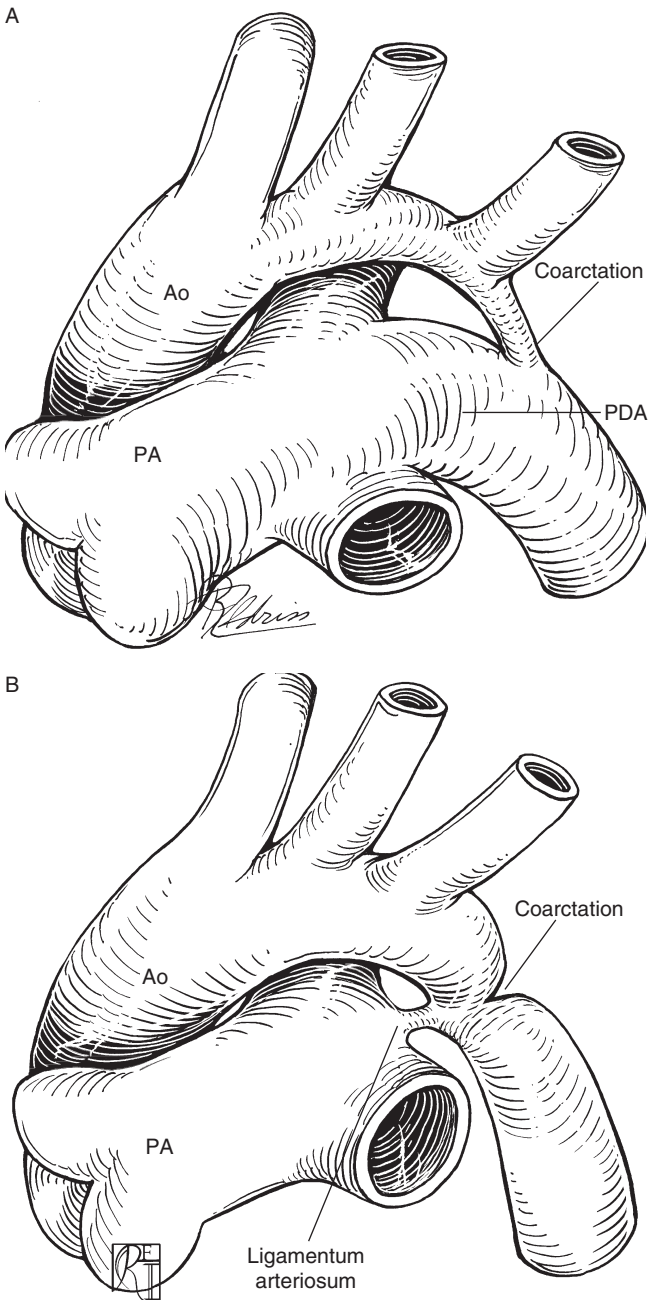

Figure 14.1 A, Infantile or "preductal" coarctation of the aorta. The patent ductus arteriosus (PDA) provides the majority of blood flow to the descending aorta. There is tubular narrowing of the transverse arch and a small aortic isthmus. **B,** Adult or "postductal" coarctation of the aorta. The area of narrowing is actually juxtaductal and consists of a prominent posterior ridge projecting into the lumen. The ductus arteriosus has closed and is now a ligamentum arteriosum. (Ao, aorta; PA, pulmonary artery.)

isolated coarctation; group II, patients with coarctation and ventricular septal defect; and group III, patients with coarctation and complex intracardiac anomalies other than isolated ventricular septal defect [19–21]. The classification system proposed by the International Nomenclature and Database Conferences for Pediatric Cardiac Surgery [22] is as follows: coarctation of the aorta, isolated; coarctation of the aorta, with ventricular septal defect; and coarctation of the aorta, with complex intracardiac anomaly. Other modifiers are isthmus hypoplasia and/or arch hypoplasia. The aortic arch can be divided into three parts, the proximal transverse arch (arch between the innominate and left carotid arteries), the distal transverse arch (arch between the left carotid and left subclavian arteries), and the aortic isthmus (arch between the left subclavian and insertion of the patent ductus arteriosus). Isthmus hypoplasia is defined as present if the isthmus is less than 40% of the diameter of the ascending aorta [23]. Arch hypoplasia is defined as present if the proximal or distal transverse arch are less than 60% or 50% respectively of the diameter of the ascending aorta [24]. We have also used a relatively simple clinical definition of hypoplastic transverse aortic arch as occurring when the transverse aortic arch dimension measured in mm is less than the weight of the patient in kgs plus one [25].

Embryology

There are two complementary theories explaining the embryology of coarctation of the aorta: 1) the flow theory and 2) the ductal sling theory. The flow theory is based on the hypothesis that blood flow through the cardiac chambers and great arteries during fetal life often determines their size at birth [26]. In a normal fetus, the left and right ventricles have approximately equal stroke volumes, although they function in parallel rather than in series. If there is an increase in blood flow through the right heart because of an intracardiac septal defect (VSD), then there is a decrease in flow through the left heart and hence the aortic isthmus. If there is an upstream left-sided obstructive lesion (i.e., mitral or aortic stenosis), again, there will be less flow through the ascending aorta and the isthmus. This theory holds that coarctation of the aorta forms because of a lack of fetal blood flow across the aortic isthmus. The intracardiac defects that would cause coarctation on the basis of the flow theory are in fact clinically commonly associated with patients with coarctation of the aorta. These include ventricular septal defect, bicuspid aortic valve, congenital aortic stenosis, and congenital mitral valve stenosis [3]. The hemodynamic disturbances in embryonic circulatory pathways that lead to reduced aortic arch flow need not be dramatic [27]. The role of the limbus of the foramen ovale is to deflect the appropriate proportion of the inferior vena caval blood to the ascending aorta. Prenatal narrowing of the foramen ovale or an improper

angulation of its limbus can lead to variable degrees of hypoplasia of the left-sided structures. This may explain Shone's syndrome [28] (coarctation of the aorta, parachute mitral valve, supravalvar mitral ring of the left atrium, and subaortic stenosis). Corroborating evidence is the corollary that lesions that reduce right heart output such as tetralogy of Fallot, pulmonary stenosis, and tricuspid atresia are almost never associated with coarctation of the aorta [26].

The flow theory, however, is not very convincing for patients with no obvious intracardiac defects. For these patients the ductal sling theory is more appealing. More than 100 years ago Skoda [29] postulated that abnormal extension of contractile ductal tissue into the aorta is a significant factor in the pathogenesis of coarctation of the aorta. More recently it has been microscopically shown that the obstructing shelf of coarctation can be composed of cells similar to that found in the ductus arteriosus [30]. Careful histological examination of resected coarctation specimens has demonstrated extension of ductal tissue in a circumferential sling extending from the ductus arteriosus and into the adjacent aorta [31]. Contraction and fibrosis of this "ductal sling" at the time of ductal closure would lead to constriction of the aorta and a primary coarctation (Figure 14.2) [31]. There is confirmatory echocardiographic evidence for this theory [32]. This may explain the origin of coarctation of the aorta when there is no associated intracardiac lesion.

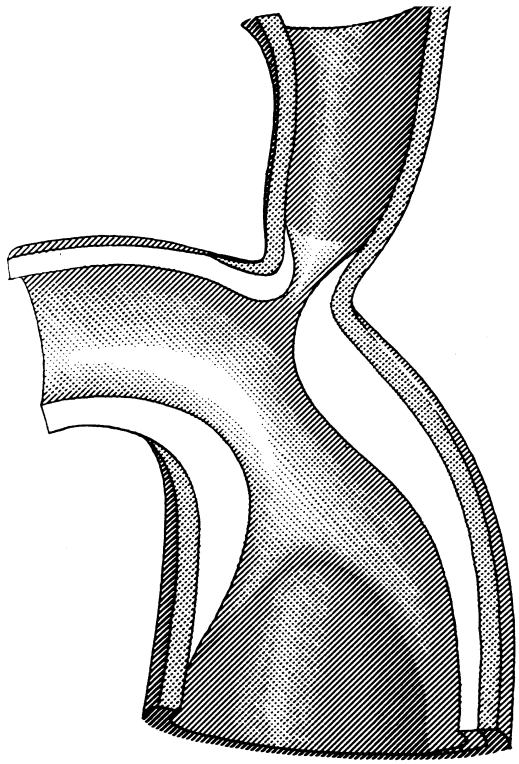

Figure 14.2 Illustration of the extent of ductal tissue present in a coarctation of the aorta specimen. The white areas show the coarctation shelf, circumferential ductal sling, and the prolongations of ductal tissue distally in the aorta. (Reproduced with permission from Russell *et al.* [31].)

Other investigators have advanced ideas that may also play some role in the embryology of coarctation of the aorta. Kappetein and colleagues [33] believe that an abnormality of neural crest development plays a role in the pathogenesis of coarctation of the aorta. There may also be genetic factors given the increased incidence of coarctation of the aorta in females with Turner's syndrome [34]. This syndrome was originally described in adult karyotype XO female patients having sexual infantilism, webbed neck, and cubitus valgus; 15–36% of these patients have associated coarctation of the aorta.

Anatomy

The anatomic features of coarctation depend on the age of the patient, whether there is an associated patent ductus arteriosus, and the degree of hypoplasia of the transverse aortic arch and isthmus. In a typical infant with coarctation of the aorta and patent ductus arteriosus, there is often a diffuse narrowing of the aorta distal to the left common carotid artery. A large patent ductus arteriosus the size of the descending aorta connects the descending aorta to the pulmonary artery. The opened aorta reveals a coarctation membrane proximal to the entrance of the ductus. There is minimal post-stenotic dilatation of the descending aorta and only minor enlargement of the intercostal arteries. In an older child with a juxtaductal coarctation, there is often a visible external narrowing of the descending aorta at the level of the ligamentum. The degree of external narrowing, however, does not necessarily correlate with the inner lumen of the aorta, which will contain a shelf-like concentric narrowing that may result in a pinpoint lumen (Figure 14.3). Rarely, there is complete occlusion of the lumen, and all flow to the descending aorta is from collateral arteries. The aorta proximal and distal to the coarctation is often dilated with enlargement of the proximal subclavian artery. The aortic wall may be very thin in the region of post-stenotic dilatation. The intercostal vessels entering the descending aorta are large, thin-walled, and may even become aneurysmal.

When a coarctation is present, there is progressive enlargement of collateral blood vessels around the coarctation. This collateral flow is predominantly from the subclavian artery and its branches; the internal thoracic, intercostal, scapular, cervical, vertebral, epigastric, and spinal arteries. These vessels enlarge steadily, and in older children (more than 4 years of age) and adults the chest radiograph may show the characteristic "rib notching" of the inferior aspect of the ribs due to the presence of dilated and tortuous collaterals. These large collateral vessels

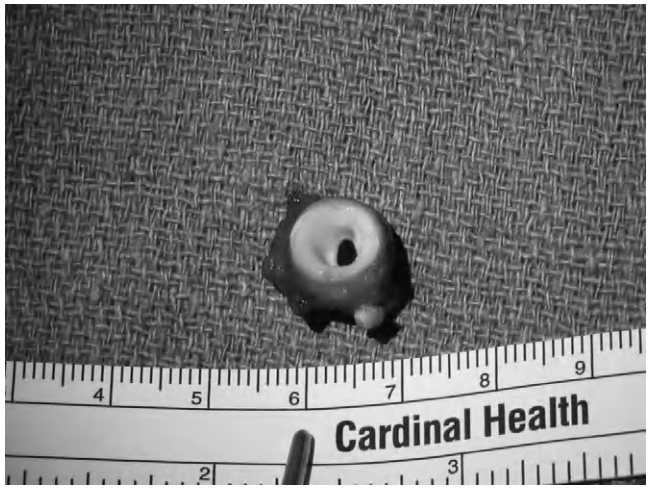

Figure 14.3 Coarctation lumen in a 14-year-old child who underwent coarctation resection and placement of an 18-mm interposition graft. Lumen measures 3 mm.

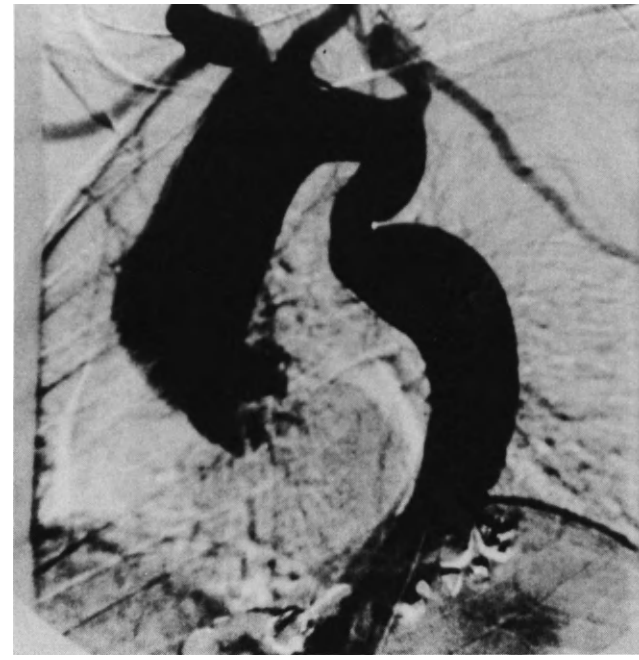

Figure 14.4 Pseudocoarctation. Aortogram showing a dilated ascending aorta, elongation of the arch, and kinking of the descending thoracic aorta in the region of the ligamentum. There was only a 20 mmHg systolic pressure gradient across the pseudocoarctation, but marked post-stenotic dilatation of the descending thoracic aorta. Resection with interposition graft was performed to relieve dysphagia. (Reproduced with permission from Kessler *et al.* [36].)

provide enough flow to the lower body to maintain organ function and growth.

Pseudocoarctation of the aorta is a rare condition presumably resulting from a congenital elongation of the aortic arch [35]. The elongation leads to redundancy and kinking of the aorta, which may appear similar to a coarctation of the aorta but has no actual obstruction to blood flow (Figure 14.4) [36]. There is usually little or no demonstrable pressure gradient present in pseudocoarctation [36]. Because of the tortuous nature of the aorta, however, there is a tendency for dilatation and aneurysm formation presumably related to turbulent flow beyond the kink [37]. These patients should be followed closely and surgical intervention may be required if dilatation compresses surrounding structures (i.e., esophagus) or aneurysm formation is discovered [38].

Coarctation of the abdominal aorta occurs in only 0.5–2% of all coarctations [1]. The embryology of abdominal coarctation may be congenital or related to congenital rubella, Takayasu's arteritis, or von Recklinghausen's disease [39]. In two-thirds of cases the narrowing is circumscribed, and in one-third there is a long diffuse hypoplasia. Diagnosis is confirmed by angiography. It is important to establish the status of the renal arteries in these patients. Effective surgical therapy has included patch aortoplasty and bypass grafts [40–42].

Natural History and Pathophysiology

The presentation of patients with coarctation of the aorta occurs in a bimodal distribution. There is a group that presents in the first week of life whose blood flow to the lower body is dependent on a patent ductus arteriosus. If they are not diagnosed before ductal closure, they present in cardiovascular shock. Collateral flow is inadequate in infancy and ischemia of organs distal to the coarctation results in renal failure and acidosis. At the same time the sudden increased afterload on the left ventricle results in acute congestive heart failure. The management of these neonates was greatly improved by the introduction of prostaglandin E1 (PGE_1), which opens and maintains the patency of the ductus arteriosus. PGE_1 was initially used (1975) successfully for infants with cyanotic heart disease (pulmonary atresia, transposition of the great arteries) [43], and later (1979) applied to infants with aortic arch interruption and coarctation of the aorta [44]. Intravenous infusion of PGE_1 dilates and maintains the patency of the ductus arteriosus, which normalizes perfusion to the lower body and unloads the left ventricle. In some patients PGE_1 may not open the patent ductus arteriosus, but it does improve flow through the coarctation site by acting on the "ductal sling" tissue [32]. This slight increase in coarctation orifice diameter is often enough to help stabilize the patient prior to elective surgical repair. The use of PGE_1 combined with intubation and ventilation, intravenous inotropic support (dopamine and dobutamine), and intravenous sodium bicarbonate acts to correct the low output state and reverse metabolic acidosis and renal failure. Surgical intervention can then be planned on a semielective basis at a

time when the function of the various organ systems has been optimized.

The other arm of this bimodal presentation is a group of patients who are "asymptomatic" but present with hypertension on a routine physical examination. The main cause of symptoms in these patients is the proximal systemic hypertension, which may cause headaches or epistaxis. They may also have claudication from inadequate lower extremity perfusion with exercise. Alterations in renal, adrenal, and baroreceptor function all contribute to the development of this proximal systemic hypertension. This may lead to circle of Willis aneurysms, aortic aneurysm proximal or distal to the coarctation, aortic dissection, and increased coronary atherosclerotic heart disease with associated myocardial infarction [45]. The following diagnoses are the causes of death in patients with unrepaired coarctation: congestive heart failure (26%), bacterial endocarditis (25%), spontaneous rupture of the aorta (21%), and intracranial hemorrhage (13%) [46]. The frequency of intracranial aneurysms among adult patients with coarctation (mean age 42 years) is 10% as compared to 2% in the general population [47]. The survival curve of patients with an unoperated coarctation of the aorta is shown in Figure 14.5 [48]. In a review of 200 autopsies in patients with coarctation of the aorta, Abbott found the average age at death was 33.5 years [49]. Reifenstein and associates [46] in a similar study of 104 autopsies quoted a figure of 35.0 years. In these patients pregnancy increases the risk of associated complications. There is essentially no medical therapy for coarctation and these patients should be referred at the time of diagnosis for surgical intervention.

Diagnosis

The newborn infant with critical coarctation and ductus closure will present in shock. On physical examination the child will be tachypneic and tachycardic, and will appear pale. Lower extremity pulses are absent, and upper extremity pulses may be thready. The child may be hypotensive, even in the arms, and the liver will be enlarged. Chest radiograph will demonstrate cardiomegaly and evidence of congestive heart failure. Electrocardiogram shows a left ventricular strain pattern. Two-dimensional echocardiography with color Doppler interrogation is diagnostic in most instances [50–52]. The echocardiogram will demonstrate lack of pulsatile flow in the descending aorta, the anatomic coarctation site, the size of the transverse arch, and any other associated intracardiac anomalies. In many instances, for newborn infants a comprehensive echocardiogram is all that is required to prepare a patient for surgical intervention after stabilization of organ systems. However, if there are complex associated cardiac anomalies cardiac catheterization can safely be performed in a stable baby who is being maintained on prostaglandin infusion. This will reveal the precise great vessel morphology, significant hemodynamic parameters, and intracardiac anatomy [27]. For the child that does not need a cardiac catheterization for the intracardiac anatomy, but has an arch that is difficult to image, computed tomography (CT) scan is our current procedure of choice. Ultrafast scan with 3D reconstruction reveals the anatomy beautifully and gives the surgeon a very clear "road map" (Figure 14.6) [53].

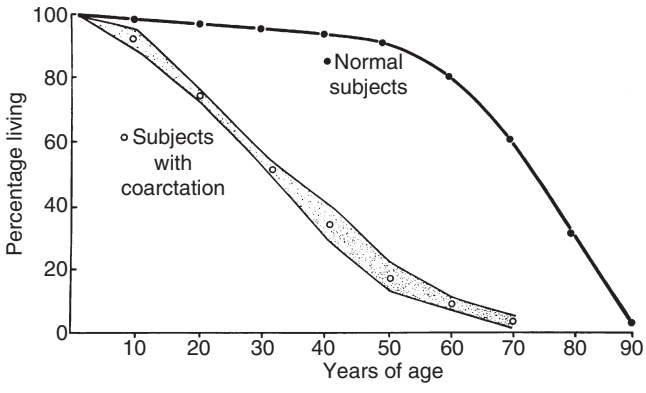

Figure 14.5 Survival curve of patients with coarctation of the aorta surviving the first year of life as compared with normal subjects. (Reproduced with permission from Campbell [48].)

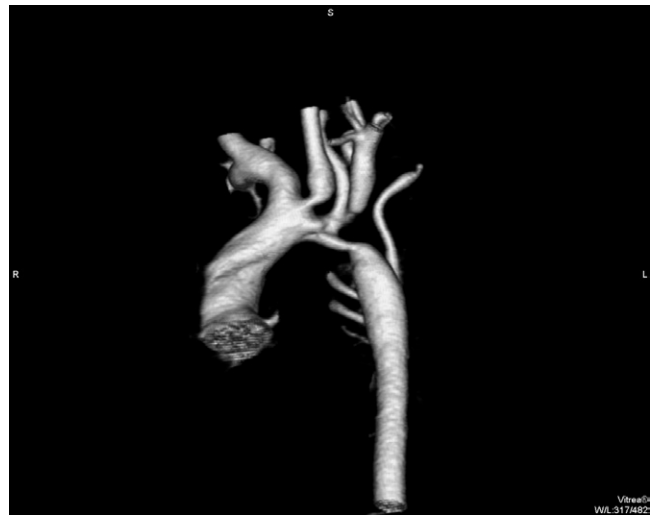

Figure 14.6 Three-dimensional computed tomographic reconstruction of a newborn with coarctation of the aorta. By echocardiographic analysis adequate visualization of the transverse arch could not be obtained. Because of the CT angiogram showing complex hypoplasia of the transverse aortic arch and stenosis of the origin of the left carotid and left subclavian artery, repair was electively performed through a sternotomy with modified cerebral perfusion. (Reproduced with permission from Kaushal *et al.* [53].)

Physical examination of an older child (often with no symptoms) reveals upper extremity hypertension and absent or greatly diminished femoral pulses. Electrocardiogram demonstrates left ventricular hypertrophy and left ventricular strain. Chest radiograph will often demonstrate "notching" of the ribs if the patient is over 4 years of age. In addition, the classic "3" sign on chest radiograph is caused by dilatation of the left subclavian artery, the narrowing of the coarctation site, and poststenotic dilatation of the descending aorta. The echocardiogram in most instances of simple coarctation in older children, adolescents, and adults will provide the diagnosis without requiring cardiac catheterization. Cardiac catheterization is required for these patients only if there are associated intracardiac anomalies, a question with regard to the size of the collateral vessels, or poor visualization by echocardiography. In all older patients who do not have a catheterization we also obtain either a CT or magnetic resonance imaging (MRI) image to fully delineate the anatomy (Figure 14.7) [18,54,55]. The presence or absence of collaterals is noted to help in predicting the need for left heart bypass. In summary, assessment of aortic coarctation can be accomplished accurately and comprehensively in many instances by using the combined methodologies of two-dimensional and Doppler echocardiography. Computed tomography is useful for infants and MRI and CT are used for older children and adults to precisely define the arch anatomy [56]. In all cases a complete two-dimensional and Doppler echocardiographic examination of intracardiac anatomy is necessary to reach appropriate therapeutic and surgical recommendations.

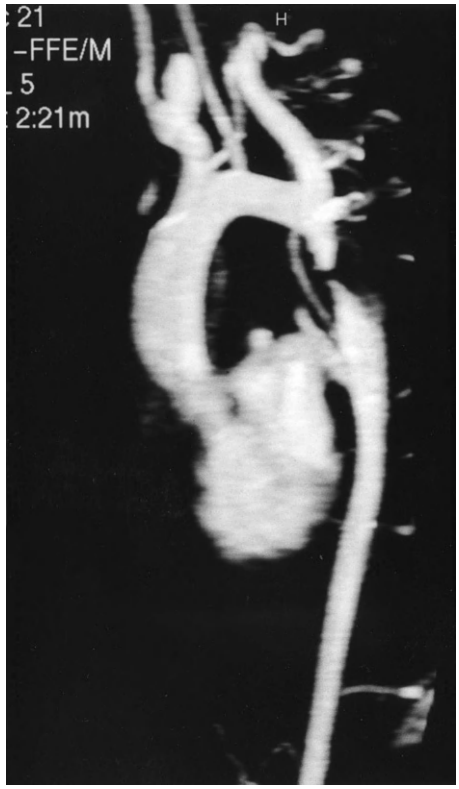

Figure 14.7 Magnetic resonance image of a severe coarctation of the aorta in a 24-year-old. The anatomy is very clearly demonstrated.

Surgical Techniques

General Considerations

The surgical approach to coarctation in most instances is through a left posterolateral thoracotomy incision entering the thorax through the third or fourth intercostal space. The exception to this is a median sternotomy approach for patients with associated cardiac anomalies that are to be repaired simultaneously or the patient with a hypoplastic transverse aortic arch. The arterial blood pressure is monitored in the right radial artery. Should the right subclavian artery arise anomalously below the coarctation the temporal artery provides a useful site for monitoring the proximal aortic pressure. One must be very careful with this site, however, as there is a chance of injecting air or debris to the cerebral circulation. In some cases like this we have done the repair with only near infrared spectroscopy (NIRS) monitoring of the brain. Using the left thoracotomy approach, we divide the latissimus dorsi muscle, but spare the serratus anterior by retracting it anteriorly. In older children the multiple chest wall collateral vessels should be individually ligated and divided to prevent hemorrhage either during the operation or postoperatively. The lung is retracted anteriorly and the mediastinal pleura overlying the coarctation site is incised. Any large lymphatic channels are either preserved or ligated and divided. The vagus nerve and recurrent laryngeal nerve are carefully preserved by retracting and dissecting these structures with the mediastinal pleura anteriorly. The descending aorta, left subclavian artery, isthmus of the aorta, ductus arteriosus (or ligamentum), and transverse aortic arch distal to the left carotid artery are mobilized. An anomalous artery originally described by Abbott is an occasionally encountered collateral vessel originating from the posterior wall of the aortic arch or left subclavian artery [57]. This vessel is not found in normal subjects or described in standard anatomy textbooks (Figure 14.8) [58]. If present it should be ligated and divided to facilitate the repair. In older children there are often large collateral intercostal vessels entering the descending aorta distal to the coarctation. These should be carefully mobilized and either encircled with vessel loops or ligated and divided in order to fully mobilize the area of the coarctation.

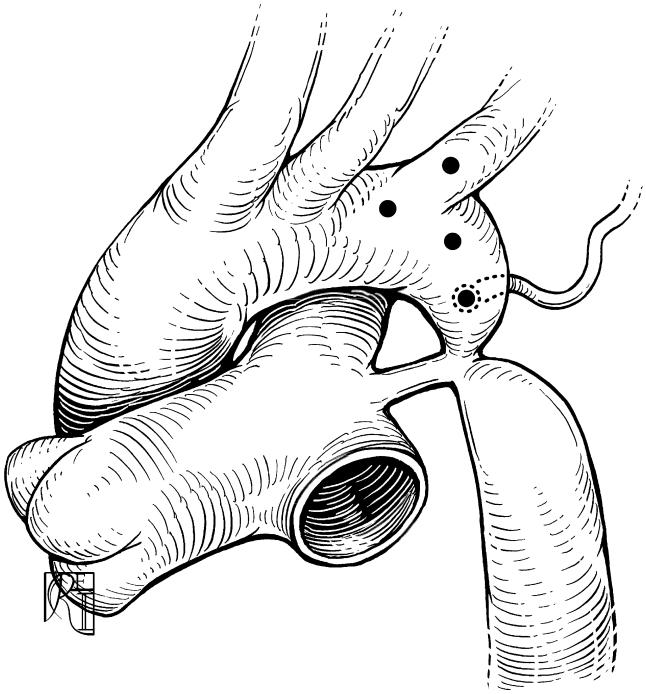

Figure 14.8 Abbott's artery. Drawing outlines the area on the posterior wall of the aortic arch or subclavian artery from which a blood vessel, which Gross chose to call Abbott's artery, may take its origin. X = possible sites of origin. (Reproduced with permission from Schuster *et al*. [58].)

Subclavian flap aortoplasty	Waldhausen and Nahrwold [7]	1966	USA
Resection with extended end-to-end anastomosis	Amato [8]	1986	USA

It is very important that the proximal aortic pressure be allowed to stay quite high (100–120 mmHg for infants, 160–200 mmHg for older children and adults) during the time of the aortic cross-clamp to provide adequate mean aortic arterial blood pressure distal to the clamp to help prevent the complication of paraplegia. Sodium nitroprusside should never be used during the time of cross-clamping for coarctation repair. The use of nipride while the aorta is clamped has actually been shown to increase the incidence of paraplegia postoperatively [59]. A distal aortic pressure monitoring line should be placed in older children in the femoral artery. In these older children the mean distal aortic pressure should be maintained above 45 mmHg during the period of aortic cross-clamp [60,61]. During the first 10 minutes of cross-clamping the mean distal aortic pressure usually increases 5 mmHg. Maintaining the distal aortic pressure can be done by the administration of volume expanders, use of inotropes such as dopamine or dobutamine, or reduced anesthetic during the time period of the cross-clamp. Other useful maneuvers are to readjust the proximal clamp (if anatomically feasible) to allow flow in the left subclavian artery or to allow more intercostal arteries to remain open. Should the mean pressure drop below 45 mmHg, alternative techniques such as the use of partial left heart cardiopulmonary bypass with left atrial and descending aortic cannulation should be used [61–63]. We are very proactive in using left heart bypass should there by any question regarding the distal perfusion pressure during the coarctation repair. Hypoperfusion of the spinal cord can lead to the dreaded complication of paraplegia which will be discussed in detail later in this chapter. The various techniques of repair are now reviewed separately (Table 14.1) [5–8,64].

Resection and End-to-End Anastomosis

Crafoord and Nylin [5] reported the first successful resection of coarctation of the aorta with end-to-end anastomosis. Their two patients were a 12-year-old boy and a 27-year-old man operated on in October 1944. Kirklin and associates [65] described the successful surgical treatment of coarctation of the aorta in an infant when they operated on a 10-week-old child performing successful coarctation resection with end-to-end anastomosis (and ligation of the left subclavian artery) in 1951. The technique of resection and end-to-end anastomosis is shown in Figure 14.9 [18]. The obviously narrowed coarctation segment is excised with a direct end-to-end circumferential anastomosis of the aorta. Early repairs utilized silk suture in a continuous fashion posteriorly and interrupted everting horizontal mattress sutures anteriorly. The mortality and recoarctation rates using resection and end-to-end anastomosis in several series are shown in Table 14.2 [13,66–72]. Although the mortality rate was very acceptable in large series [73] several institutions reported a relatively high recoarctation rate (20–86%) particularly in the age group <1 year [13,66,69,71]. This high rate of stenosis in retrospect is attributed to: 1) the use of silk sutures instead of the currently available fine monofilament suture [58]; 2) inadequate resection of all ductal tissue, which may extend into

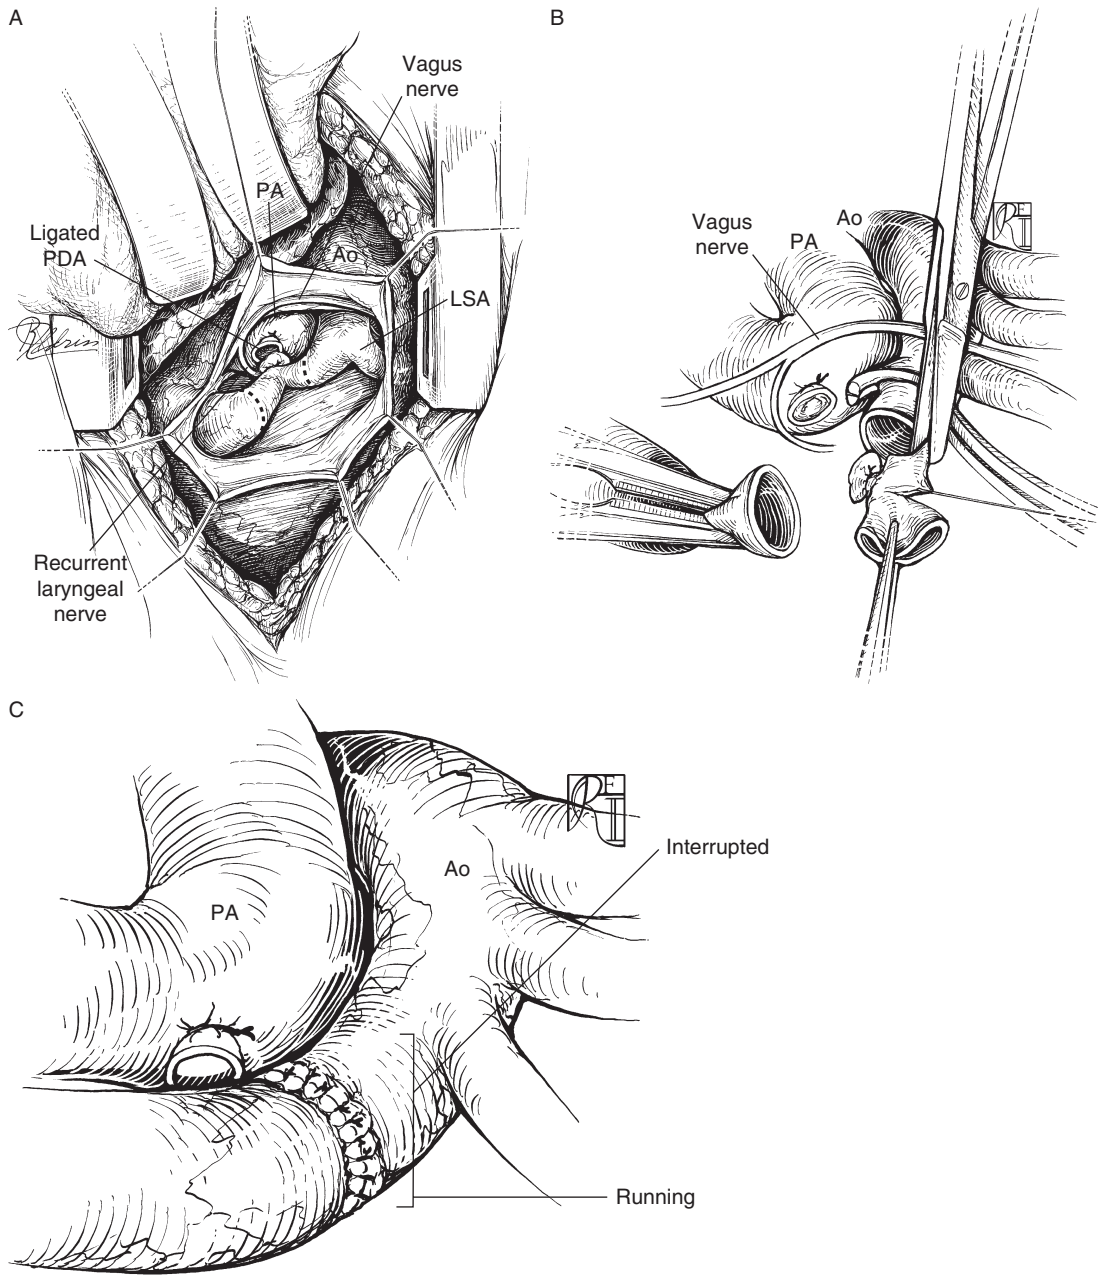

Figure 14.9 Resection with end-to-end anastomosis. **A,** Exposure through a left thoracotomy. The patent ductus arteriosus (PDA) has been ligated and divided. Dotted lines show area to be resected. **B,** Clamps have been applied and the coarctation segment is being resected. **C,** Anastomosis has been constructed with running suture for the back wall and interrupted suture anteriorly. (Ao, aorta; LSA, left subclavian artery; PA, pulmonary artery.)

areas of normal-appearing aorta [69]; 3) lack of growth at a circumferential suture line [74]; and 4) lack of growth of a hypoplastic transverse arch. More recent series [70,72] tend to indicate that with modern sutures and microvascular techniques, the recoarctation rate is reduced. However, this technique does not address the issue of a hypoplastic transverse arch, which is present in many infants. This technique is not easily applicable to older children in whom the location of the arch and descending aorta is more "fixed" than in infants and is difficult to mobilize for a safe tension-free anastomosis. Simple resection with end-to-end anastomosis has been essentially abandoned at most centers because of new, superior techniques that prevent recoarctation.

Prosthetic Patch Aortoplasty

Chiefly because of the high rate of recoarctation with the classic end-to-end anastomosis technique, the technique of prosthetic patch aortoplasty was introduced. Vossschulte [6] in 1957 described an "isthmusplastic" procedure that developed into the prosthetic patch aortoplasty. For many years this was our procedure of choice for older children (1–16 years of age). However, as will be seen in this section, the potential for aneurysm formation has led us to now only rarely use this technique [75–77]. As discussed earlier under general considerations, this operation is performed through a left thoracotomy and fourth intercostal space incision. After vessel dissection and ductus ligation, the aorta is occluded proximal and distal to the coarctation with vascular clamps. The aorta is then incised longitudinally through the site of the coarctation with the incision being extended well beyond the level of the coarctation both distally and proximally. Proximally this means that the patch often extends up onto the left subclavian artery. If the isthmus is hypoplastic with stenosis between the left subclavian and left carotid artery, the patch may be extended up into this area by placing the proximal clamp proximal to the left carotid artery. In the initial descriptions of this procedure, the posterior coarctation membrane or fibrous shelf was excised. This maneuver, however, can cause disruption of the intima and predispose to aortic aneurysm formation and is no longer recommended [78]. A circular prosthetic patch (slightly elliptical) made of polytetrafluoroethylene is sutured in place longitudinally along the aortotomy edge. An effort is made to use the largest patch feasible and place the widest portion of the patch at the level of the aortic constriction (Figure 14.10) [18]. The pleura should be closed as completely as possible over the patch.

The prosthetic patch technique offers several advantages over simple resection with end-to-end anastomosis, 1) the collateral vessels are all preserved and do not require ligation and division; 2) the technique allows simultaneous enlargement of isthmic hypoplasia if necessary; 3) the anastomosis is tension free; 4) the posterior aortic wall and even a hypoplastic aortic arch will grow after prosthetic patch repair [79]. The primary worrisome late complication of this technique is aneurysm formation of the posterior aortic wall opposite the patch [75–77]. This may be explained by several different factors. Most reported aneurysm formation occurred after resection of the coarctation membrane with violation of the intimal layer [80,81]. The patch causes altered hemodynamics arising from the different tensile strengths of the prosthetic patch and the posterior aortic wall, the pulsatile waveform being completely directed to the posterior aortic wall by the inflexible anterior patch [82]. Resection of the coarctation ridge (which is no longer performed) significantly predisposes to this complication. Another theory to explain aneurysm formation is a congenital abnormality of the aortic wall at the coarctation site [83]. Mortality, recoarctation rates, and incidence of aneurysm formation in several series [79–82,84–87] of patch aortoplasty are shown in Table 14.3. In a collected series of 815 patients, 9% had recoarctation and 4% had aneurysm formation. The issue of aneurysm formation is addressed in greater detail in the section on postoperative complications.

For many years the patch aortoplasty was our operation of choice for children older than 1 year and less than 16 years of age. The potential for late aneurysm formation however has now led us to use this procedure only in rare cases. In our experience the younger children (<5 years of age) are frequently candidates for a resection with an extended end-to-end anastomosis (to be discussed later in the chapter). The older children and certainly those over 10 years of age are now in our opinion better served by an interposition graft with essentially no risk for aneurysm formation or disruption of the anastomosis because of

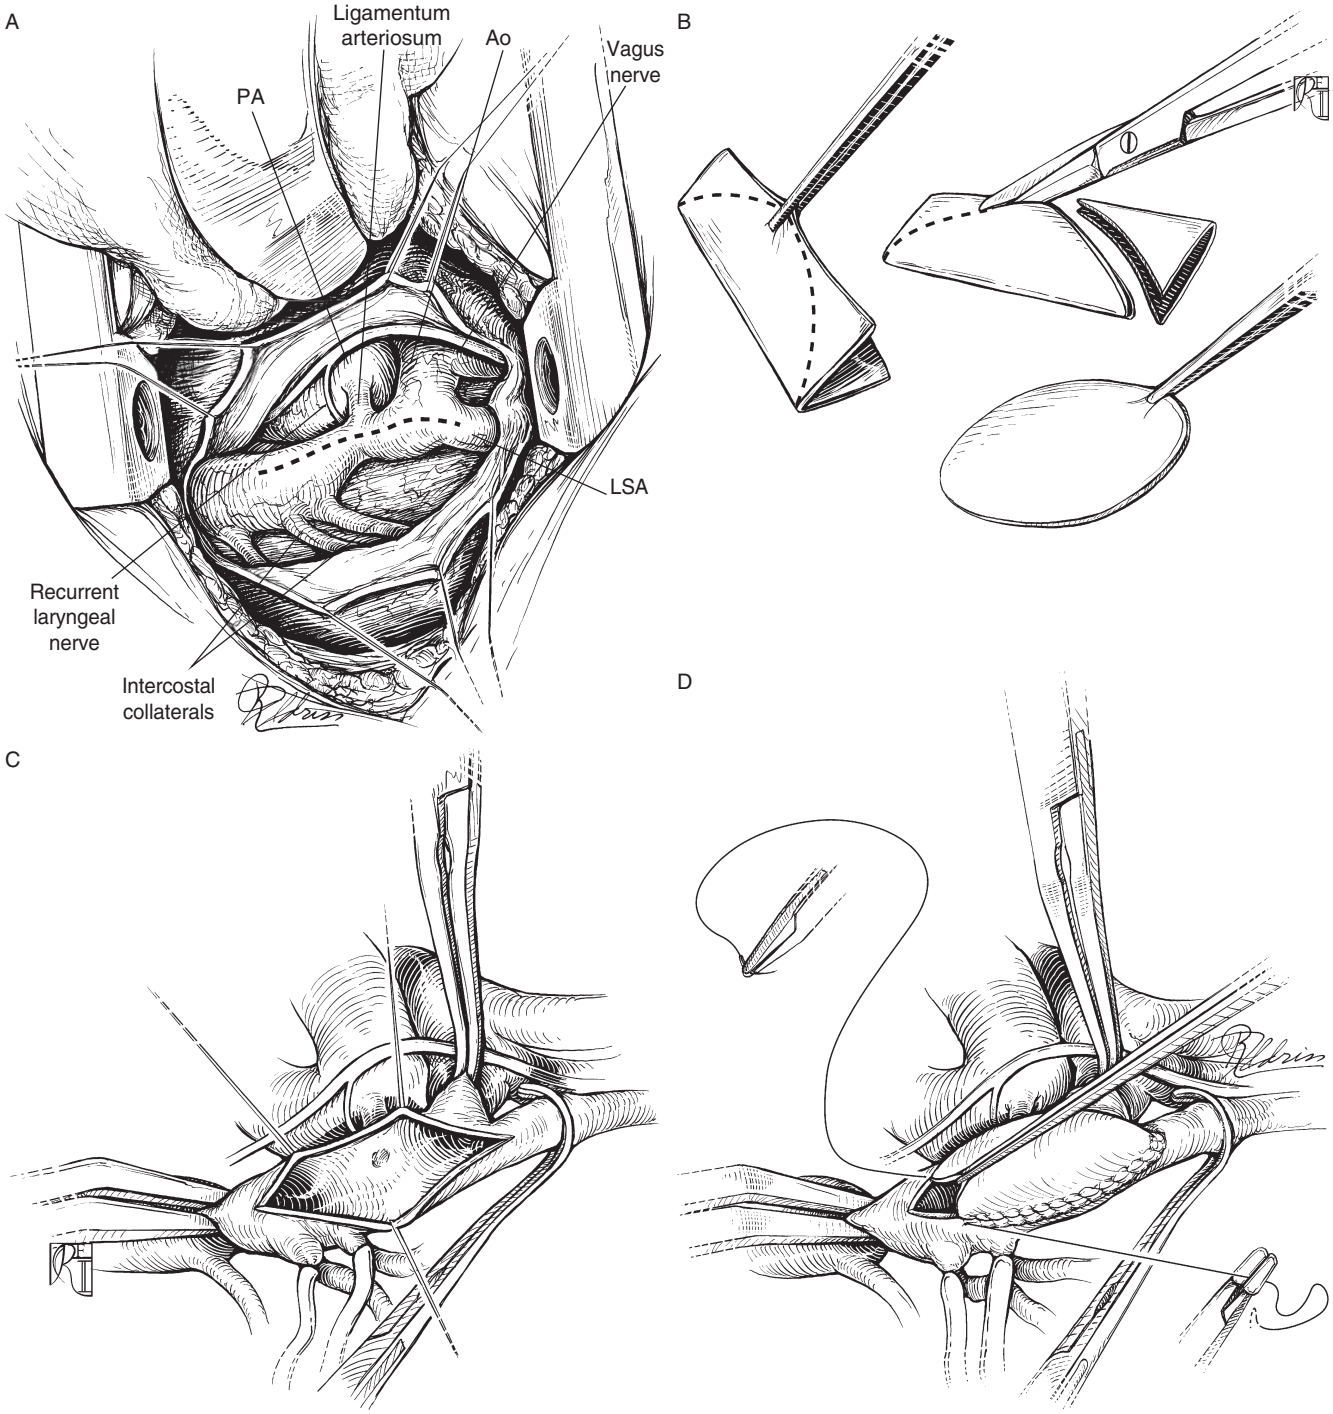

Figure 14.10 Patch aortoplasty. **A,** Exposure of the coarctation through a left thoracotomy. Note juxtaductal coarctation and enlarged intercostal collateral arteries. **B,** An elliptical polytetrafluoroethylene (PTFE) patch is fashioned prior to clamp placement. **C,** Clamps have been applied and the aorta opened laterally opposite the site of the ligamentum. Note intercostal arteries are controlled with small Rumel tourniquets. The coarctation ridge is *not* excised. **D,** The patch is sutured in place in such a manner that the PTFE creates a "roof" over the coarctation ridge. (Ao, aorta; LSA, left subclavian artery; PA, pulmonary artery.)

tension. We last used a patch aortoplasty for a primary coarctation repair in 2002. We reported our results with this procedure in 1995 [87]. Between 1979 and 1993, 125 infants and children underwent polytetrafluoroethylene patch aortoplasty. The posterior coarctation ridge was *not* excised in any patient. There were 111 primary repairs and 14 reoperations. The mean age at the time of surgery was 5.1 years. There were no cases of intraoperative mortality or postoperative paraplegia. There were four deaths (3% mortality) at 10–40 days postoperatively all neonates having additional intracardiac procedures for complex lesions. We have had only one patient develop an aneurysm and this was a false aneurysm detected 4 months after the surgery. One of the lessons that we did learn from this series was that infants who have this approach at less than 1 month of age had a high incidence of residual or recurrent coarctation. That experience has been confirmed by others [81,88]. Because of these experiences we do not recommend the patch aortoplasty for infants who are less than 1 year of age. We also do not use patch aortoplasty in patients older than 16 years of age because of the increased risk of aneurysm formation in older patients [75]. In summary, we currently believe that the patch aortoplasty should only be used in the rare patient who is too small for an interposition graft and whose anatomy precludes resection with extended end-to-end anastomosis, and for recoarctation. All patients having patch aortoplasty should be carefully followed for aneurysm formation.

Prosthetic Interposition Graft

The use of a prosthetic interposition graft was first described by Robert Gross [64] in 1951 when he used an aortic homograft as a replacement for a coarctation in a child with a long narrowed coarctation segment. In 1960 Morris, Cooley, DeBakey, and Crawford [89] described the use of a Dacron prosthetic interposition graft in 3% of 171 patients undergoing coarctation repair. Currently we recommend prosthetic interposition grafts (Figure 14.11) [18] for patients over 10 years of age, patients with an associated aneurysm, patients with complex long-segment coarctation, and selected patients with recurrent coarctation. It is also a useful technique if during a planned resection and end-to-end anastomosis it appears that the anastomosis will be under tension or the aorta requires further resection because of a thinned aortic wall secondary to post-stenotic dilatation. Aris and colleagues [90] reported successful use of this technique in eight patients over 50 years of age, using 16- or 18-mm Dacron tube grafts. We have used Hemashield or Gelweave (Vascutek-Terumo, Renfrewshire, Scotland) grafts for these patients to minimize bleeding, especially if partial cardiopulmonary bypass is used (Plate 14.1, see plate section opposite p.594). The obvious disadvantage of the interposition graft is the developmental size discrepancy in the growing child, making the operation more applicable for older patients. Another consideration is the longer aortic cross-clamp time taken to perform two circular anastomoses. This is now our procedure of choice for patients over 10 years of age where an adult sized graft can be inserted. We have used this technique in 24 patients in the past 20 years.

Subclavian Flap Aortoplasty

The subclavian flap aortoplasty technique was introduced by Waldhausen and Nahrwold [7] in 1966. Successful coarctation repair was reported in three patients aged 4 months, 6 months, and 3 years (Figure 14.12) [18]. The operation is performed through the left fourth intercostal space as described earlier under general considerations. The ligamentum or ductus arteriosus is ligated. The aorta is clamped proximal to the left subclavian artery as well as distal to the coarctation. The left subclavian artery is ligated distally (near the origin of the vertebral artery), which may or may not be included in the ligature. The subclavian artery is then opened along its lateral margin and divided near the ligature. The incision is extended through the isthmus across the coarctation site into the area of poststenotic dilatation. The subclavian artery is folded down onto the incision in the aorta and then the

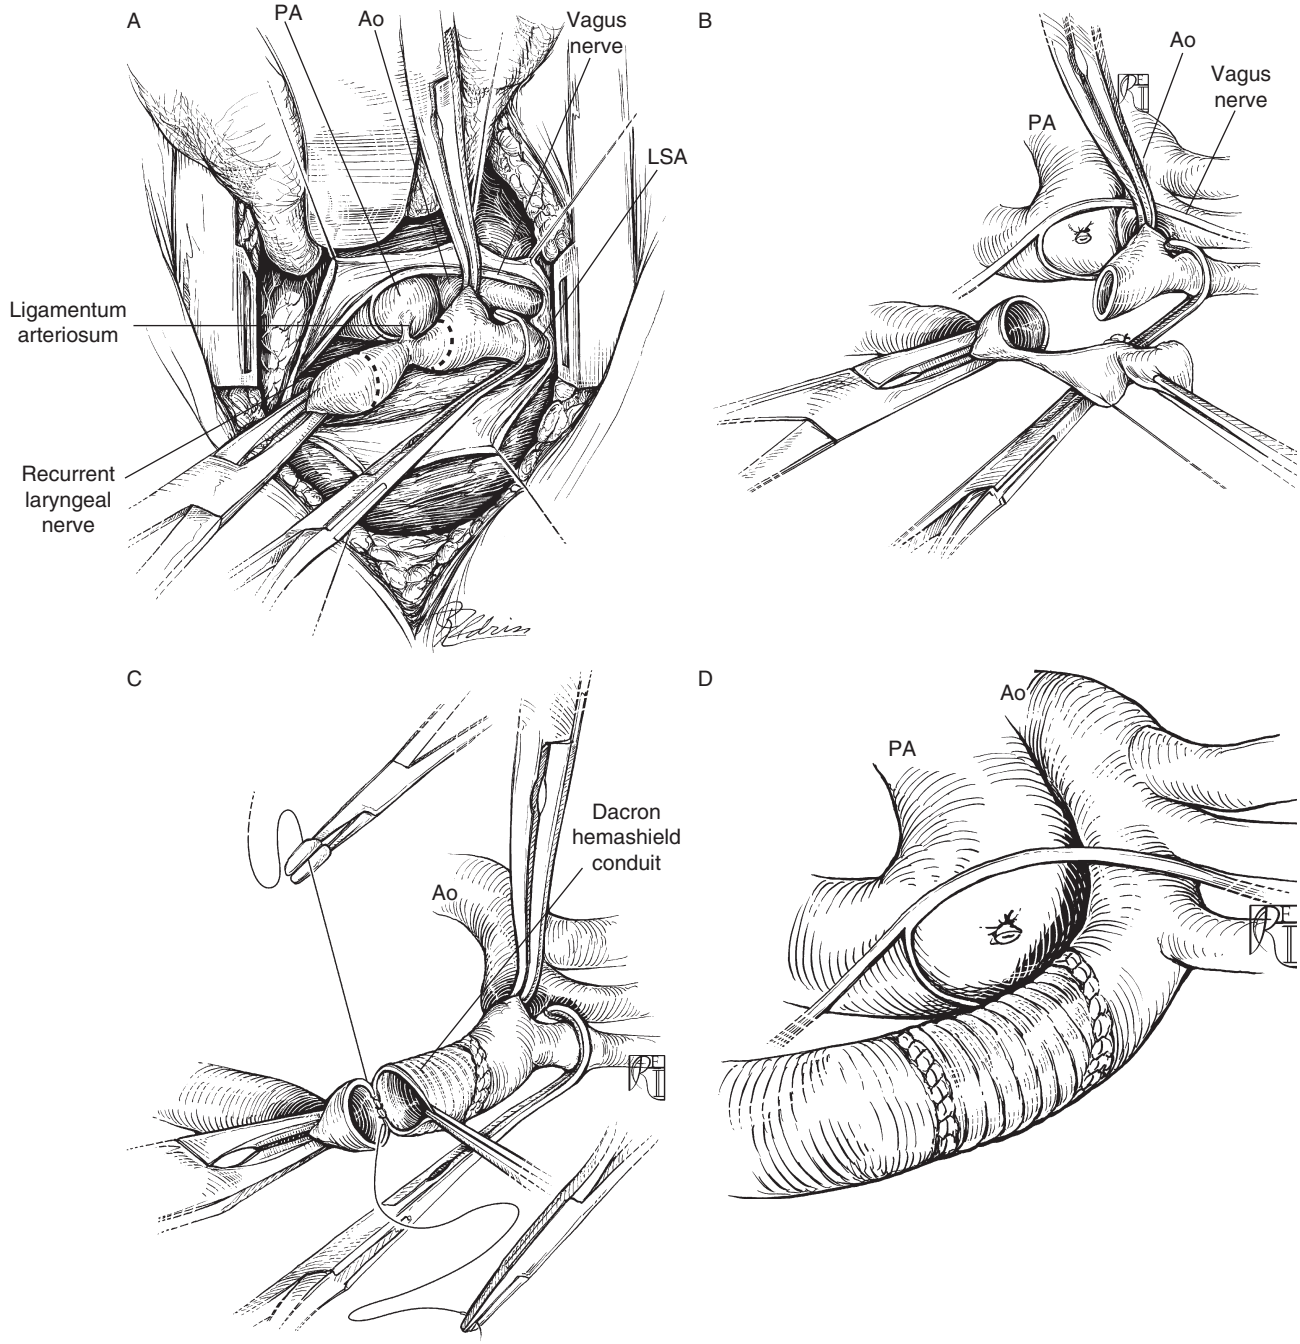

Figure 14.11 Interposition graft. **A,** Exposure through a left thoracotomy. Clamps are in place and the ligamentum has been ligated. The area to be resected is shown by the dotted lines. Frequently, in long-standing coarctation there is pre- and post-stenotic dilatation of the aortic wall. **B,** Coarctation resection. **C,** Proximal oblique anastomosis has been completed and the distal anastomosis is being performed. **D,** Completed interposition graft. (Ao, aorta; LSA, left subclavian artery; PA, pulmonary artery.)

subclavian "flap" is sutured in place with continuous fine polypropylene suture. The clamps are released and the appearance is of the subclavian patch creating a "roof" over the area of the previous coarctation. The issue of ligation of the vertebral artery is decided on a case-by-case basis. Leaving it intact provides collateral circulation to the arm but may possibly cause subclavian steal syndrome as the child grows. If possible, the internal mammary artery and the thyrocervical trunk are left intact to provide collateral circulation to the left arm. Occasionally more length

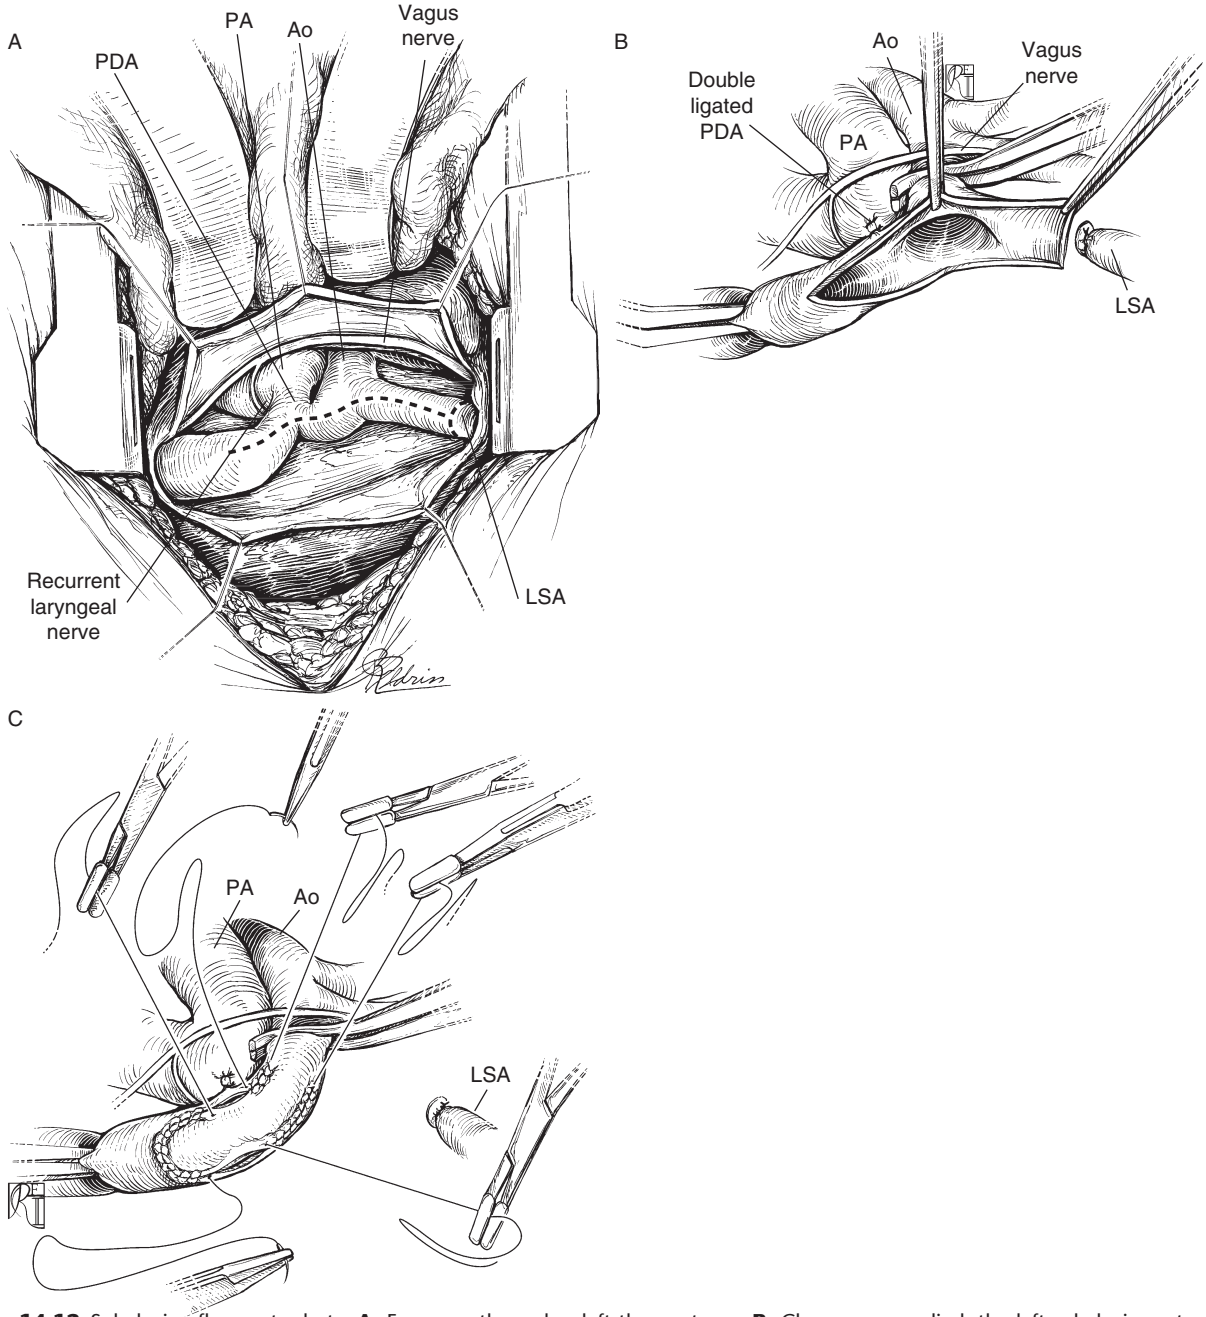

Figure 14.12 Subclavian flap aortoplasty. **A,** Exposure through a left thoracotomy. **B,** Clamps are applied, the left subclavian artery (LSA) is ligated, opened, and divided. **C,** The LSA is then turned down as a flap over the coarctation site, carrying the flap as far distal as is possible. Three polypropylene sutures are then used to create the anastomosis. (Ao, aorta; PA, pulmonary artery; PDA, patent ductus arteriosus.)

is required to span the coarctation site and sacrifice of these vessels is required. Failure to extend the incision far enough downstream across the coarctation and onto the area of post-stenotic dilatation may contribute to restenosis at a later date. Several variations of this technique have been described for complex coarctations. In 1983 Hart and Waldhausen [91] described the reversed subclavian flap technique for repair of a coarctation proximal to the left subclavian artery. Meier and colleagues [10] also described a technique for subclavian reimplantation in 1986 to preserve the arterial blood flow to the left arm. Dietl and associates [92] used a combined technique of coarctation resection and subclavian flap aortoplasty. Allen and coworkers [93] recently described a modification of the subcla-

vian flap adding a side-to-side transverse aortic anastomosis at the level of the coarctation. Kanter [94] has described using a reverse subclavian flap for repair of a hypoplastic transverse arch.

The advantages of the subclavian flap technique include its simplicity, short cross-clamp time, avoidance of prosthetic material, easy anastomotic hemostatic control, and increased anastomotic growth owing to the use of an autogenous noncircumferential flap [95]. Until the late 1980s the subclavian flap repair was widely utilized as the method of choice for repair of coarctation of the aorta in infants and children under 1 year of age [96,97]. However, there are some significant disadvantages of this technique which have led to many centers abandoning it in the current era. We do not perform this procedure in older children because of the fear of left arm ischemia following ligation of the subclavian artery [98–100]. We are aware of a patient who actually required amputation of a gangrenous arm after subclavian flap aortoplasty [101]. In addition, sacrifice of the left subclavian artery may affect long-term growth and function in the left upper limb [102]. Aneurysm occurrence has been described after subclavian flap aortoplasty [103] and in our institution we had one child who developed a false aneurysm following a subclavian flap aortoplasty utilizing absorbable suture. Subclavian flap aortoplasty was widely used from the mid-1970s to the late-1980s [104]. As the long-term follow-up was continued it appeared that the incidence of recoarctation, initially thought to be low, was higher than expected ranging up to 42% in some series [13,69,72,93,97,105,106,107–110]. In a collected series from 10 authors, 1181 patients had subclavian flap aortoplasty with a 13% recoarctation rate (Table 14.4) [13,69,72,93,97, 105,106,107–110]. It was particularly in the smaller infant less than 2 months in age that the subclavian flap aortoplasty appeared to have a high recurrence rate [106]. Because of this, surgeons became interested again in the resection with end-to-end anastomosis technique, this time, however, with an "extended" anastomosis. Some surgeons continue to feel that subclavian flap aortoplasty is the procedure of choice for neonatal coarctation of the aorta, although they appear to be in the minority [105,109,110].

Resection with Extended End-to-End Anastomosis

In 1977, Amato [8] reported four infants with hypoplasia of the distal transverse arch who underwent a new technique of resecting the coarctation and performing an extended anastomosis under the left carotid artery. In 1986 Lansman and associates [9] reported a series of 17 infants operated on between 1977 and 1985 having resection with extended end-to-end anastomosis. Forty-seven percent of these patients had a hypoplastic distal aortic arch and isthmus. Brown and colleagues [111] described an "isthmus flap" aortoplasty in 1985 as an alternative to subclavian flap for long-segment coarctation of the aorta in infants. This procedure is essentially a resection with extended end-to-end anastomosis.

Resection with extended end-to-end anastomosis can be performed via a left thoracotomy or through a median sternotomy. We have used a thoracotomy approach for 80% of our coarctation repairs [53]. We use a sternotomy approach if there is an associated intracardiac lesion or a hypoplastic transverse aortic arch. We also favor a sternotomy approach if there is an aberrant right subclavian artery or a common brachiocephalic trunk. Our current frequent use of CT imaging for these issues has been extremely helpful. The illustrations show the approach via a left thoracotomy (Figure 14.13) [18]. The initial exposure is as described earlier for the other techniques. The ductus arteriosus is ligated. The descending aorta is extensively mobilized – usually the first two or three sets of intercostal

vessels are ligated and divided. The left subclavian and left carotid arteries are dissected and encircled with vessel loops. The proximal aortic clamp is positioned between the innominate artery and the left carotid artery. The distal vascular clamp is placed well below the coarctation. The entire coarctation segment and ductus are excised. Proximally, an incision is made on the inferior surface of the transverse arch up to the proximal clamp. Distally the descending aorta is incised laterally in a "mirror" fashion to the other incision and the anastomosis is then performed with running polypropylene suture. We have used 7-0 prolene for neonates, 6-0 prolene for infants (30 days – 1 year) and 8-0 prolene for babies less than 1.5 kg. In our series from Children's Memorial Hospital (n = 201) mean clamp time was 18 minutes, operative mortality was 2% and reintervention for recoarctation was 4% [53]. Zannini and colleagues [112] described a similar technique in the Italian literature. Elliott [113] modified the technique to address transverse arch hypoplasia utilizing a clamp proximally to occlude the left subclavian artery, the left carotid artery, and even part of the right innominate artery. This allowed extension of the aortic arch incision more proximally than the "radically extended end-to-end anastomosis." Zannini and colleagues described another modification of this technique using a median sternotomy approach and cardiopulmonary bypass, with ligation of the isthmus and end-to-side anastomosis of the descending to the ascending thoracic aorta [114]. Although an interrupted suture technique would be theoretically attractive to promote growth of the anastomosis, Lansman proposed a running suture technique to decrease cross-clamp time. Growth of the anastomosis will occur because of eventual disruption of the suture line as the anastomotic site matures. This appears to be substantiated by indirect evidence of growth of a circumferential suture line following the arterial switch procedure [115]. Results of resection with extended end-to-end anastomosis are shown in Table 14.5 [9,13,19,21,71,110,112,115,119]. In 1209 patients, operative mortality was 6% and the recoarctation rate was also 6%.

Many surgeons now feel that this is the procedure of choice for the infant with coarctation. There are several advantages of this technique. All coarctation tissue with uncertain potential for future growth is completely resected. The left subclavian artery is preserved, avoiding potential left arm ischemia or growth disorders. The procedure addresses and corrects hypoplasia of the transverse arch, the distal aortic arch, and the aortic isthmus. The technique avoids prosthetic material, limits the potential for aneurysm formation, and preserves normal vascular anatomy. Paraplegia has not been reported as a complication of resection with extended end-to-end anastomosis, despite the ligation of multiple collaterals in 1209 patients (Table 14.5) [9,13,19,21,71,110,112,115,119]. When applied to the infant with complex associated cardiac lesions, one-stage total repair with this technique through a median sternotomy is quite successful [120]. Surgeons have demonstrated that a hypoplastic arch will grow with increased flow across a standard end-to-end anastomosis [121] or subclavian flap aortoplasty [122]. Extended arch repair is particularly useful for the small group of infants with transverse aortic arch-to-ascending aorta diameter ratios of less than 0.25 [123]. Resection with extended end-to-end anastomosis is currently our procedure of choice for all infants under 1 year of age and many children over one year of age.

Balloon Dilation Angioplasty

In 1979 Sos and associates [124] demonstrated that a surgically resected neonatal aortic coarctation could be successfully enlarged with a balloon dilation catheter. Lock and colleagues [125] performed dilatation on seven resected

coarctation segments and showed that eight atmospheres of pressure produced considerable increase in internal aortic diameter as a result of linear intimal tearing with medial extension. Lababidi and coworkers [126] reported successful balloon angioplasty in 27 patients with native coarctation in 1984. In 1986 Marvin and colleagues [127] first reported the development of aortic aneurysms near the site of balloon dilation angioplasty for native coarctation. Four of 11 patients undergoing dilation had aneurysm formation at the previously dilated site within 1 year. Surgical excision of the coarctation segments revealed an absence of muscle and elastic lamella in the area of the aneurysms [128]. This report led to an immediate suspension of the technique in patients with native coarctation of the aorta at all but a few centers. Cooper and associates [129] reported aneurysm formation in three of seven patients. Microscopy revealed disruption of the intima and elastic media, which resulted in thinning of the intact adventitial wall of the vessel. In 1989 the Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) Registry reported data from 140 patients for native coarctation of the aorta. A residual gradient of more than 20 mmHg was detected in 23 patients (16%) and late aneurysms were detected in six patients (4%) [130]. The study group concluded that although balloon angioplasty reduced the pressure gradient and increased the coarctation diameter, concerns about femoral artery injury and the late appearance of aneurysms called into question inclusion of the technique in the armamentarium of the interventional cardiologist [131]. Controversy continues to exist regarding the safety and efficacy of balloon angioplasty in the management of native coarctation of the aorta [132]. One of the few comparison studies (surgery vs. balloon) was reported by Fiore from St. Louis University [133]. Between 1994 and 2004, 17 patients had balloon angioplasty and 15 had surgery. Fifty-seven percent of the balloon angioplasty patients went on to require surgical intervention. Based on our experience we limit the use of balloon angioplasty for native coarctation of the aorta to patients with major systemic illnesses that significantly increase the risk of surgical intervention, and to older patients with mild discrete coarctation of the aorta and poorly developed collaterals. Some centers are still investigating balloon angioplasty for native coarctations [134,135]. Outcomes in these patients may be improved by the use of balloon-expandable stents [136]. However, stents are not a panacea for transcatheter therapy. There are multiple case reports of aortic rupture with stents [137,138]. In addition, younger age (9.8 vs. 18.6 years) and lower weight (37 kg vs. 59 kg) at the time of the initial procedure was associated with the development of in-stent stenosis [139]. Finally, Forbes recently reported a 31% incidence of complications in stents placed in patients over 40 years of age, "making this a high risk group" [140]. We recently operated on a patient who had unsuccessful dilation of a coarctation with a stent (Plate 14.2A, see plate section opposite p. 594). The coarctation and stent were excised (Plate 14.2B, see plate section opposite p. 594) and replaced with a 24-mm Gelweave Interposition graft.

In contrast to the above described results with balloon dilation for native coarctation the results of dilation for *recurrent* coarctation (Figure 14.14) [132] have been consistently more successful with a much lower incidence of aneurysm formation [141,142]. Saul and colleagues [143] reported a 90% success rate in a large series of patients with recurrent coarctation. The fibrous perivascular postsurgical scar appears to allow safe use of this technique for recoarctation in contrast to the danger of aneurysm formation when balloon dilation is used for native coarctation of the aorta. A multicenter prospective study [144] of balloon angioplasty for recurrent coarctation of the aorta reported 200 patients from 26 institutions. The prior method of surgical repair did not affect the postangioplasty gradient relief or diameter. A residual gradient of more than 21 mmHg was present in only 41 patients (20%). There were five deaths (2.5%) from aortic rupture (1), unexplained sudden death (2), cerebrovascular accident (1), and left heart failure (1). One patient had a cerebrovascular accident, another aortic dissection requiring urgent surgical intervention. There were no late aneurysms. Hijazi and associates [142] reported 27 patients undergoing balloon angioplasty for recurrent coarctation of the aorta. One patient was undilatable, one patient developed a stable aneurysm, and two patients developed restenosis. Yetman [145] reported 90 patients having balloon dilation of recurrent coarctation, with one death and one aortic tear requiring urgent surgical intervention. Good early results were obtained in 88% of the patients and at long-term follow-up (12 years) 72% of these patients remained free of intervention. Reich reported 99 patients with a 93% success rate of balloon angioplasty for recurrent coarctation [146]. We feel that balloon angioplasty is the procedure of choice for recurrent coarctation of the aorta following surgical repair.

Complications

The list of possible complications both during and following coarctation repair is extensive and their prevention requires careful attention to all details of the technique (Table 14.6).

Hemorrhage

During the time period that the aortic clamps are in place and following their removal, the anesthesiologist should have blood available and prepared for administration so that it is immediately accessible in the event of excessive suture line hemorrhage after clamp release. Even though none of the techniques utilized requires intravenous heparin (except if cardiopulmonary bypass is used) the suture lines nearly always have an initial moderate degree of bleeding until clots form within the needle holes. At the

termination of the procedure, chest tubes (or Blake drains) should be left in position to monitor and evacuate postoperative blood loss. Any sudden increase in the amount of bleeding from the chest tube should result in the patient's immediate return to the operating room for control of bleeding.

Paradoxical Postoperative Hypertension

That the correction of a coarctation of the aorta, an apparently straightforward cause of hypertension, can provoke a postoperative increase in blood pressure is unexpected and illogical, hence the name paradoxical hypertension [147]. The etiology of the postoperative hypertension is felt to occur secondary to two hypertensive responses [148]. The first response occurs immediately and subsides in most patients within 24 hours and is due to the release of the stretch on the baroreceptors in the carotid arteries and aortic arch after removal of the aortic obstruction. This increase in blood pressure occurs until the baroreceptors are set at a lower level. The best evidence for this is the marked increase in sympathetic activity indicated by elevations in norepinephrine level after operation [149]. This

occurs in slightly over half of patients and in most cases subsides within 24 hours [150]. The second phase (which is more pronounced in diastole) appears within 48–72 hours and occurs in about one-third of those experiencing the first phase of hypertension. It is associated with elevated levels of renin and angiotensin, which may be stimulated by the first phase of paradoxical hypertension [151,152]. This second response may be the adaptation gone awry that ensures adequate flow to exercising muscles below the coarctation, above and beyond that delivered by increasing the systolic pressure.

Unchecked hypertension in either postoperative phase can have disastrous results. Because the mesenteric arteries have been accustomed to a very low blood pressure, the sudden increase of arterial pressure in these arterioles may lead to severe reactive acute inflammatory changes. This may result in mesenteric arteritis and subsequent evolution to mesenteric ischemia [153,154]. The child then develops severe abdominal pain, distension, and tenderness. On occasion this will cause gastrointestinal bleeding and may require laparotomy with bowel resection. Thus postoperative hypertension must be very carefully monitored and managed. In the immediate postoperative period the administration of esmolol or nicardipine intravenously can be used to titrate the blood pressure [155]. We have also found it useful to use intravenous enalapril (angiotensin converting enzyme inhibitor) beginning shortly after the procedure with eventual conversion to oral captopril or vasotec after several days. Oral propranolol is also quite useful in blunting the sympathetic response and managing the hypertensive response [156]. Gidding and coworkers [157] showed that *preoperative* administration of propranolol helped prevent the postoperative hypertensive response. Because of the risk of mesenteric arteritis, we usually keep our patients NPO for the first 24–36 hours following coarctation repair. We have only had one (mild) case of mesenteric arteritis in the past 20 years with careful postoperative management of hypertension.

The tendency to have persistence of the hypertension late after coarctation repair is proportional to the age of the child at the time of the operative repair [158]. Seirafi and colleagues [159] reported only 2 of 48 infants (<12 months of age) operated on for coarctation having late hypertension (4%) versus 16 of 59 (27%) patients operated on after 1 year of age (Figure 14.15) [159]. Sigurdardottir [160] confirmed these findings in exercise studies. Of course persistent hypertension following repair of coarctation of the aorta despite medical intervention merits investigation to rule out a recurrent coarctation. All patients with coarctation should have life-time follow-up by a cardiologist. Warnes and colleagues have made the point that coarctation should be regarded not as a localized abnormality but as a diffuse arteriopathy deserving long-term follow-up [161,162].

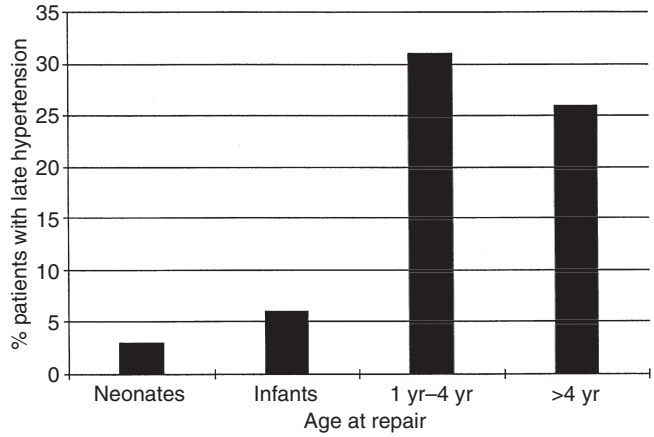

Figure 14.15 Percentage of patients with persistent or late hypertension listed according to age at operation. The percentage of patients with late hypertension was significantly less in the neonatal and infant groups (n = 48, 4.2%) than in toddlers and older children (n = 59, 27.1%; $p < 0.002$). YR, years. (Reproduced with permission from the Society of Thoracic Surgeons from Seirafi *et al.* [159].)

Paraplegia

Paraplegia was first reported by Gross and Hufnagel [4] as a possible complication in animals following coarctation repair and to this day remains a serious and feared complication. Bing and colleagues [163] reported the first human to develop paraplegia after coarctation repair in 1948. In a landmark review from 1972, Brewer and coworkers [164] surveyed 12 532 cases of coarctation of the aorta repair and found an incidence of 0.41% spinal cord complications (1 in 250 patients). They were unable to correlate these complications with any specific factor such as number of intercostals divided or length of cross-clamp time. Lerberg and associates [165] more recently reported an incidence of paraplegia of 1.5% (5/334). Paraplegia correlated with the length of aortic cross-clamping (mean cross-clamp time in those patients with paraplegia was 49 minutes) and the presence of an aberrant origin of the right subclavian artery below the coarctation (one of eight patients). Crawford and Sade [166] reported three patients in whom intraoperative hyperthermia appeared (temperature maximum 38.7 °C, 39.8 °C, 40 °C) to play a significant role in the development of postoperative spinal cord injury. As previously discussed under operative technique, the distal aortic pressure during clamp placement is very important and this pressure should be kept over 45 mmHg [60]. To effect this the proximal aortic pressure must be kept high (120–200 mmHg, depending on the age of the patient) during the clamp time. Acidosis should be avoided during the time of the aortic cross-clamp as this may contribute to low cardiac output and hypotension [63]. Somatosensory evoked

potentials (SSEP) are a possible method of assessing reversible spinal cord ischemia [167].

In summary, to avoid paraplegia we recommend: 1) aortic cross-clamp time as short as possible, 2) careful technical anastomosis so reapplication of clamps is not necessary, 3) moderate hypothermia (34–35 °C), 4) high proximal blood pressure, 5) no acidosis, and 6) adequate distal mean blood pressure (>45 mmHg). The key among these is perhaps the distal mean blood pressure. In patients over 1 year of age we monitor both the radial artery pressure and the distal femoral pressure. At the time of test clamp if the pressure drops below 45 mmHg we perform the case with partial left heart bypass [61]. Left heart bypass is performed with systemic heparinization and a venous cannula placed in the left atrial appendage by opening the pericardium. The descending thoracic aorta is cannulated with an appropriately sized aortic cannula. Typical left heart bypass flows are 50–60% calculated total flow, all of which goes to the lower extremities. Our mean cardiopulmonary bypass time was 27 minutes, the mean aortic clamp time was 21 minutes. The mean hospital stay in the patients where cardiopulmonary bypass was used was not different from the mean hospital stay in the patients where cardiopulmonary bypass was not used. There were no complications related to the cardiopulmonary bypass (bleeding, recurrent laryngeal nerve injury, recurrent coarctation, or neurologic injury). We have now used left heart bypass for coarctation repair in 22 patients without complications.

Aneurysm Formation

Both true and false aneurysms have been reported as complications after all types of coarctation of the aorta repair [168]. Aneurysms are also known to occur in patients with coarctation *not* undergoing surgical treatment [77]. However, there have been more reports of true aneurysm formation following prosthetic patch aortoplasty than any other technique. In 1980 Bergdahl [76] reported four adult patients with aneurysm formation in the aortic wall opposite a Dacron patch. Two of the patients had the patch placed at the time of reoperation after prior resection with end-to-end anastomosis. Microscopy revealed degenerative changes in the aortic wall opposite the patch. They postulated that the reason for the aneurysm formation was that part of the circumference of the aorta was replaced by a material with tensile characteristics differing from those of the aorta itself. In 1986 Rheuban and associates [169] reported eight aneurysms in a follow-up of 45 patients who had Dacron patch aortoplasty at a mean age of 8.5 years. In this series if a significant coarctation ridge was noted it was excised, even though the authors state this did not increase the incidence of aneurysm formation. Clarkson and colleagues [82] reported "aneurysm" formation in 5 of 38 patients (13%) in whom a Dacron patch aortoplasty was performed. In 20 of these patients the intimal ridge was excised. Only one patient had a true aneurysm after primary coarctation repair without excision of the intima, four patients had false aneurysms. Del Nido and associates [85] reported a 5% incidence of aneurysm formation after 63 patch aortoplasties. Two of the three patients developing an aneurysm had the patch placed as a repair of recoarctation following primary resection of coarctation with end-to-end anastomosis during infancy.

In one of the largest series reported, starting with the patients originally operated on by Vossschulte, Hehrlein and coworkers [80] reported 18 aneurysms occurring in 317 patients (6%). Of the 14 patients for whom detailed information was available, 12 of 14 had an extensive resection of the fibrous coarctation membrane. Hehrlein and associates concluded that resection of a fibrous membrane of the aortic isthmus at the first intervention seemed to be an essential predisposing factor for development of aneurysms and the posterior ridge should not be excised. Experimental evidence confirming this observation was provided by DeSanto and colleagues [78] who studied Dacron and PTFE patches in dogs with and without concomitant intimal excision opposite the patch. Aneurysms formed in 8 of 12 dogs undergoing intimal excision and none of the control animals. Heikkinen and associates [83] reported histopathological studies of aneurysms and found medionecrosis in 13 of 14 patients and foreign body reaction in 11 patients. They concluded that these patients have an inherent weakness of the segment of the aortic wall owing to medial cystic degeneration. The same group reported successful management of such patients with aneurysm resection and insertion of a tubular prosthesis using femorofemoral or left atriofemoral bypass [75]. This group, which has the highest reported incidence of aneurysm formation (33%), speculated that this might reflect the fact that most of the patients were adults when the primary repair was done. Prolonged hemodynamic stress may have weakened the aortic wall of these patients. Bogaert and colleagues [170] reported that transverse arch hypoplasia also predisposes to aneurysm formation. The risk of aneurysm formation would appear to be higher for patients having a patch at >16 years of age or operated on as a recoarctation following resection with end-to-end anastomosis. The incidence of aneurysm formation also appears to be significantly higher after Dacron patch as compared to PTFE patch use [171]. Bertolini and associates [172] performed MRIs on 26 patients at a mean of 7 years after PTFE patch placement and found no aneurysms.

The risk of aneurysm formation is what has led us to significantly reduce the number of patients undergoing patch aortoplasty at our institution. We essentially now reserve that operation for patients who are having transverse arch repair or recoarctation repair and the child is not large enough for an interposition graft.

Recoarctation and Reoperation

Recurrent or residual coarctation has been reported after every type of coarctation repair. Numerous factors have been shown to increase the risk of recoarctation including age less than 2 to 3 months [71,106,107], weight less than 2 kg [173], silk suture material instead of polypropylene [58], and residual ductal tissue [174]. Recoarctation is defined as a postoperative arm-to-leg peak systolic pressure gradient exceeding 20 mmHg across the repaired area [175]. The resting gradient is not necessarily sensitive enough to "rule out" significant hypertension seen with exercise. Simultaneous arm/leg pressure measurements after exercise are the best way to exclude the possibility of residual obstruction at the coarctation repair site [176]. Magnetic resonance imaging, digital subtraction angiography, and bicycle exercise testing may also be useful in detecting residual coarctation of the aorta [177]. The most "cost-effective" approach may be to combine physical examination with MRI [178].

It seems clear that the initial reports of resection and end-to-end anastomosis had a high recoarctation rate (19%) [66]. This was probably secondary to the use of silk sutures instead of the currently available fine monofilament suture, inadequate resection of all ductal tissue that may extend into areas of normal-appearing aorta, lack of growth at a circumferential suture line, and lack of growth of a hypoplastic transverse arch. Recent reports of resection and end-to-end anastomosis using microvascular technique appear to have a much lower recoarctation rate [53]. The subclavian flap aortoplasty, although originally felt to nearly eliminate recoarctation, definitely has a rate of recoarctation higher than initially thought (13%) [66]. The patch aortoplasty should not be used in infants because of the high recoarctation rate. Resection with extended end-to-end anastomosis appears to have the lowest recoarctation rate (6%) [53]. Our current approach is to use resection with extended end-to-end anastomosis for all neonates and infants and some older children. For children over 10 years of age we use an interposition graft.

As discussed in the section on balloon angioplasty, this procedure is now considered the initial procedure of choice for most children with recurrent coarctation of the aorta [130,144]. The initial success rate is high with a low incidence of complications. If balloon dilation is not successful or not indicated, reoperation may be required. In most cases reoperation is considerably more difficult owing to dense scarring in the region of the previous repair. The gradient is usually not high, decreasing the impetus for collateral formation and possibly increasing the risk of spinal cord complications [179]. The previously discussed indications for partial left atriofemoral bypass to maintain adequate distal aortic perfusion pressure should be seriously considered for every reoperation. No single technique of reoperation is applicable to all patients but the majority of patients can be managed by either patch graft angioplasty, resection and interposition graft, or a local bypass graft technique [180,181]. Resection and primary end-to-end anastomosis may be difficult secondary to adhesions and the amount of mobilization required to avoid tension on the suture line of what is usually a very friable aorta.

Sweeney and associates [180] reported 53 patients who underwent reoperation for aortic coarctation. Interestingly, no temporary shunts or left heart bypass was used, all patients survived, and there were no instances of paraplegia. Twenty-six patients had Dacron patch angioplasty, 16 had bypass grafts around the coarctation, 8 had resection and interposition grafting, and 3 had resection and end-to-end anastomosis. Only three patients had a postoperative gradient more than 10 mmHg and none more than 20 mmHg. Kron and colleagues [182] reported 24 reinterventions in 23 patients with recoarctation with one death and no paraplegia. Techniques employed included patch aortoplasty (13), balloon dilation (6), end-to-end anastomosis (2), interposition graft (2), and subclavian flap (1). They recommended balloon dilation as primary therapy for restenosis. Sakapoulos and colleagues [183] reported reoperation for recurrent coarctation in 56 patients, the vast majority of repairs using a prosthetic patch technique. There were no deaths or major complications and a 96% success rate. For patients with a long segment recoarctation, very dense adhesions, or requiring a cardiac operation, Jacob and coworkers [184] reported success in 10 patients using an ascending aorta-to-descending aorta bypass graft placed with a combined left thoracotomy, median sternotomy approach. Kanter [185] also reports successful extra-anatomic bypass for complex recurrent coarctation. Moderate-to-severe hemodynamic abnormalities may persist during exercise after reoperation for coarctation of the aorta [186]. Diligent efforts to repair all hemodynamically significant residual and recurrent coarctations are necessary if the natural fate of premature death is to be avoided for patients with these lesions.

Conclusion

The management of the infant and child with coarctation of the aorta has become fairly standardized. Echocardiography is the primary diagnostic tool. Computed tomographic imaging is very useful if the echocardiogram is not fully diagnostic. PGE_1 has dramatically improved the outcome for neonates with critical coarctation. Coarctation should be repaired at the time of diagnosis to minimize the incidence of late hypertension. We recommend resection with extended end-to-end anastomosis for neonates, infants, and young children. For complex coarctation of the aorta (associated intracardiac lesions), we recommend transmediastinal repair of the cardiac defect and resection

with extended end-to-end anastomosis. We recommend resection with interposition graft placement for older children. In older children femoral artery pressure should be monitored and strong consideration should be given to partial left heart bypass to avoid paraplegia. Balloon dilatation is the initial procedure of choice for recoarctation. If this is unsuccessful, reoperation with patch aortoplasty or graft interposition has excellent results.

CHAPTER 15

Interrupted Aortic Arch

Richard A. Jonas
Children's National Medical Center, Washington, DC, USA

Introduction

Interrupted aortic arch (IAA) is a rare abnormality that accounts for approximately 1.5% of all congenital heart anomalies [1]. It is a fascinating example of the role that apoptosis plays in both normal and abnormal development. Apoptosis is usually responsible for resorption of most of the original six branchial arches in the embryo. However, when it occurs in excess, apoptosis can interrupt the aortic arch [2,3]. Although early mortality for primary one-stage surgical repair is now relatively low in centers managing large volumes of neonates, there is a frequent association with underdevelopment of left-sided structures that can result in the need for late reintervention, particularly for subaortic stenosis. Previous controversy regarding one-stage versus two-stage repair and the role of direct anastomosis versus interposition graft have largely subsided in favor of one-stage, direct anastomotic repair. However, new controversy has emerged regarding the role of selective cerebral perfusion in protecting the brain during repair. Developmental studies to resolve this controversy will be complicated by the important association of IAA with microdeletion of chromosome 22, which has important implications for cognitive development.

Pathologic Anatomy of the Aortic Arch

The arch of the aorta has a proximal component, the proximal aortic arch, and extends from the takeoff of the innominate artery to the left common carotid artery. The distal component, the distal aortic arch, extends from the left common carotid artery to the takeoff of the left subclavian artery. The segment of aorta that connects the distal aortic arch to the juxtaductal region of the descending aorta is termed the *isthmus* (Figure 15.1) [4]. In the embryo, these different segments are derived from different components: the proximal arch is derived from the *aortic sac*, the distal arch from the *fourth embryonic arch*, and the isthmus from the junction of the *sixth embryonic arch* (ductus) with the left dorsal aorta and fourth embryonic arch.

A useful classification of IAA was introduced by Celoria and Patton in 1959 (Figure 15.2) [5,6]. Type A interruption occurs at the level of the isthmus. It is often seen in a milder form in which a short fibrous chord connects across the interruption even though there is no luminal continuity. This has been termed aortic arch *atresia* and generally represents less of a surgical challenge than a long segment complete discontinuity.

Type B interruption occurs between the left common carotid artery and the left subclavian artery. It is the most common type seen. In a review of the experience at Children's Hospital Boston between 1974 and 1987 by Sell *et al*., 69% of the 71 patients had type B interruption [7]. In a more recent multi-institutional study by the Congenital Heart Surgeon's Society (CHSS) [8], updated in 2005 [9], 70% of 468 neonates with IAA and associated ventricular septal defect (VSD) had type B interruption. Type B interruption is often associated with an aberrant origin of the right subclavian artery from the descending aorta. This is important because in this subtype, more flow must pass through the ductus arteriosus during fetal development and less flow through the left ventricular outflow tract and ascending aorta than with the standard type B interruption, with normal origin of the right subclavian from the innominate artery. Thus, it is not surprising to find that the risk of subaortic stenosis is increased when the right subclavian artery arises aberrantly.

Type C interruption occurs between the innominate artery takeoff and left common carotid. It is extremely rare, having been described in less than 4% of most large clinical

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

and pathologic series. There were seven cases among the 468 patients with IAA reviewed by the CHSS [9].

Associated Anomalies

Isolated IAA is exceedingly rare. Apart from patent ductus arteriosus (PDA), a single VSD is the most common associated anomaly. In a CHSS study, 72% of 472 patients had an isolated VSD as the only associated anomaly [9]. There is frequently posterior malalignment of the conal septum relative to the ventricular septum, which contributes to left ventricular outflow tract obstruction (LVOTO) [10]. Other anatomic features that may contribute to LVOTO include the aortic annulus itself, which is usually at least moderately hypoplastic. The aortic valve is frequently bicuspid, and there may be commissural fusion. Opposite the septum, there may be a prominent muscle bundle on the left ventricular free wall that projects into the outflow tract, the so-called "muscle of Moulaert" (Kreutzer J and Jonas R, unpublished observations). A fibrous subaortic membrane is almost never seen in the neonate with IAA but sometimes develops within a year or two of repair.

An atrial septal defect is frequently seen in conjunction with IAA. This is usually in the form of a stretched patent foramen ovale but can be quite large and therefore hemodynamically important. Perhaps this is caused by the left-to-right shunt that occurs during *in utero* development because of the left-sided obstruction that results from the interruption itself as well as associated LVOTO.

There are other anomalies seen in association with IAA (Table 15.1) [9]. Various forms of single ventricle are seen in 3% of patients with IAA and truncus arteriosus is seen in 11%.

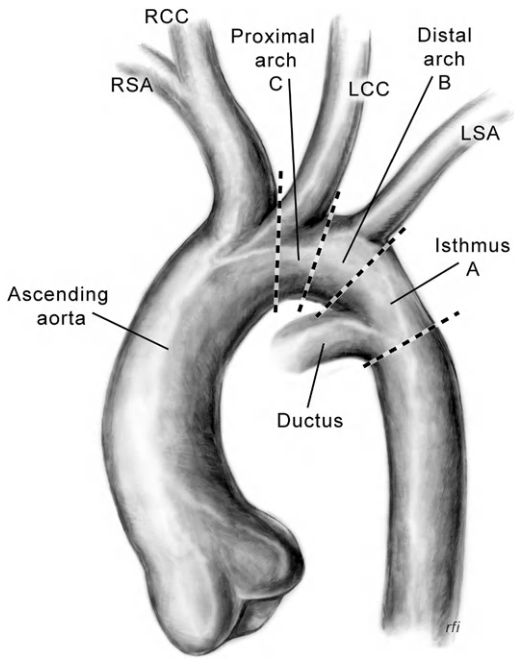

Figure 15.1 Helpful terminology for the segments of the aortic arch include *proximal arch* for the segment between the innominate artery and left common carotid artery (C), *distal arch* for the segment between the left common carotid and left subclavian arteries (B), and *isthmus* for the segment between the left subclavian artery and the ductus arteriosus (A). (LCC, left common carotid artery; LSA, left subclavian artery; RCC, right common carotid artery; RSA, right subclavian artery.)

Pathophysiology and Clinical Features

Prenatal diagnosis by ultrasound is becoming increasingly common. Prostaglandin E1 (PGE_1) is started immediately after birth, and an acidotic insult is avoided. For the patient who is not diagnosed prenatally with the most common form of IAA (an associated PDA and posterior malalignment VSD) there may be little suspicion of serious heart disease during the early neonatal period until ductal closure begins. If that should occur abruptly or is not recognized rapidly, the child will soon become profoundly

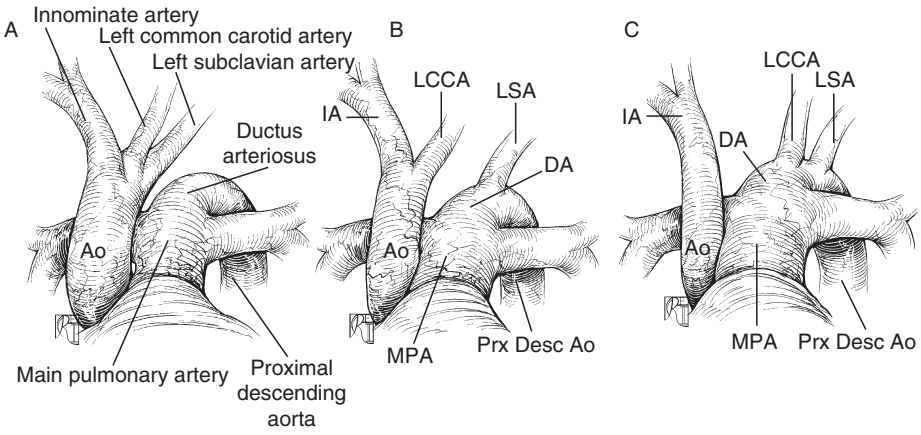

Figure 15.2 Anatomic types of interrupted aortic arch. **A,** Type A, interruption distal to the left subclavian artery. **B,** Type B, interruption between the left subclavian and left carotid arteries. **C,** Type C, interruption between the left carotid and innominate artery. Variable	No.	Missing	Value	Deaths (n = 186)
None – isolated VSD	472	0	341 (72%)	121 (35%)
None – intact ventricular septum	472	0	7 (1%)	2 (29%)
Aortopulmonary window	472	0	20 (4%)	3 (15%)
Complete atrioventricular septal defect	472	0	3 (<1%)	3 (100%)
Atrioventricular discordance	472	0	2 (<1%)	1 (50%)
Double-outlet right ventricle	472	0	8 (2%)	4 (50%)
Partial anomalous pulmonary venous return	472	0	1 (<1%)	1 (100%)
Single ventricle	472	0	13 (3%)	9 (69%)
Transposition of great arteries with VSD	472	0	26 (6%)	9 (35%)
Truncus arteriosus	472	0	51 (11%)	34 (67%)
Bicuspid aortic valve	229	243	149 (65%)	57 (38%)
Anomalous right subclavian artery	427	45	108 (25%)	45 (42%)
Left superior vena cava	440	32	35 (8%)	19 (54%)
Large patent ductus arteriosus	281	191	251 (89%)	94 (37%)
Large VSD	392	80	322 (82%)	123 (38%)
Multiple VSDs	383	89	31 (8%)	14 (45%)
Malalignment of VSD	472	0	165 (35%)	74 (32%)

acidotic and anuric as perfusion of the lower body becomes entirely dependent on collateral communications between the two separate aortic systems. The distribution of palpable pulses will depend on the anatomical subtype. For example, with the common type B IAA, the right arm pulse will be palpable when the left arm pulse and femoral pulses become impalpable secondary to ductal closure. Ischemic injury to the liver will be reflected in a marked elevation of hepatic enzymes (serum glutamic oxaloacetic transaminase [SGOT] and lactic acid dehydrogenase [LDH]), and ischemic injury to the gut may be followed by evidence of necrotizing enterocolitis, such as bloody stools. Renal injury can be quantitated to some extent by the elevation observed in serum creatinine.

A very severe degree of systemic acidosis (prolonged pH < 7.0) will ultimately result in injury to all tissues of the body, including the brain and the heart itself. The child may have seizures and become flaccid and poorly responsive. Myocardial injury will be apparent in the form of a low cardiac output state despite normalization of parameters. Since pulmonary blood flow is preserved during ductal closure, it is rare to see evidence of pulmonary insufficiency.

Occasionally the ductus will not close during the neonatal period, and diagnosis may be delayed for several weeks. As pulmonary resistance falls, there will be an increasing left-to-right shunt, and the child will present with evidence of congestive heart failure, including failure to thrive.

Historical Perspective

Interrupted aortic arch was first described by Steidele in 1778 [11]. Celoria and Patton reported their anatomical classification in 1959 [5]. Successful surgical repair was first described by Merrill *et al*. in 1955 in a patient with short segment type A IAA [12]. A direct anastomosis was possible; however, the associated VSDs were not closed at the time of the arch repair. One-stage repair was first accomplished by Barratt-Boyes [13]. In the procedure he described, arch continuity was established using a synthetic conduit. One-stage repair, including direct arch anastomosis, was first described by Trusler in 1975 [14]. Interrupted aortic arch carried an extremely high mortality risk until the introduction of PGE_1 by Elliott *et al*. in 1976 [15]. Over the next 5–10 years, it became apparent that careful resuscitation of the neonate, often over a time span of days, before proceeding to surgery was associated with a dramatic improvement in surgical outcome (Figure 15.3) [6,7]. The concept of selective cerebral perfusion to minimize or eliminate the use of circulatory arrest has been described by many authors including Sakurada *et al*. and Asou *et al*. in 1996 [16,17].

Diagnosis of Interrupted Aortic Arch

Anatomy

Accurate anatomic diagnosis can currently be made using echocardiography alone. This is an important advantage to

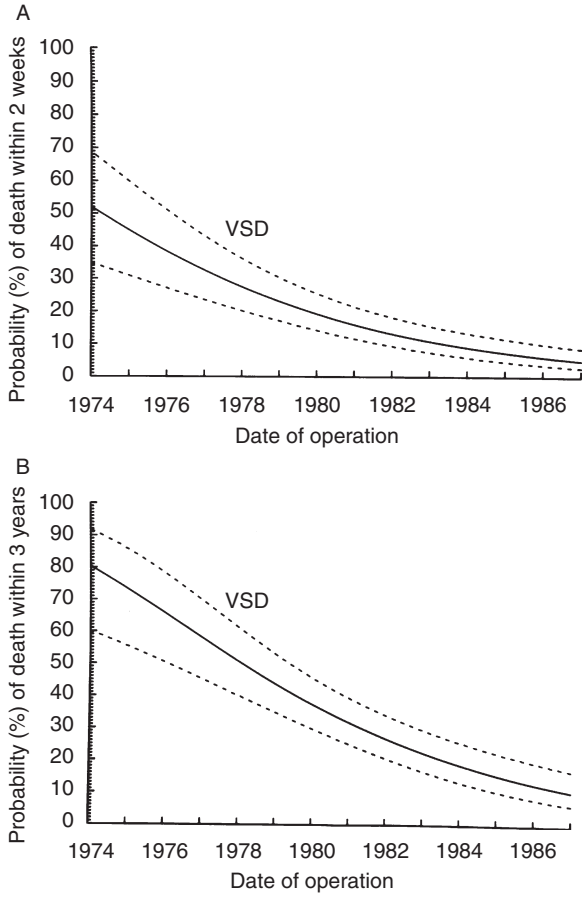

Figure 15.3 Results of surgery for interrupted aortic arch with ventricular septal defect according to year of operation at Children's Hospital, Boston, illustrating the remarkable effect of the introduction of prostaglandin E1 in the late 1970s. **A,** Probability of death within 2 weeks. **B,** Probability of death within 3 years. (VSD, ventricular septal defect.) (Reproduced with permission from Sell *et al.* [7].)

the neonate who presents in extremis and in whom invasive cardiac catheterization may be a serious additional insult. In addition to localizing the site of the interruption, the echocardiographer should provide the following information. The length of the discontinuity should be measured. The narrowest dimension of the left ventricular outflow tract (generally secondary to posterior displacement of the conal septum), the diameter of the aortic annulus, and the diameter of the ascending aorta should also be measured. It is unusual for segments of the arch that are present to be so hypoplastic that they cause hemodynamic compromise. The features of associated anomalies must be carefully defined. For example, the location of an associated VSD should be defined in relation to its margins. The conal septum is often severely hypoplastic, rendering approach to the superior margin of the defect through the tricuspid valve particularly difficult. Additional VSDs are very rare. The presence or absence of the thymus can usually be ascertained by echocardiography. An absent thymus has important implications because of its association with microdeletion of chromosome 22 and DiGeorge syndrome.

Magnetic resonance angiography is emerging as a useful adjunct to echocardiography [18]. For uncomplicated cases of IAA with VSD, it would appear to have little advantage in the unrepaired neonate over echocardiography alone [19]. However, if there are important associated anomalies or unusual features (e.g., aortic atresia with hypoplastic ascending aorta and retrograde flow through the carotid arteries to the coronary circulation from the circle of Willis), it can be helpful [20].

Hemodynamic Assessment

Because diagnosis will generally be made when ductal patency has been re-established using PGE_1, pressure data will be of little use in formulating a plan for surgical management. The question that most commonly arises is the adequacy of the left ventricular outflow tract. Attempts to quantitate the degree of obstruction by measuring a pressure gradient are hampered by lack of information regarding the amount of flow passing through this area. The VSD will usually be nonrestrictive. There is no evidence that multiple VSDs are more accurately identified by angiography than by color flow Doppler echocardiography [21].

Management of Interrupted Aortic Arch

Medical and Interventional

The introduction of PGE_1 in 1976 revolutionized the management of IAA. Before this time, which also predated the introduction of two-dimensional echocardiography, it was necessary to manage acidotic neonates symptomatically as they underwent emergency cardiac catheterization and were then rushed from the catheterization laboratory to the operating room. Not surprisingly, few actually survived this sequence.

Prostaglandin E1 must be infused through a secure intravenous line. If ductal patency does not become apparent in any neonate younger than 1 week of age within 1 hour, it should be assumed until proven otherwise that there is a technical problem with delivery of the medication into the central bloodstream. Establishing ductal patency represents just the first step in medically resuscitating the neonate with IAA. Because the lower half of the body is dependent on perfusion through the ductus, and because blood in the ductus also has the choice of passing into the pulmonary circulation, it is important that pulmonary resistance be maximized. This can be achieved by

avoiding a high level of inspired oxygen (usually room air is appropriate), as well as avoiding respiratory alkalosis caused by hyperventilation. In fact, control of ventilation is best achieved by intubating the neonate as well as sedating the child and inducing paralysis. A peak inspiratory pressure and ventilatory rate should be selected that will achieve a $pC0_2$ level of 40–50 mm. Metabolic acidosis should be aggressively treated with boluses of sodium bicarbonate, although care must be taken to avoid producing an overall alkalotic pH. Because myocardial function is likely to be depressed somewhat at the time of presentation, and it may be necessary for the heart to handle a moderate volume load (depending on the success with which pulmonary resistance is maximized), an inotropic agent such as dopamine is almost routinely employed. Dopamine has the added advantage of maximizing renal perfusion in this context of an ischemic renal insult. It is not uncommon to persist with medical resuscitation in the manner described for 1–2 days before surgery is undertaken. It should be very unusual that a child is taken to the operating room with any abnormalities of acid-base, renal, or hepatic indices [7].

Surgical Techniques: Interrupted Arch and Ventricular Septal Defect

The ideal method of surgical management has become less controversial over the last decade. There is now fairly widespread agreement that primary one-stage repair in the neonatal period is optimal management, although minor controversy persists regarding some of the details. Palliative options were commonly used in the past but are less frequently employed now as more units have become familiar with corrective neonatal surgery [22]. Noncorrective procedures include application of a pulmonary artery band during the neonatal period, with closure of the associated VSD at some time beyond infancy and usually before 5 years of age. Rather than a corrective direct anastomosis, arch continuity can be achieved by insertion of a synthetic conduit [23]. Both of these palliative options are generally undertaken working through a left thoracotomy, although some surgeons prefer to use a combined thoracotomy and sternotomy approach for placement of an ascending to descending aortic conduit. Our current preference is to undertake one-stage repair during the neonatal period including a direct aortic arch anastomosis [8].

During transport to the operating room and while preparing and positioning the child, it is important to maintain scrupulously the management principles that have been employed during the resuscitation of the child over the previous few days in the intensive care unit. In particular, a high level of inspired oxygen and hyperventilation must be avoided. In addition to the usual monitoring equipment, careful consideration must be given to monitoring arterial pressure. It is preferable to be able to measure blood pressure both above and below the forthcoming arch anastomosis. Often this is achieved by placing a right radial arterial line in addition to an umbilical arterial line. Not only does this allow one to immediately assess any pressure gradient across the anastomosis, but also the adequacy of perfusion of the separate upper and lower body circulation can be assessed during the cooling phase on cardiopulmonary bypass. Near infrared spectroscopy is also emerging as a useful technique, particularly with the application of two sensors, one for the brain and one for the lower body, either thigh or flank [24].

Approach is via a median sternotomy alone. If a thymus is present, it is largely excised. Pericardium is not usually harvested. Accurate arterial cannulation is an essential key to the success of the procedure. Although a single arterial cannula will usually ultimately achieve complete cooling, cannulation of both the ascending aorta and pulmonary artery optimize tissue perfusion, particularly of the brain and heart in the critical early phase of cooling when all organs are still warm. Generally an 8 or 6-Fr thin-walled wire-wrapped (e.g., Bio-Medicus®; Medtronic) arterial cannula is used for the ascending aorta. This cannula should be inserted on the right lateral aspect of the ascending aorta exactly opposite the anticipated location of the arch anastomosis (Figure 15.4) [4]. The tip of the cannula should not extend more than 1.5–2 mm into the lumen of the ascending aorta. This will decrease the chance that either retrograde flow to the coronary arteries or antegrade flow to the brain will be compromised. This is also an advantage of the 6-Fr cannula, although this cannula is too small to accommodate full flow in larger neonates (e.g., >3 kg) during the rewarming phase. The second arterial cannula is connected to the arterial tubing by a Y connector and is inserted in the anterior surface of the distal ductus. Because of the larger size of the main pulmonary artery relative to the ascending aorta (often 10–12 mm vs. 5–6 mm), a larger cannula (e.g., 8 Fr) can be employed. Immediately after beginning bypass, it is necessary to tie a suture ligature of 5/0 Prolene around the proximal ductus, as is done for the Norwood operation for hypoplastic left heart syndrome. Venous cannulation is routine, with a single straight cannula in the right atrium.

During cooling, the ascending aorta and its branches are thoroughly mobilized. The ductus and descending aorta are also mobilized to minimize tension on the arch anastomosis. If an aberrant right subclavian artery is present, it should be ligated and divided at its origin from the descending aorta. It is also often useful to divide the left subclavian artery in a type B interruption to further minimize anastomotic tension as well as simplifying the anastomosis, thereby decreasing the risk of bleeding and stenosis. When both rectal and tympanic temperatures are less than 18 °C, bypass is discontinued. Tourniquets are no

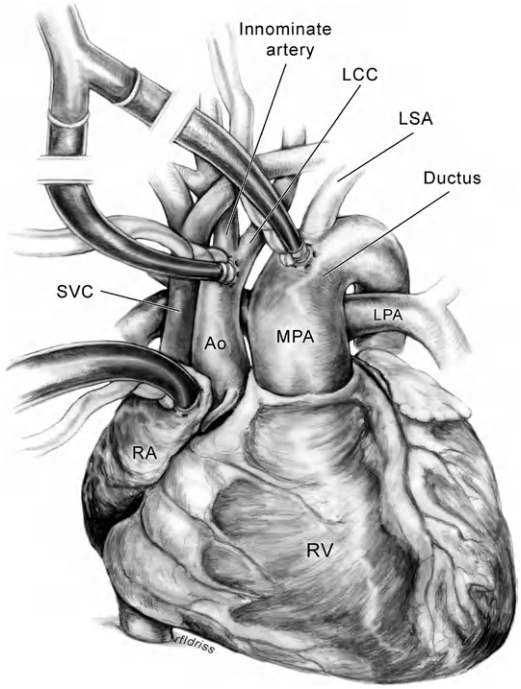

Figure 15.4 Arterial cannulation is a critically important component of the repair of interrupted aortic arch in the neonate. For type B interruption, two arterial cannulae are employed connected by a Y. Generally an 8-Fr thin-walled cannula is inserted into the small ascending aorta. The cannula should be positioned on the right side of the ascending aorta opposite the intended site of aortic anastomosis. A single venous cannula is placed in the right atrium. Either the branch pulmonary arteries are controlled with separate tourniquets or, alternatively, the second arterial cannula can be placed in the ductus and a ligature tightened around the proximal ductus immediately after commencing bypass. (Ao, aorta; LCC, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.)

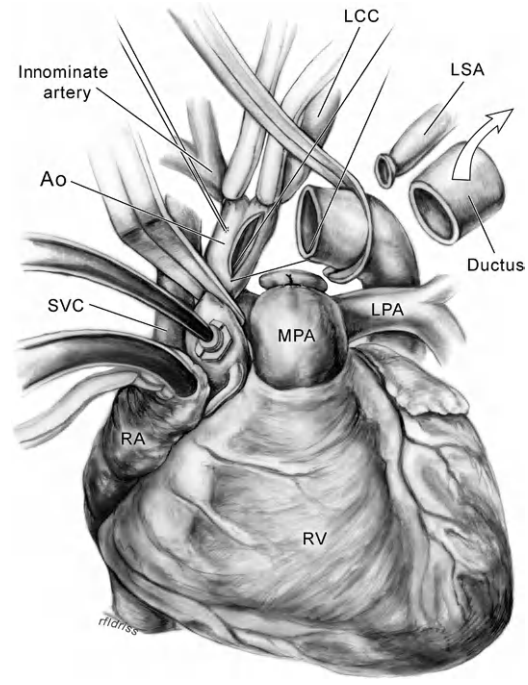

Figure 15.5 After the onset of hypothermic circulatory arrest, both arterial cannulae are removed. A cardioplegic cannula is noted with an aortic cross-clamp. The ductus is ligated proximally. Ductal tissue is excised up to the level of the descending aorta opposite the left subclavian artery. It may be helpful to divide the left subclavian artery to reduce tension on the arch anastomosis. The intended site of the anastomosis on the ascending aorta is indicated. A "C" clamp applied across the descending aorta is helpful in minimizing tension on the anastomosis as it is performed. (Ao, aorta; LCC, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.)

longer placed around the right and left common carotid arteries, as has become standard practice in adult aortic arch surgery where clamps and tourniquets are no longer used. Cardioplegia is infused through a sidearm on the ascending arterial connector, with temporary occlusion of the distal ascending aorta with forceps. Both arterial cannulae are then removed together with the venous cannula.

The ductus is ligated and divided at its junction with the descending aorta. Any residual ductal tissue is excised from the descending aorta. A C-clamp applied across the descending aorta helps to draw the ascending aorta to the level of the anastomosis, which can be performed with the opposing tissues under no tension (Figure 15.5) [4]. The anastomosis should be sited on the ascending aorta where tension will be minimized. Although many surgeons believe that this requires siting the anastomosis partially on the left common carotid artery, some generally prefer to site the anastomosis completely on the ascending aorta. The anastomosis will be exactly opposite the ascending aortic cannulation site (Figure 15.6) [4]. Continuous absorbable polydioxanone 6-0 suture may be used, although there is no evidence that use of this suture results in a lower incidence of anastomotic stenosis. Many surgeons continue to prefer polypropylene suture, either 6/0 or 7/0. Its lesser tissue drag distributes tension more evenly through the suture line, which appears to enhance hemostasis. Data from the CHSS study supports not supplementing the anastomosis with a patch of pericardium or arterial allograft tissue when associated left heart obstruction is present, although this is practiced by some. One arterial cannula (the 6 or 8-Fr cannula, depending on the child's size) is carefully reinserted in the ascending aorta only before tying the anastomotic suture line. Aortic cross-clamped brachiocephalic vessel snuggers are preferred by

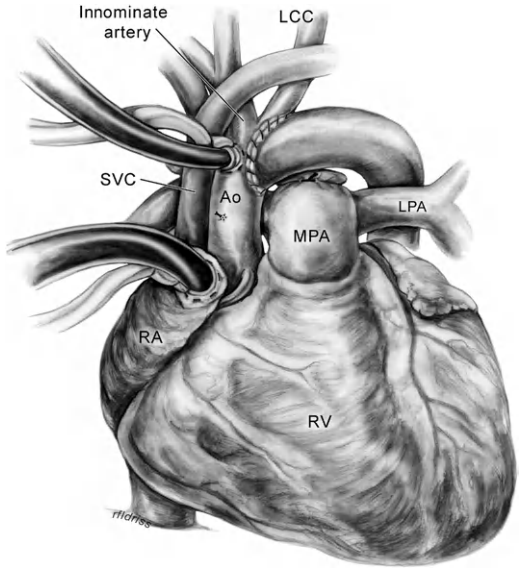

Figure 15.6 The ascending aortic cannula has been reinserted after carefully de-airing the aorta and arch vessels. A period of cold reperfusion of 5 minutes may be employed if a second period of hypothermic circulatory arrest is necessary for transatrial approach to the ventricular septal defect. However, commonly, the ventricular septal defect is approached through the main pulmonary artery, and bypass can be continued. (Ao, aorta; LCC, left common carotid artery; LPA, left pulmonary artery; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.)

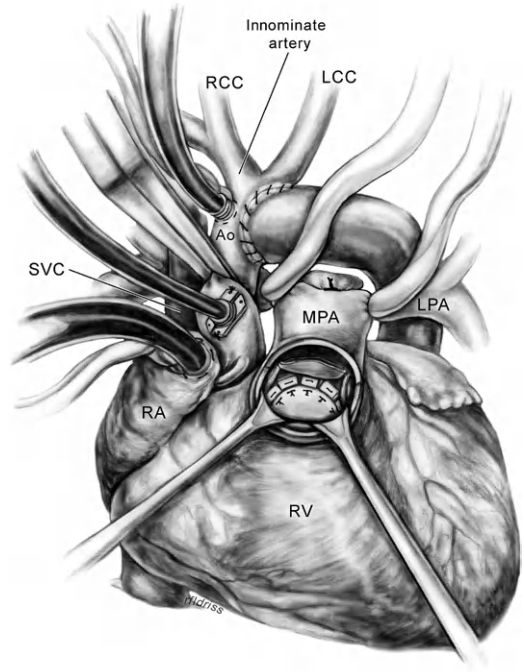

Figure 15.7 Because there is frequently severe hypoplasia of the conal septum the best approach for ventricular septal defect closure for interrupted aortic arch is often through a transverse incision in the main pulmonary artery. This can usually be performed with hypothermic bypass continuing. An aortic cross-clamp is usually applied to the ascending aorta during this period as illustrated. Vessel loops are placed to control bleeding from the left and right pulmonary arteries. (Ao, aorta; LCC, left common carotid artery; LPA, left pulmonary artery; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.)

some authors (Figure 15.5) [4]. The author generally does not apply the cross-clamp on snuggers, preferring to perform the anastomosis without the instruments in the field. Trickle flow allows air to be displaced from the arch before the suture is tied. Bypass is recommenced at a flow rate of 50 mL/kg/min. Deep hypothermia is maintained.

The approach to the VSD will depend on the preoperative echocardiographic assessment that must be carefully viewed by the surgeon preoperatively. Frequently, there will be marked hypoplasia of the conal septum. In such cases, the optimal approach for VSD closure is via a transverse incision in the proximal main pulmonary artery immediately distal to the pulmonary valve (Figure 15.7) [4]. This approach has the advantage that bypass can be maintained with a single venous cannula in the right atrium. The VSD is closed in the routine fashion for a subpulmonary VSD [25]. At the superior margin, sutures are passed through the pulmonary annulus, with the pledgets lying above the pulmonary valve leaflets. Although this has the potential to distort the pulmonary valve, thereby excluding its use for a Ross procedure, there is at least one report of a successful Ross procedure after transpulmonary approach to the VSD [26].

A preoperative decision should be made regarding the need to close an atrial septal defect, which will be present in most patients. Because of the poor left-sided compliance that is often present with IAA with VSD, even a small atrial septal defect can result in a large left-to-right shunt postoperatively. The atrial septal defect can usually be closed by direct suture, working through a short low right atriotomy during a brief second period of circulatory arrest.

Routine monitoring lines (i.e., a left atrial and right atrial line) are placed during rewarming. Separating from bypass and early postoperative management should be uncomplicated because a biventricular repair has been achieved. If problems are encountered, a residual VSD or anastomotic stenosis must be excluded. It is unusual for LVOTO to result in hemodynamic compromise early after surgery.

Selective Cerebral Perfusion

It is usually possible to complete the dissection, mobilization, and anastomosis with a circulatory arrest time of little more than 20 minutes. With modern methods of circulatory

arrest (i.e., hematocrit of at least 25, pH stat strategy, and a cooling time of at least 15–20 minutes), this is unlikely to lead to any detectable neurologic consequences. Nevertheless, many surgeons feel more comfortable and under less time pressure if they maintain flow to the brain using the technique of selective cerebral perfusion. Many different methods have been described, although probably the most popular involves direct cannulation of the innominate artery with tourniquet occlusion of the head vessels, including the innominate artery. A clamp is also required for the distal descending aorta to prevent a steal of flow from the head. One of the unresolved issues with this technique is how to decide on the optimal flow rate. Various formulas have been empirically applied, some of which include near infrared monitoring [27–29]. The only prospective randomized trial of selective cerebral perfusion failed to demonstrate any advantage over circulatory arrest, with a trend toward a worse outcome [30].

Interrupted Aortic Arch with VSD and LVOTO

Occasionally, LVOTO in the neonatal period may be sufficiently severe to justify a radical alternative primary procedure that has come to be known as the "Yasui procedure" [31]. The principle employed is analogous to the Damus-Kaye-Stansel procedure described for transposition (Figure 15.8) [6,8,31]. Left ventricular output is directed through the VSD by a baffle patch to the pulmonary artery. The main pulmonary artery is divided proximal to its bifurcation. The proximal divided main pulmonary artery is anastomosed to the side of the ascending aorta. A tube graft bridges the arch interruption itself [31]. A conduit, preferably an aortic or pulmonary homograft or, more recently, a valved cryopreserved femoral vein, is placed between the right ventricle and the distal divided main pulmonary artery. Another variation of this theme is to supply pulmonary blood flow with a shunt following the pulmonary to aortic anastomosis and arch repair [32]. This is essentially a Norwood procedure with the addition of arch repair [33]. However, since two ventricles are present, it is difficult to recommend such a palliative procedure, although satisfactory results have been reported with this approach from centers very familiar with the Norwood procedure.

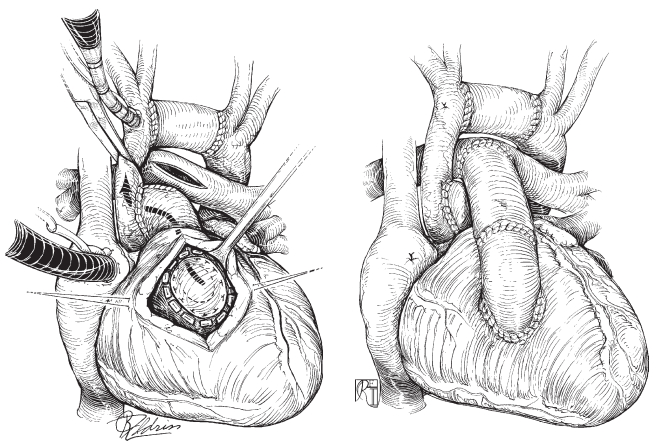

Figure 15.8 Modification of the Damus-Kaye-Stansel procedure described by Yasui *et al.* [31] for interrupted aortic arch with ventricular septal defect and very severe subaortic stenosis. This procedure carries a high mortality in the Congenital Heart Surgeons Society reports [8] and is rarely indicated.

Interrupted Arch with Other Anomalies

The general principle should be applied that if two ventricles are present, a biventricular repair incorporating growth potential should be undertaken during the neonatal period. For example, the child with transposition of the great arteries, VSD and interrupted arch should undergo an arterial switch procedure with VSD closure and direct arch anastomosis. Although this complex procedure requires a long cross-clamp time, it is generally well tolerated so long as an accurate repair is achieved [34]. Transfer of the aorta posteriorly as part of the arterial switch in fact helps to reduce tension on the arch anastomosis. Various technical modifications have been proposed [35]. Similarly, with truncus arteriosus and interrupted arch, the large size of the truncus decreases the difficulty with which aortic cannulation is achieved relative to the child with simple interrupted arch where the ascending aorta is often very hypoplastic. An analysis of the results of surgery at Children's Hospital Boston suggests that IAA is no longer a risk factor for early death after repair of truncus with IAA in the current era [36].

Management of the child with a single functional ventricle and interrupted arch remains a significant challenge, presenting many of the same problems experienced with management of hypoplastic left heart syndrome, particularly when arch interruption is combined with aortic atresia and severe hypoplasia of the ascending aorta. There is frequently important obstruction present within the single ventricle when it is associated with IAA, often in the form of an obstructive bulboventricular foramen. This must either be bypassed using a pulmonary to aortic anastomosis (Damus-Kaye-Stansel; Norwood) or must be relieved by resection of the bulboventricular foramen. Residual arch obstruction is very poorly tolerated with either a shunt dependent circulation (after a pulmonary-aortic anastomosis) or a pulmonary artery band if bulboventricular foramen enlargement is undertaken. Such obstruction will result in excessive pulmonary blood flow unless the band itself is very tight. This creates a highly unstable situation.

Postoperative Management of Interrupted Aortic Arch

After biventricular repair of simple IAA with VSD, postoperative management should be routine. Failure to progress appropriately (e.g., minimal inotropic requirement within 24–48 hours and satisfactory progress toward extubation within 2–3 days, depending largely on preoperative status) should stimulate an aggressive search for residual hemodynamic lesions. A residual VSD should be excluded by oxygen saturation data collected from the pulmonary artery line on the first postoperative morning. An anastomotic gradient should have been excluded both intraoperatively and in the early postoperative period by appropriate blood pressure determination. Echocardiography, including intraoperative transesophageal echocardiography and, if there is any doubt, cardiac catheterization, can exclude important LVOTO. A left-to-right shunt at atrial level should also be excluded. If an important residual hemodynamic lesion is identified, the child should be expeditiously returned to the operating room for correction of the problem.

Results of Surgery

Dramatic improvement in both early and late results of surgery for IAA with VSD occurred at Children's Hospital Boston between 1974 and 1987 (Figure 15.3) [6,7]. The risk of death within 2 weeks of surgery in 1974 was greater than 50%, and by 1987, the risk was less than 10%. There were many changes in the management of neonates during this timeframe that may have contributed to this improvement. Our analysis in 1988 did not conclusively demonstrate that one-stage repair during the neonatal period or that direct arch anastomosis rather than placement of a conduit contributed to the reduction in mortality. This was also the case in the analysis by the CHSS in 1994 [8], as well as a more recent report by Brown *et al.* [22]. Nevertheless, current results and recent reports from large neonatal centers have encouraged an approach of one-stage direct anastomotic repair because of the multiple psychosocial, economic, and logistical advantages [37–39]. Furthermore, the most recent analysis by the CHSS demonstrated that techniques other than direct anastomosis are associated with a higher risk of reintervention [9].

Complications of Surgery

Early

Potential technical complications have been enumerated above. In addition, bleeding can be troublesome. Bleeding is more likely if the arch anastomosis is performed under excessive tension, which will usually be the result of inadequate mobilization of the ascending and descending aorta. Extreme friability of tissue also contributes to the risk of bleeding. Friability can be associated with prematurity and can result from severe preoperative acidosis but is also apparent if ductal tissue is incorporated in the anastomosis. Including ductal tissue presumably also increases the risk of late anastomotic stenosis. As with all neonatal surgery, hemostasis must be accelerated by appropriate use of blood replacement, with fresh blood representing the optimal choice. In the absence of fresh blood, judicious but nevertheless aggressive transfusion of concentrated factors, including cryoprecipitate as well as platelet concentrates, is indicated. The selection of an appropriate perfusion hematocrit is also an important factor in achieving rapid hemostasis. Crystalloid hemodilution to 20% can result in inadequate levels of fibrinogen and other coagulation factors. Both conventional and modified ultrafiltration have roles to play in maintaining an ideal hematocrit. Aprotinin has been widely and effectively used to optimize hemostasis. However, the possibility of renal failure in adults raised the concern of the manufacturer and hospitals that this might be duplicated in neonates. New drugs are being developed to simulate the beneficial properties of aprotinin without the significant side effects. Lysine analogues, such as tranexamic acid, are less effective than aprotinin.

Both the left recurrent laryngeal and phrenic nerves are at risk during repair of IAA. Phrenic nerve injury is particularly common after placement of an ascending to descending aortic conduit, despite meticulous care of the nerve itself. It is speculated that direct compression of the nerve by the synthetic material may be the cause of this problem. Phrenic nerve palsy has been rare after direct arch anastomosis.

Late

Pressure Gradient Across Arch

Ultimately all patients who have a tube graft inserted during the neonatal period will develop obstruction (defined as a pressure gradient >30 mmHg) across the graft secondary to somatic growth alone. In addition, synthetic grafts have a variable rate of accumulation of a pseudointima that may accelerate the rate of obstruction. The actuarial freedom from tube graft obstruction in our early experience was 55% by 5 years [7]. In contrast, patients who had a direct arch anastomosis were more likely to have obstruction, with only 40% having less than a 30 mm gradient within 18 months of surgery [7]. However, balloon dilation can successfully relieve such gradients in most children who have had a direct arch anastomosis, and conduit replacement is inevitable for those with conduits. In the earlier analysis by the CHSS, the freedom from reintervention for arch obstruction was approximately

86% at 3 years for patients who had undergone a direct anastomosis, with a trend to a higher rate of reintervention for those patients who had undergone some form of arch reconstruction, including placement of a tube graft ($p = 0.15$) [8]. This also held true in the more recent analysis [9]. It is likely that the lower rate of reintervention in the more recent timeframe reflects increasing familiarity with wide mobilization of the ascending aorta, arch vessels, and the descending aorta.

LVOTO

The large CHSS experience suggested that performance of conal septal resection or performance of a pulmonary to aortic (Damus-Kaye-Stansel) anastomosis during the neonatal period carries a greater risk of early death than simple repair [8]. This is true by multivariate analysis of either the entire group or by analysis of just the subgroup with important left heart hypoplasia in addition to IAA. It is important to remember, however, that this report describes a multi-institutional experience in which there was a very wide range of patient volume and outcomes. Reports by Jacobs *et al*. [40] and Suzuki *et al.* [41] suggest that the Norwood procedure or conal septal resection can be performed with an acceptable mortality but probably should not be attempted at centers unfamiliar with these approaches. Another approach described by Luciani *et al.* [42] involves anchoring VSD sutures on the left side of the conal septum, thereby resulting in a rightward shift of the posteriorly displaced septum when the left ventricle is pressurized (Figure 15.9) [6]. There is no evidence, however, that this approach has any advantage from this perspective than the usual placement of sutures on the right side of the conal septum.

Although LVOTO is rarely sufficiently severe to justify an alteration in surgical strategy during the neonatal reparative procedure, it is by contrast not uncommon for surgical intervention to be required for LVOTO late postoperatively [10]. Among 33 patients reviewed by Sell *et al*. who underwent repair of a conoventricular VSD as the only associated anomaly with IAA, only 58% were free of evident LVOTO (defined as a gradient of greater than 40 mm) by 3 years postoperatively [7]. In the initial CHSS report, 77% were free from reintervention at 3 years. Since the morphology of LVOTO with IAA is variable, surgical management for LVOTO beyond the neonatal period will vary according to the specific circumstances. In some cases, it is possible to resect the posteriorly deviated conal septum working through the aortic valve. An aortic valvotomy may also be required if there is valvar stenosis. If there is tunnel subaortic stenosis, we perform a modified Konno procedure (i.e., ventricular septoplasty) [43]. Working through a right ventricular infundibular incision, an incision is made in the ventricular septum into the left ventricular outflow tract. The incision is carried up to the aortic valve. A patch is placed on the right ventricular aspect of the surgically created VSD. If there is also aortic annular hypoplasia as well as tunnel subaortic stenosis, our current approach is to perform a Ross/Konno procedure (i.e., placement of a pulmonary autograft in the aortic position with an anterior incision into the ventricular septum). Alternative procedures used in the past include the Konno procedure and left ventricular apical to descending aortic conduit [44]. There is little place for the latter procedure today.

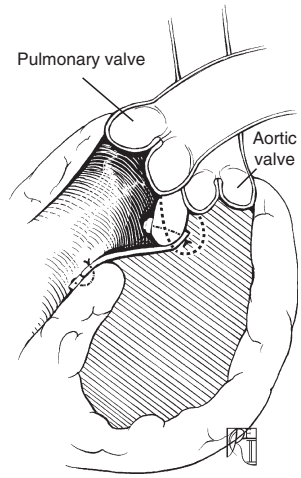

Figure 15.9 Technique of one-stage repair of interrupted aortic arch with ventricular septal defect and posteriorly malaligned conal septum. The technique involves (1) tailoring the patch to the shape of the ventricular septal defect but downsizing its area to avoid bulging toward the left ventricular outflow tract, and (2) positioning the stitches relative to the apical portion of the ventricular septal defect patch on the left side of the conal septum to promote deflection of the displaced septum (dashed line) away from the left ventricular outflow tract.

DiGeorge Syndrome

Absence or severe hypoplasia of the thymus was commonly seen in the Children's Hospital Boston series with IAA but was limited to patients with type B interruption [7]. Comprehensive testing of lymphocyte function was undertaken in only a small number of patients so that no concrete inferences can be drawn regarding the incidence of the complete syndrome. Although a large calcium requirement is often seen during the early postoperative period, it is rarely necessary for children to leave the hospital receiving oral calcium supplements (fortunately, because these are often poorly tolerated). Occasionally vitamin D supplements are useful to maintain serum calcium levels during the first few postoperative weeks. We are not aware that serious problems with immune function have been encountered among long-term survivors of IAA surgery. The association of IAA with microdeletion of chro-

mosome 22 should be tested by fluorescence in situ hybridization (FISH) analysis. There are important implications for the developmental potential with respect to both cognitive and motor abilities of affected children [45].

Left Bronchial Obstruction

The left main bronchus usually passes under the arch of the aorta. If a direct anastomosis is performed without adequate mobilization, a bowstring effect over the left main bronchus may result. This will cause air trapping in the left lung with hyperexpansion seen on plain chest X-ray. The diagnosis can be confirmed by bronchoscopy together with computed tomography scan or magnetic resonance imaging. Surgical management may entail placement of an ascending to descending aortic conduit after division of the arch. With adequate initial mobilization of the ascending and descending aorta, this should almost never be necessary.

Conclusion

Prostaglandin E1 revolutionized the management of IAA in the late 1970s. Complete resuscitation should proceed over several days, if necessary, before surgery is undertaken. One-stage primary neonatal repair with direct arch anastomosis and VSD closure is the preferred surgical approach. Selective cerebral perfusion with near infrared monitoring is being used with increasing frequency. Although repair of interrupted arch is physiologically corrective, it should not be viewed as fully corrective because of the high incidence of important LVOTO. This may respond to a simple surgical reintervention such as subaortic resection, but in some cases an extensive procedure to enlarge the left ventricular outflow tract will be necessary. However, procedures directed against subaortic stenosis should rarely, if ever, be employed as part of the initial surgical management during the neonatal period.

CHAPTER 16

Atrial Septal Defect, Partial Anomalous Pulmonary Venous Connection, and Scimitar Syndrome

Carl L. Backer[1] and Constantine Mavroudis[2]

[1]Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Chicago, IL, USA
[2]Florida Hospital for Children, Orlando, FL, USA

An atrial septal defect (ASD) is defined as an opening, or hole, in the interatrial septum. Ostium secundum ASD is one of the most common congenital heart defects to occur as an isolated lesion. ASD occurs in 1 in every 1500 births and represents 6–10% of all congenital heart defects. ASD is more frequent in females, by a 2:1 ratio. Surgical closure of an ASD was first performed in 1952 by F. John Lewis [1,2] at the University of Minnesota using hypothermia and inflow occlusion. Atrial septal defect was also the first congenital cardiac defect to be repaired using cardiopulmonary bypass. On May 6, 1953 John Gibbon [3] used the pump oxygenator that he had developed in his laboratory to close an atrial septal defect. Atrial septal defect was also the first intracardiac lesion to be successfully treated using percutaneous transcatheter techniques [4]. In fact, with advances in technology and the evolution of transcatheter techniques, the majority of ostium secundum ASDs are now closed in the catheterization laboratory rather than in the operating room.

Anatomy and Pathology

The normal intraatrial anatomy as viewed through the opened right atrium is illustrated in Figure 16.1 [5]. The normal atrial septum is made up of two components, the septum secundum and the septum primum. The septum secundum is the thick, rounded superior portion derived from the infolded atrial roof. The septum primum is the lower portion of the atrial septum and is usually a relatively thin flap. The septum primum extends superiorly and to the left of the limbus of the septum secundum, so that it will close the foramen ovale as a flap valve. Normally, the left atrial pressure exceeds right atrial (RA) pressure and causes physiologic closure of this opening over time. The foramen ovale, of course, is necessary for the shunting of blood *in utero* from the right to the left atrium when the lungs are not functioning. The other significant anatomic structures within the right atrium are the orifice of the coronary sinus and the eustachian valve, guarding the orifice of the inferior vena cava. The crista terminalis is a thickened portion of infolding of the lateral right atrial wall running from superior to inferior.

There are three main types of ASDs, the ostium secundum (80%), sinus venosus (10%), and ostium primum (10%) type defects. Because it is a phenotypic variation of an atrioventricular septal defect (AVSD), the label "ostium primum" should probably be replaced by "partial AVSD" or "partial AV canal." In the Congenital Heart Surgery Nomenclature and Database Project [6], three other types of ASDs were identified. These included the common atrium (single atrium), coronary sinus type (unroofed coronary sinus), and patent foramen ovale. An atrial septal defect can coexist with multiple other anomalies, both simple and complex.

Ostium Secundum Atrial Septal Defect

As illustrated in Figure 16.2 [5], this is an ASD confined to the region of the fossa ovalis. The etiology is a deficiency of the septum primum. The resulting defect varies in size from a small pinhole to a large opening with essentially no inferior rim.

Sinus Venosus Atrial Septal Defect

Sinus venosus defects occur most commonly at the junction between the superior vena cava and the right atrium (Figure 16.3) [5]. They are posterior in the atrial septum and cranial to the superior limbic band. They are almost always associated with anomalous drainage of the right superior pulmonary vein. This vein (veins) tends to enter at the junction of the superior vena cava and right atrium, along the rightward margin of the ASD, as illustrated in Figure 16.3B [5]. Sometimes these veins drain directly into the superior vena cava, adjacent to the entrance of the azygos vein (Figure 16.3A) [5]. Rarely, sinus venosus defects occur adjacent to the inferior vena cava orifice, and the anomalous vein is the right inferior pulmonary vein. This defect is an anomalous venoatrial communication rather than an actual atrial septal defect, but results in a left-to-right shunt of blood at the atrial level. The defect is produced by anomalous pulmonary venous connections to the inferior vena cava with retention of the pulmonary venous connection

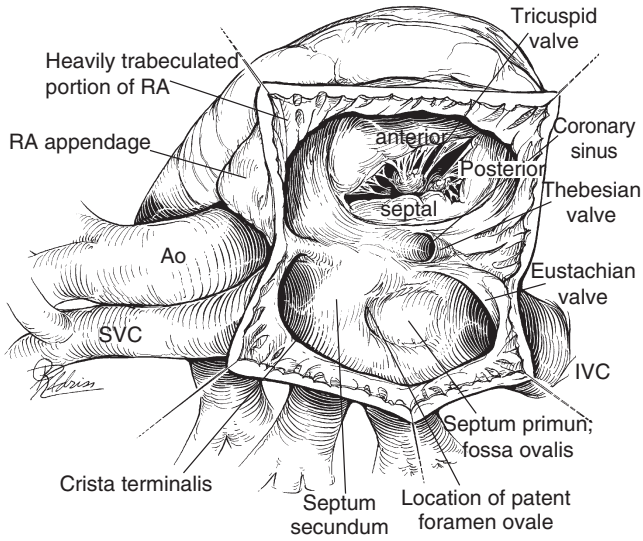

Figure 16.1 Normal intraatrial anatomy as viewed through the opened right atrium. (Ao, aorta; IVC, SVC, inferior, superior vena cava; RA, right atrium.)

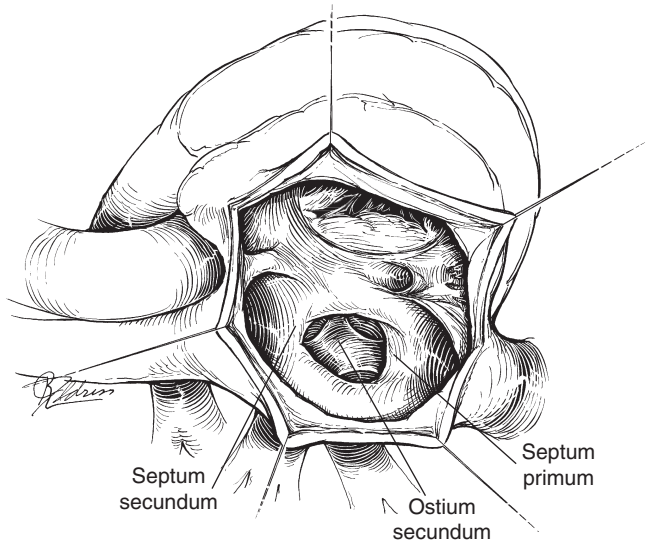

Figure 16.2 Ostium secundum atrial septal defect. This is the most common type of atrial septal defect, created by a deficiency in the septum primum.

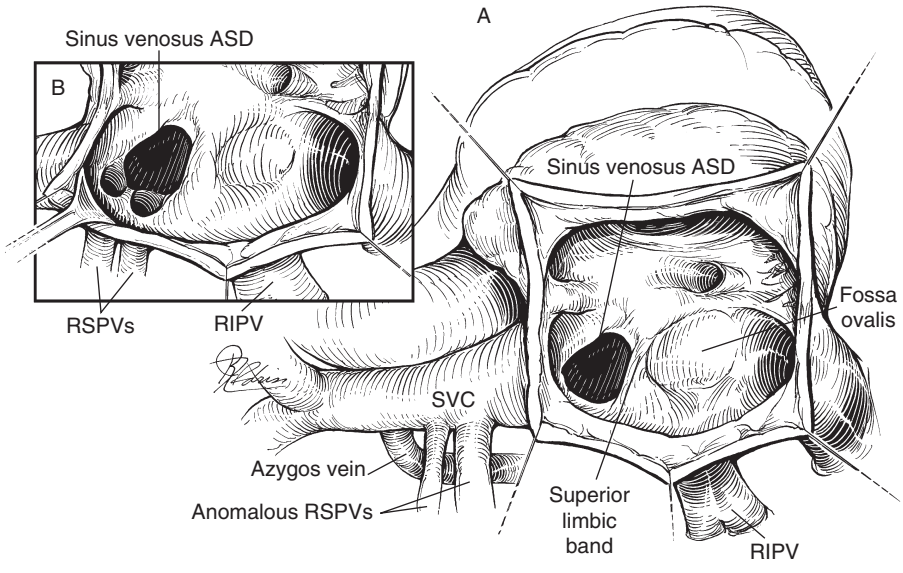

Figure 16.3 Sinus venosus ASD. **A,** The opening between the superior vena cava orifice and the superior limbic band is illustrated, with anomalous drainage of the right superior pulmonary veins directly to the superior vena cava, adjacent to the azygos vein. **B,** Another variant of sinus venosus defect is illustrated, showing the right superior pulmonary veins draining to the confluence of the superior vena cava and right atrium. (ASD, atrial septal defect; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein; SVC, superior vena cava.)

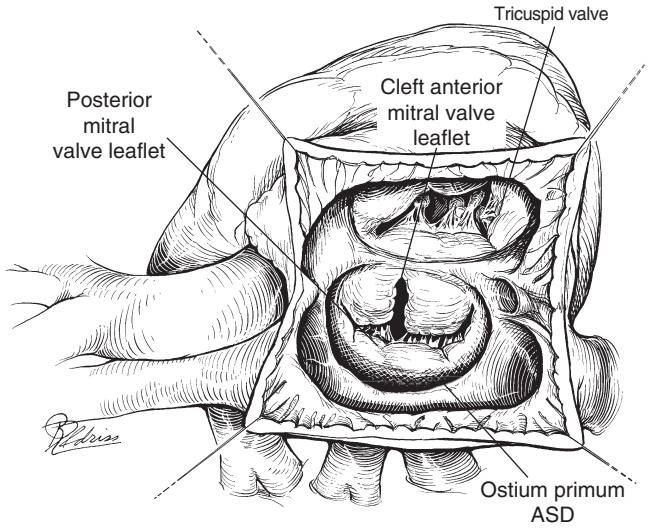

Figure 16.4 Partial atrioventricular canal defect or partial atrioventricular septal defect. These patients commonly have a cleft in the anterior leaflet of the mitral valve, as illustrated. (ASD, atrial septal defect.)

to the left atrium [7]. Anomalous drainage of the pulmonary veins to the right atrium can occur *without* an ASD.

Partial Atrioventricular Septal Defect

A partial atrioventricular septal defect (AVSD) defect is a crescent-shaped defect in the inferior portion of the atrial septum immediately adjacent to the atrioventricular valves (Figure 16.4) [5]. This was previously called an ostium primum ASD which is somewhat of a misnomer as it has nothing to do with the septum primum. Patients with a partial AVSD frequently have a cleft in the anterior leaflet of the mitral valve that may cause mitral valve insufficiency.

Common Atrium

Occasionally, the entire atrial septum will fail to develop and this will result in a "common atrium," or "single atrium." This is frequently found in patients with heterotaxy syndromes.

Patent Foramen Ovale

A patent foramen ovale is a small interatrial communication between the septum secundum and septum primum that is characterized by no deficiency of the septum primum and a normal limbus with no deficiency of the septum secundum. The flap of the patent foramen ovale is normally kept closed by the higher left atrial pressure. A true patent foramen ovale opens only when the right-sided pressure increases above that of the left, i.e., during coughing or Valsalva maneuver.

Unroofed Coronary Sinus

The coronary sinus is the confluence of the coronary veins draining the heart itself. A communication directly between the tube-like structure of the coronary sinus and the left atrium is called a coronary sinus ASD. This allows blood to shunt in an indirect fashion from the left atrium through the coronary sinus defect out of the actual coronary sinus and into the right atrium. Although there is no opening in the interatrial septum per se, the coronary sinus defect allows blood at the atrial level to shunt from left to right, physiologically exactly like an ASD that is a true opening in the atrial septum. These patients frequently have a left superior vena cava draining to the coronary sinus and that finding should be used as a "tip-off" to look for this defect. In some instances, the left superior vena cava may drain directly to the left atrium, which then causes an obligatory right-to-left shunt and cyanosis.

Pathophysiology and Natural History

The degree of left-to-right shunting at the atrial level is determined by the size of the ASD and the right and left ventricular compliance. Normally, the compliance of the left ventricle is less than that of the right ventricle, therefore there is a left-to-right shunt. This leads to right ventricular dilatation and excessive pulmonary blood flow. Patients with a large ASD can have a Qp/Qs ratio of greater than 4:1. There are very rare anatomic variations reported where a large persistent eustachian valve actually directs inferior vena caval blood flow through the ASD into the left atrium. These patients would then present with cyanosis. Patients with an unroofed coronary sinus and a left superior vena cava may also present with cyanosis. Finally, patients with a common atrium may have enough interatrial mixing of pulmonary and systemic venous return to cause a mild degree of cyanosis.

The natural history of an ASD has been determined by retrospective studies on patients who were not surgically repaired prior to the availability of surgical closure of ASDs. These patients are known to be at risk of atrial arrhythmias (most commonly, atrial flutter and atrial fibrillation), right ventricular dysfunction, pulmonary hypertension, paradoxical emboli, and eventual congestive heart failure. Without surgical intervention, the mean age of death in patients with a significant ASD is 36 years of age [8]. In young children, atrial septal defects larger than 8–10 mm in diameter are very unlikely to undergo spontaneous closure; defects smaller than 4–5 mm are

reported to commonly undergo spontaneous closure [9,10]. Spontaneous closure occurring after the age of 4 years is very rare [11]. Bacterial endocarditis does not occur in patients with ostium secundum ASD unless they have an associated cardiovascular lesion. Of note, the existence of an isolated ASD is not an indication for prophylaxis of endocarditis, as per the American Heart Association guidelines [12].

Patients with an uncomplicated ASD typically do not have symptoms and present only with an audible murmur. The murmur typically has two components, a fixed split second heart sound related to the prolonged time period for flow of blood through the right side of the heart and delay of the pulmonary valve closure, and a systolic murmur of relative (physiologic) pulmonary stenosis. Patients with a large ASD may have a diastolic rumble secondary to relative (physiologic) tricuspid stenosis. The volume overload of the right ventricle and the pulmonary vascular bed is usually well tolerated for many years. There are only rare infants who develop congestive heart failure secondary to an uncomplicated atrial septal defect. The chance of developing obstructive pulmonary vascular disease is much less than for patients with ventricular septal defects or atrioventricular septal defects, however, it can occur in ASD patients. In a review of 169 adult patients with an ASD, pulmonary hypertension (defined as mean pulmonary artery pressure >30 mmHg) occurred in 10–25% of adults with an ASD and elevated pulmonary vascular resistance occurred in 5–15% of adults with an ASD [13]. Pulmonary hypertension was more common in adults with a sinus venosus ASD (16% of 31 patients) as compared to an ostium secundum ASD (4% of 138 patients). In these patients, the pulmonary vascular resistance may increase to a point where it is greater than the systemic vascular resistance. The intracardiac shunt will reverse (instead of left-to-right, right-to-left shunting occurs), and at that time surgical closure will be contraindicated [14]. The most common cause of late mortality in ASD patients is congestive heart failure and arrhythmias, which increase in frequency as the patient ages and in rough proportion to the shunt magnitude. In Murphy's review [15] of 123 patients undergoing repair of an ASD at the Mayo Clinic, the incidence of late atrial fibrillation was 4% if the ASD was closed before the age of 11, versus 55% if the ASD was closed after the age of 41.

Because of the known eventual complications of atrial arrhythmias, right ventricular dysfunction, and pulmonary hypertension, resulting in a dramatic reduction in life expectancy from congestive heart failure, closure of ASD is recommended. This can now be accomplished either with surgical or transcatheter techniques. Closure of an uncomplicated ASD is recommended in any patient with physical signs of an ASD or catheterization or echocardiographic evidence of a left-to-right shunt exceeding 1.5:1. In general, patients with a significant ASD do not have a shunt less than 1.5:1 if they have physical findings of a significant systolic murmur and a fixed split second heart sound. In our series of 271 patients operated on between 1990 and 2009 at Children's Memorial Hospital for an ostium secundum defect, the median age at ASD closure was 3.3 years. Most centers prefer to electively close an ostium secundum ASD before a child starts school.

Diagnosis

Physical examination of a patient with an ASD typically reveals a fixed split second heart sound and a systolic murmur of relative physiologic pulmonary stenosis. There may also be a diastolic murmur or rumble of relative (physiologic) tricuspid stenosis. Chest X-ray evaluation will show cardiomegaly. When there is significantly increased pulmonary blood flow, there may be a bulging pulmonary artery at the upper left cardiac border. Electrocardiogram will demonstrate right ventricular hypertrophy. Typically, there is an rSr′ or rsR′ pattern in lead V_1 and right axis deviation. Of note, the appearance of left axis deviation on the electrocardiogram should alert the surgeon to the possible presence of a partial AVSD type of defect.

The most common and widely used diagnostic technique to definitively arrive at the diagnosis of ASD is two-dimensional echocardiography with color Doppler interrogation. The echocardiogram will visualize the defect in the atrial septum, estimate its size, and determine the location of the pulmonary veins. For patients with a partial AVSD, the degree of mitral insufficiency and evaluation of the mitral valve cleft can be obtained with color Doppler examination. In our series of patients with an ASD, less than 10% of the patients underwent cardiac catheterization and this percentage has dropped as the accuracy of echocardiographic techniques has improved. Cardiac catheterization is now only indicated when the diagnosis is uncertain or associated anomalies are suspected. Cardiac catheterization will reveal, on blood gas analysis, an oxygen step-up from the right atrium onward with a pulmonary blood flow typically two to four times the systemic flow. Quite commonly, there can be a gradient of 10–30 mmHg across the pulmonary valve because of the increased flow of blood through the right side. Pulmonary artery pressures are frequently normal unless pulmonary vascular obstructive disease has developed, usually only in older patients (over 20 years of age). Cardiac catheterization, computed tomographic (CT) scan, and magnetic resonance imaging (MRI) can be used to localize the pulmonary veins and rule out partial anomalous pulmonary venous connection if the veins are unable to be visualized with echocardiography. A left superior vena cava will be present in approximately 2% of patients with an ASD.

Transcatheter Closure

In the current era, transcatheter closure has evolved [4,16] and is now commonly used for many patients with ostium secundum ASDs that have an adequate rim for anchoring the device. There are currently two different FDA-approved devices available: the Amplatzer® device (AGA Medical Corp., Golden Valley, MN) [17–19] and the HELEX device (W.L..Gore and Associates, Flagstaff, AZ) [20]. These devices are currently used only for ostium secundum ASDs. These devices are not indicated for closure of a sinus venosus defect with anomalous drainage of the right superior pulmonary vein because of the potential for creation of superior vena caval or right superior pulmonary vein stenosis; or for partial AVSDs where the device would interfere with mitral and tricuspid valve function. As experience with these devices has been obtained, the incidence of complete closure has improved and the incidence of complications, such as device malposition or migration, has decreased significantly. Currently at Children's Memorial Hospital over 90% of ostium secundum ASDs are closed with the Amplatzer® device (Figure 16.5) [21]. The most common reason for referral of a patient with an ostium secundum ASD for surgery is that there is no inferior rim to anchor the device. Fischer reported that in 236 patients with an ostium secundum ASD 18 patients (8%) were not suitable for device closure because of anatomic issues determined in the catheterization lab [18]. At Children's Memorial Hospital, out of 143 patients undergoing attempted device closure, 11 (8%) were referred for surgery because a device could not be safely positioned.

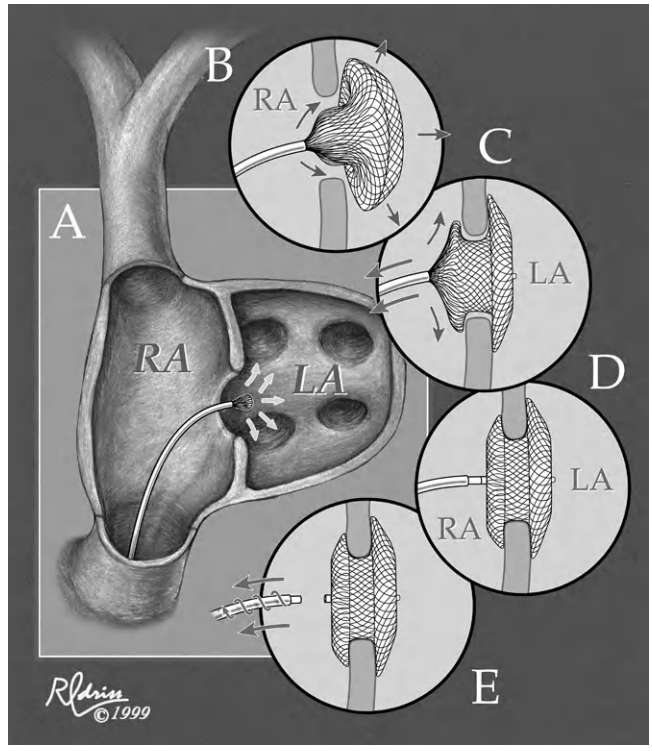

Figure 16.5 Implantation of the Amplatzer ASD occluder. **A,** The delivery catheter is positioned across the atrial defect. **B,** The left atrial disc with the self-centering connecting stalk is delivered. **C,** The device is withdrawn so that the connecting stalk is within the ASD and the left disc is firm against the atrial septum. **D,** The right atrial disc is delivered. **E,** The delivery cable is disconnected from the device. Until the delivery cable is disconnected, the device can be withdrawn back into the catheter and removed from the body. (LA, RA, left, right atrium.) (Reproduced with permission from Wax [21].)

Surgical Technique

Our preferred surgical technique for ASD closure is through a median sternotomy approach. Over the years, the length of the median sternotomy incision for ASD has steadily shortened, and many centers now close ASDs without opening the entire sternum [22–24]. This allows for a cosmetic closure, especially for females. An alternative technique is the right thoracotomy [25]. We have not used this approach because of the increased risk of air embolus and reports of right phrenic nerve injury [26]. The median sternotomy incision in particular permits repair of associated intracardiac lesions should they be discovered at the time of surgery. We currently use transesophageal echocardiography (TEE) in all ASD cases to confirm the diagnosis, to assess the pulmonary veins, and to confirm complete closure at the end of the case. In most cases, the thymus can be divided in the midline and resection of the thymus is not necessary. Our preferred closure technique has been to use an autologous pericardial patch. This patch is harvested at the beginning of the operation with stay sutures to retract the corners and placed in a sterile Petri dish filled with saline. We do not "tan" this patch with glutaraldehyde. Cardiopulmonary bypass is initiated with an aortic cannula and two venous cannulas. For an ostium secundum defect, the right atrial appendage can be cannulated first. This cannula is later advanced into the superior vena cava. The inferior vena cava should be cannulated at the junction with the right atrium, low enough so that if there is no inferior rim to the ASD adequate exposure in this area can still be obtained. A different cannulation strategy is used for sinus venosus ASD. The superior vena cava should be cannulated directly with a right-angled cannula superior to the azygous vein. Our preference for ASD closure has been to cool to 32 °C. We do not use a vent for ostium secundum or sinus venosus ASDs. In both defects, the left side is effectively decompressed through the ASD. We do use a vent for patients with a partial AVSD.

Following the initiation of cardiopulmonary bypass and the placement of caval tapes around the superior and inferior venae cavae, cold blood cardioplegia is administered

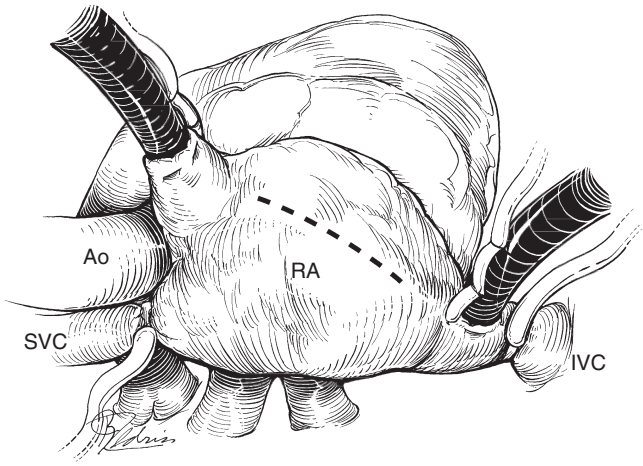

Figure 16.6 Operative closure of an ostium secundum ASD. This patient has been placed on cardiopulmonary bypass with bicaval cannulation. Dotted line indicates incision site in the right atrium. Aortic cannula is not shown. (Ao, aorta; IVC, SVC, inferior, superior vena cava; RA, right atrium.)

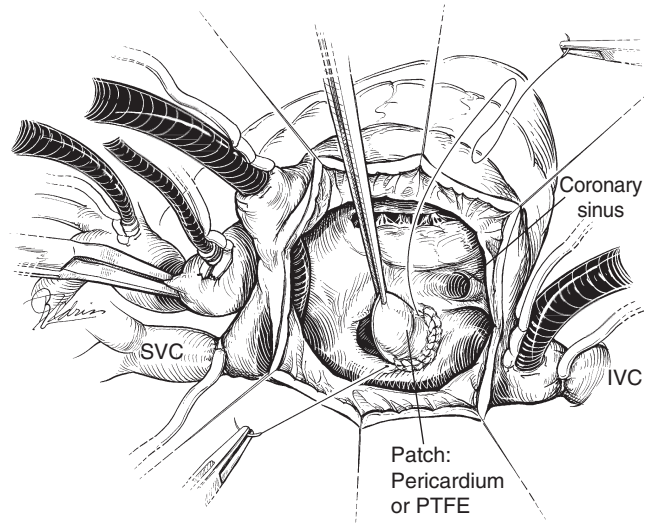

Figure 16.7 Closure of an ostium secundum atrial septal defect with a patch. Cardioplegia has been delivered and the heart arrested. The right atrium has been opened. The ASD is being closed with a patch – usually of autologous pericardium, although PTFE (polytetrafluoroethylene) may also be used. (IVC, SVC, inferior, superior vena cava.)

through the ascending aorta. Once the cardioplegia is begun, the caval tapes are deployed and the right atrium is opened. Our incision for an ostium secundum ASD is an oblique incision that is carried from the right atrial appendage in the direction of the inferior vena caval cannula (Figure 16.6) [5]. An attempt is made not to cross the crista terminalis, to preserve all possible conduction fibers from the sinoatrial node to the atrioventricular node. For sinus venosus ASDs, the incision in the right atrium is different, and is carried from the tip of the right atrial appendage in the direction of the superior vena cava–right atrial junction. The incision stops short of the crista terminalis and we do not cut across the cavoatrial junction. Superior retraction on the atrial wall nicely exposes the superior vena cava–right atrial junction.

For closure of an ostium secundum defect, the opening in the atrial septum is easily visualized through the opened right atrium (Figure 16.7) [5]. The cardiotomy sucker is used to control the blood coming up through the opening of the atrial septal defect from the left atrium. Excessive amounts of blood coming up from the left atrium should make the surgeon consider the possibility of a patent ductus arteriosus or relatively high cardiopulmonary bypass pump flow. Care is taken not to suction the left atrium empty; this prevents air from going across the mitral valve into the left ventricle. In cases where there is a question about pulmonary venous drainage, of course the atrium can be emptied of blood, but additional care must be taken at the conclusion of the operation to remove the air from the left side. The autologous pericardial patch is brought onto the field. In most cases, a 5-0 polypropylene suture is sufficient to anchor this patch to the edges of the ASD. This suture is started at the inferior aspect of the defect, adjacent to the inferior vena cava. At this point, care must be taken to assure that the eustachian valve is not mistaken for the edge of the ASD. Suturing the eustachian valve to the septum secundum would create an obligatory shunt of the inferior vena cava blood into the left atrium; the patient would be cyanotic following the procedure [27]. The suturing of the patch is carried superiorly along the edge of the ASD, first adjacent to the crista terminalis and then adjacent to the coronary sinus. In the area of the coronary sinus some care must be taken not to take deep bites or grasp the area with pickups to avoid injury to the atrioventricular node. The suturing is completed superiorly, which is the "highest" point of the left and right atrial junction. When the suturing has been completed, but prior to tying the knot, an opening is created at the junction between the patch and the ASD and a Valsalva maneuver is performed by the anesthesiologist. This effectively pushes blood and air from the left atrium and pulmonary veins up through the opening in the patch. Usually there is an initial bubbling of air as the left side is de-aired, then followed solely by blood with no air. During the Valsalva maneuver, the suture is pulled tight and the knot is tied. The initial Valsalva maneuver is then relaxed, and then a second Valsalva maneuver is performed to test the suture line for leaks. Leaks will be seen as blood from the left atrium being forced out between the edges of the patch and the ASD. At

this point the left side of the heart can be decompressed by venting through the cardioplegia needle site. Care must be taken not to vent too strongly and pull air into the left side of the system. The right atrial incision is then closed. The right side is also de-aired prior to releasing the cross clamp. During the suturing of the right atrium, the patient can be rewarmed.

Air embolism is one of the most feared possible complications of ASD closure. The left side of the heart has been open to air and the atmosphere during the repair period. Besides the maneuvers mentioned above, de-airing is performed by aspirating the cardioplegia needle site while gently massaging the left ventricle and left atrium, after the right atrial incision is closed. In addition, another Valsalva maneuver can be performed to push blood through the left side and out of the cardioplegia needle, along with any residual air. The aortic cross-clamp is then removed, applying suction to the ascending aorta at the time the cross-clamp is removed. Transesophageal echocardiography can be used to assess for air in the cardiac chambers during the weaning process from cardiopulmonary bypass. A vent tubing can be attached to the cardioplegia needle site to aspirate any air that might come up from the pulmonary veins or left atrium during the weaning from cardiopulmonary bypass. Warming is completed and the patient is ventilated and weaned from cardiopulmonary bypass. In most cases at Children's Memorial Hospital ASD patients are weaned from cardiopulmonary bypass with intravenous milrinone and low-dose dopamine. The venous cannulas are removed and we perform modified ultrafiltration (MUF) for 10 minutes. The use of MUF has been shown to decrease the need for blood transfusion in patients undergoing ASD closure [28]. The heparin is reversed with protamine, the aortic cannula is removed, and the patient is closed in the usual fashion. We do not place pacemaker wires at the conclusion of an ostium secundum defect repair. These patients are frequently able to be extubated in the operating room or shortly thereafter and usually spend only 24 hours in the intensive care unit.

Alternative techniques of closure for an ostium secundum ASD include direct suturing of the edges of the defect and the use of a polytetrafluoroethylene patch. We have preferred not to use a Dacron patch because the Dacron in some cases does not become completely endotheliazed. If there should be any mitral valve insufficiency, the jet of mitral insufficiency striking the patch can place the patient at risk for hemolysis. In our series of patients, we have previously used direct suturing in approximately 50% of the patients. In the current era, however, we use a patch in nearly all cases because the only referrals for ASD closure are those with large holes not amenable to device closure. The direct suture closure of an atrial septal defect is done with two layers of running 5-0 polypropylene suture. Several reviews [29,30] have shown that the incidence of ASD recurrence may be reduced when a patch is employed, presumably because there is less tension on the suture line. However, if there is adequate useful septum primum tissue, we feel that successful suture closure can nearly always be accomplished.

Sinus venosus defects always require closure with a patch because of their location at the junction between the superior vena cava and the right atrium. Direct suture closure can lead to right superior pulmonary vein or superior vena caval stenosis (or both). We use transesophageal echocardiography for all sinus venosus defects. The preoperative study is useful for assessing the drainage point of the right pulmonary veins. At the conclusion of the procedure one can look for residual atrial level shunting, pulmonary vein stenosis, and superior vena cava stenosis. Another goal is to preserve sinus rhythm, which is complicated by the close proximity of the sinoatrial node. Another anatomic structure at risk is the right phrenic nerve, located on the other side of the pericardium immediately adjacent to the right lateral aspect of the superior vena cava. Great care in dissection of the superior vena cava is required in this area to prevent phrenic nerve injury with resultant diaphragm paralysis.

Between 20% and 45% of sinus venosus ASDs can be closed by a simple autologous intracardiac pericardial patch (Figure 16.8) [5, 31,32]. The suture line is started between the orifice of the right superior pulmonary vein and the orifice of the superior vena cava. Once the suturing has been completed in the superior aspect, it simply is carried around the remaining orifice of the ASD. At the posterior aspect of the junction of the superior vena cava and the right atrium, suturing should be relatively superficial to avoid injuring the sinoatrial node by deep bites into the atrial septum and junction with the superior vena cava. If the atrial septal defect requires enlargement to allow an adequate channel to the left atrium for the anomalous pulmonary veins, this is performed by making an incision towards the fossa ovalis and resecting a portion of the limbus of the septum secundum. Very rarely, partial anomalous pulmonary venous return of the right upper lobe or the right upper and middle lobes will occur to the superior vena cava–right atrial junction without an ASD. In these patients, an opening must be created in the atrial septum so that the pulmonary veins can be diverted into the left atrium underneath the pericardial baffle.

When the anomalous pulmonary veins enter the high superior vena cava, an alternative technique to the single patch must be used. In the past we used a "two-patch" technique where the cavoatrial junction was incised and a second pericardial patch was placed to augment the superior vena cava. Because of a high incidence of sinus node dysfunction with that technique, we have abandoned it and now use the "Warden" procedure for these patients

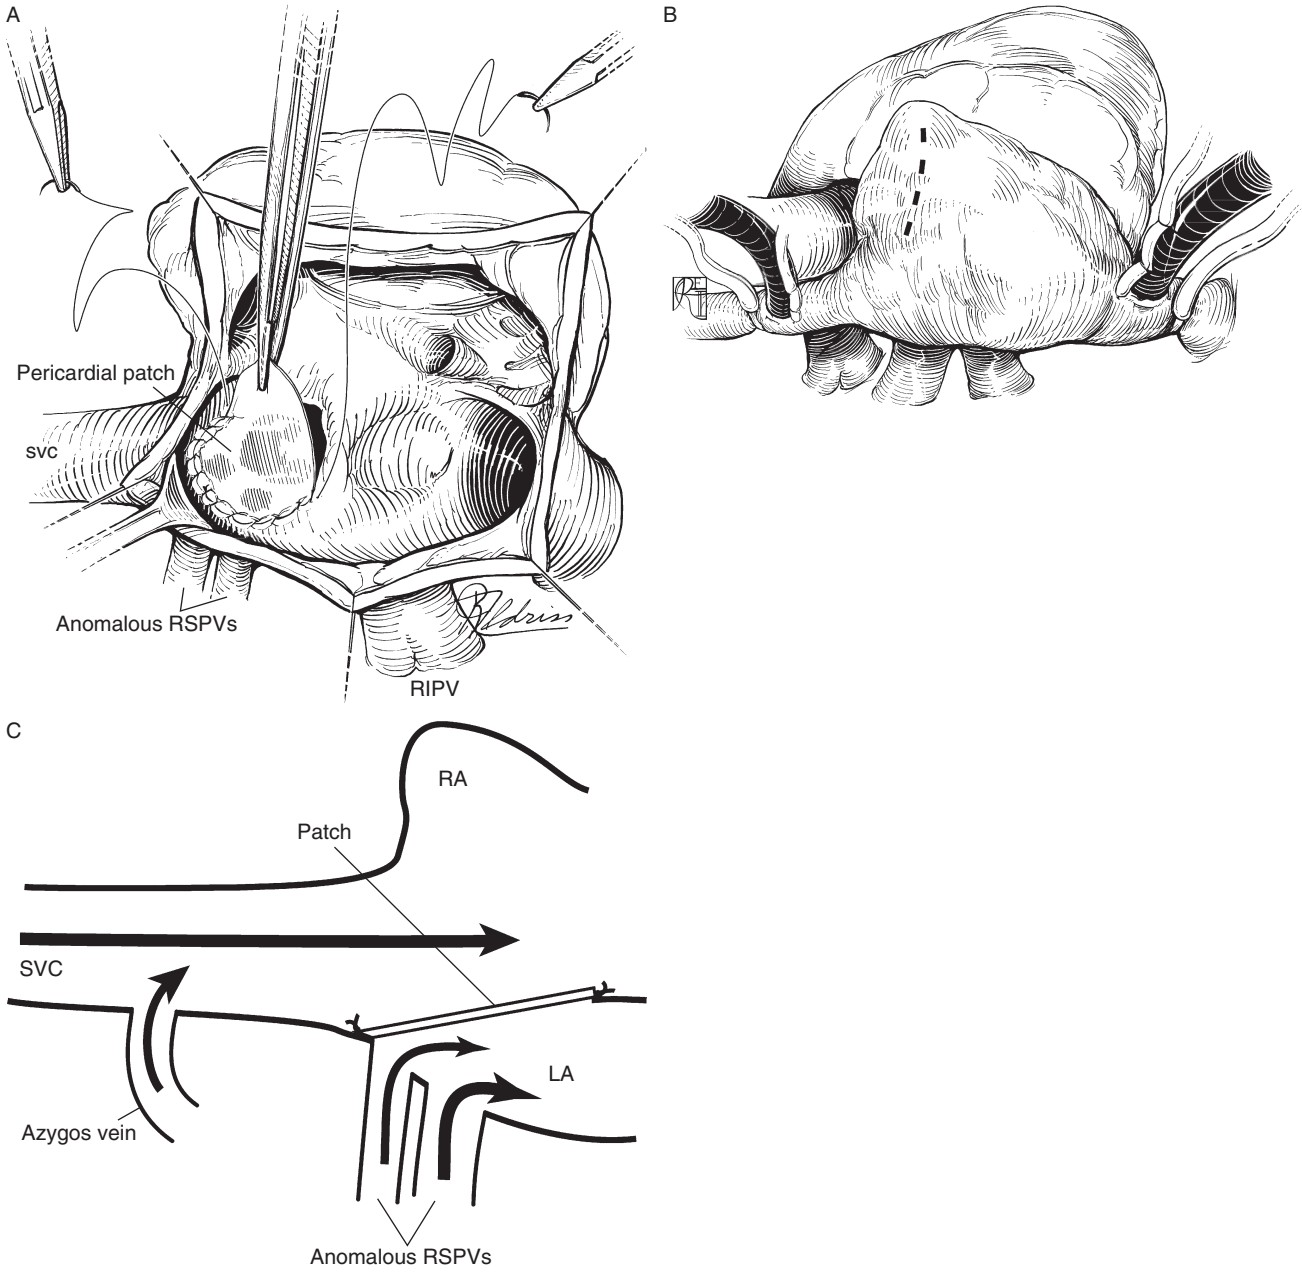

Figure 16.8 Single-patch closure of sinus venosus atrial septal defect. **A,** Pericardial patch closure of sinus venosus atrial septal defect where the anomalous veins drain to the superior vena cava-right atrial junction. **B,** Dotted line indicating incision for sinus venosus ASD closure. **C** shows in cross-section the relationship of the completed patch to the superior vena cava, right atrium, left atrium, and anomalous pulmonary veins. The postoperative blood flow in the superior vena cava and anomalous pulmonary veins is unobstructed. (LA, RA, left, right atrium; RIPV, right inferior pulmonary veins; SVC, superior vena cava.)

[31]. Warden first described this technique in 15 patients with partial anomalous pulmonary venous connection to the superior vena cava [33]. The Warden technique is illustrated in Figure 16.9 [31]. Important details of our technique include high cannulation of the superior vena cava (right-angle cannula) with division of the superior vena cava immediately above the partial anomalous pulmonary venous connection to save proximal superior vena cava length (Figure 16.9A) [31]. A pericardial patch is used to patch the cardiac stump of the superior vena cava to prevent stenosis or obstruction of the pulmonary venous return. The right atrial appendage is opened with an incision in the tip and care is taken to excise all trabeculations to avoid late stenosis (Figure 16.9B) [31]. The superior vena

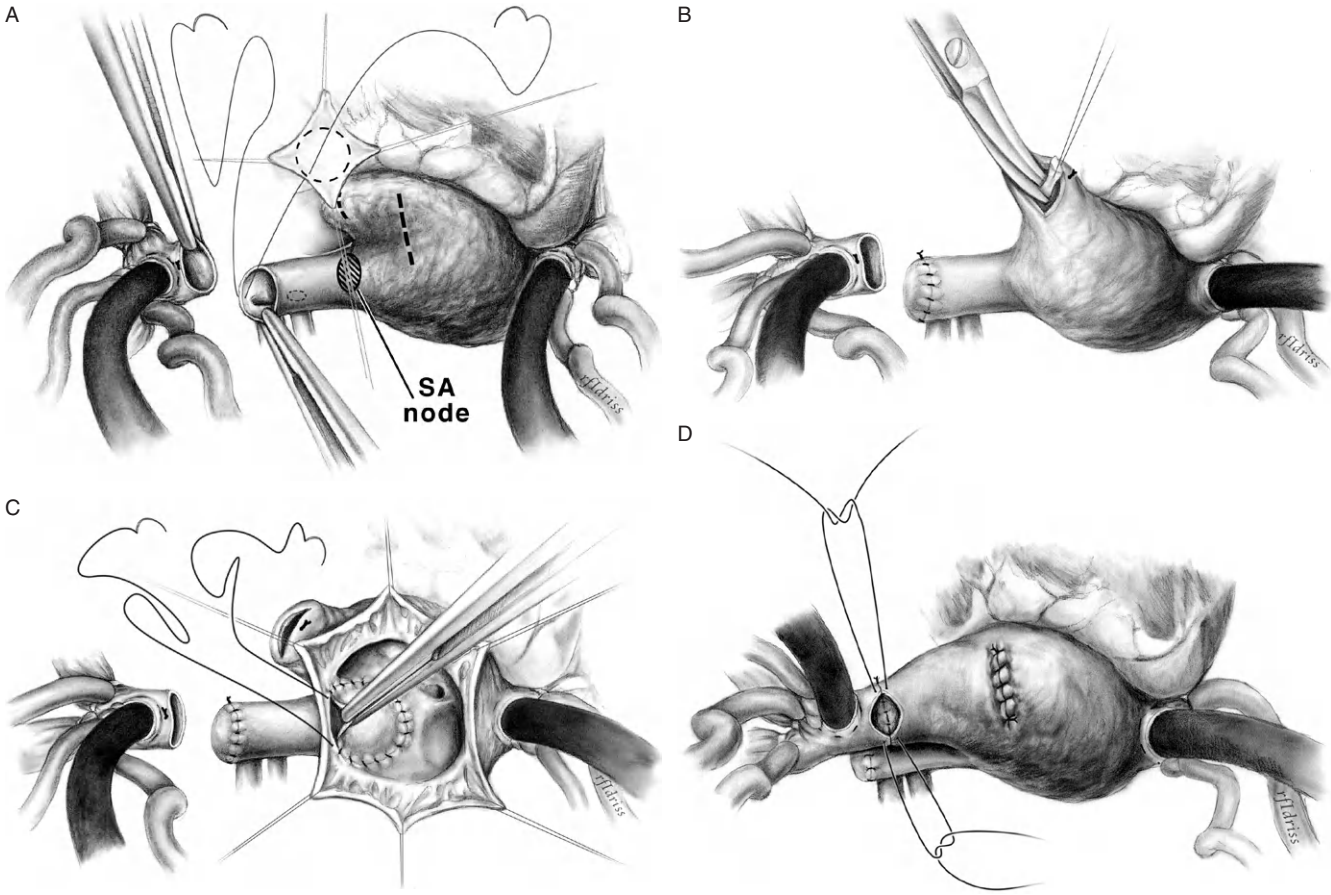

Figure 16.9 A, Details of the Warden technique. High cannulation of the superior vena cava (SVC) is performed with a right-angle cannula with division of the SVC immediately above the partial anomalous pulmonary venous connections to save proximal SVC length. A pericardial patch is used to patch the cardiac orifice of the SVC to prevent stenosis or obstruction of the pulmonary venous return (SA, sinoatrial). **B,** The right atrial appendage is opened with an incision in the tip, and care is taken to excise all trabeculations to avoid late stenosis. The completed pericardial patch on the superior vena cava is shown. **C,** The sinus venosus atrial septal defect is not "closed" but is used as an orifice through which the superior vena cava is baffled to the left atrium. The partial anomalous pulmonary venous connection blood flow goes through the remnant of superior vena cava through the sinus venosus atrial septal defect to the left atrium. **D,** The cut superior vena cava is anastomosed to the right atrial appendage using interrupted absorbable sutures to prevent purse-stringing and to allow growth. (Reproduced with permission from Stewart *et al*. [31].)

cava orifice in the right atrium is baffled to the left atrium through the sinus venosus atrial septal defect with a fresh autologous pericardial patch (Figure 16.9C) [31]. Finally, the cut superior vena cava is anastomosed to the right atrial appendage using absorbable interrupted sutures to prevent purse-stringing and to allow growth (Figure 16.9D) [31]. The azygos vein is preserved in case there is superior vena cava stenosis.

Partial atrioventricular septal defects are also closed with a pericardial patch (Figure 16.10) [5]. We use transesophageal echocardiography in all these cases. We use a vent placed through the right superior pulmonary vein. After cardioplegia has been administered and the right atrium opened, the vent is removed from the orifice of the mitral valve and left ventricle and placed in the posterior left atrium. The mitral valve can then be irrigated with cold saline to assess the patient for mitral insufficiency and to assess the area of the cleft in the mitral valve. The cleft in the mitral valve leaflet is closed with simple interrupted polypropylene sutures. This repair is facilitated by placing the first suture at the leading edge of the mitral valve at the junction of the chordae tendineae with the edge of the mitral valve on either side. This then splays out the cleft and it can be closed with simple interrupted polypropylene sutures. We do not like to use a running suture technique because of the risk of foreshortening the valve when the suture is tied. Some surgeons have elected not to repair this cleft in those patients who do not have mitral regurgitation.

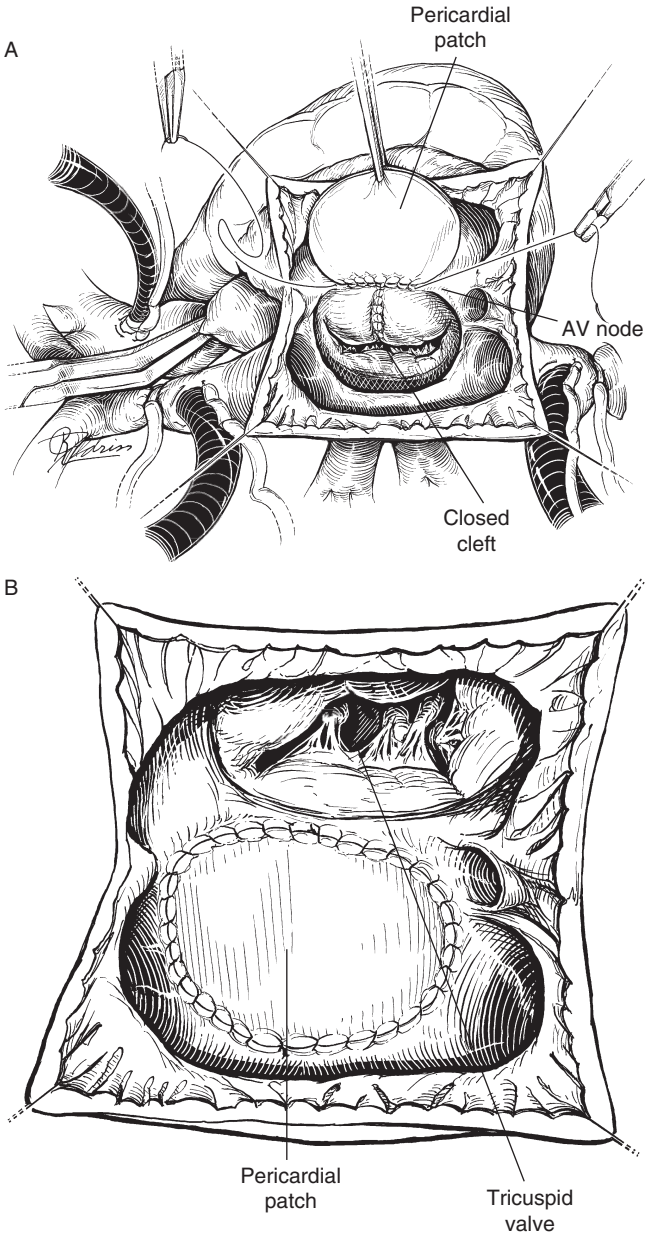

Figure 16.10 Partial atrioventricular septal defect closure. **Inset A:** Pericardial patch placement between the tricuspid and mitral valves has started and the cleft in anterior mitral valve leaflet has been closed. Vent in the right superior pulmonary vein is not illustrated. **B** shows completed ASD closure. (AV, atrioventricular.)

In our experience, we have had several patients with this type of repair performed elsewhere; these patients have then been referred with moderate or severe mitral insufficiency and sometimes with elevated pulmonary artery pressures. It is our opinion that all patients with a partial atrioventricular septal defect and a mitral valve cleft should have the cleft closed at the time of ASD closure. The pericardial patch is then brought onto the field and secured to the leaflet tissue that bridges the crest of the ventricular septum between the mitral and tricuspid valves. As the surgeon progresses with the suturing in a clockwise fashion and gets close to the coronary sinus, superficial bites must be taken to avoid the atrioventricular node. Injury to the atrioventricular node can be minimized by carrying this suture line almost into the left ventricle, very close to the mitral valve. Once one passes the area of the coronary sinus, firmer bites can be taken. The suture line is completed by bringing a second suture line counterclockwise, again along the area of bridging leaflet tissue and up to the edge of the ASD. The remainder of the closure and de-airing are similar to that for an ostium secundum defect. Some surgeons prefer to carry the suture line on the right side of the coronary sinus, allowing the coronary sinus to drain to the left side to the left atrium. We have not found this necessary to prevent creation of atrioventricular heart block. After completing the cleft repair, the vent can be replaced across the mitral valve and into the left ventricle. The vent can then be used as part of the deairing process.

Postoperative Care

Following ASD closure, most patients can be extubated in the operating room or shortly thereafter. Our policy has been to monitor them in the intensive care unit for arrhythmias, postoperative bleeding, and potential airway problems for the first 24 hours postoperatively. They are then transferred to the regular ward. Chest tubes are removed usually on postoperative day 2 and the patients are discharged home on postoperative day 3 or 4. Most patients following ASD repair require only minimal short-term inotropic support and oxygen is usually only necessary while the patient is sedated. Price and colleagues [34] have confirmed that the use of critical pathways can reduce the length of hospitalization for ASD closure to a mean of 3.1 days. Most patients can be discharged with only medications for pain. After being seen by their cardiac surgeon at 1 week postoperatively, patients follow-up with their pediatric cardiologist. Nearly all of these patients will have no residual hemodynamic abnormalities.

Technical Pitfalls

As mentioned, the lower edge of a large ostium secundum defect may be difficult to visualize, especially if the inferior vena cava cannula has been placed too high. This is particularly true for the patient who has no inferior rim and who has been declined for device closure. Another pitfall in this area is a large, prominent eustachian valve that can be mistaken for the lower edge of the ASD. Suturing the edge of the ASD to the eustachian valve would cause an obligatory right-to-left shunt from the inferior vena cava to the left atrium. This would become immediately obvious due to severe oxygen desaturation of the patient following the procedure [27]. Proper cannulation of the inferior vena

Table 16.1 Results of surgical repair of ostium secundum ASD.

*post-pericardiotomy syndrome

cava, adequate sized atriotomy, and careful placement of the initial sutures in the inferior area where the visualization is most critical, should prevent these complications. Small fenestrations in the interatrial septum primum are a potential cause of residual shunting. These defects can be closed, often primarily, with interrupted 5-0 polypropylene simple or mattress sutures, depending on the size of the fenestration. Another unusual cause of persistent postoperative interatrial shunting is a partially unroofed coronary sinus [35]. This allows left atrial blood to enter into the right atrium through the coronary sinus ostium. This entity should be suspected when no atrial septal defect or anomalous pulmonary vein can be found in the right atrium in a patient with a documented oxygen step-up. To expose the defect in the roof of the coronary sinus, an incision should be made in the interatrial septum. A right-angle clamp can then be passed into the orifice of the coronary sinus and the opening into the left atrium visualized. This opening can be closed with a pericardial patch or primarily if the coronary sinus is dilated. Frequently these patients have a left superior vena cava that makes the coronary sinus quite large. In some cases, the left superior vena cava will drain directly into the left atrium with complete absence of the coronary sinus [36]. In these cases, the left superior vena cava must be ligated (if small) or in some fashion connected to the right side of the circulation. Our current preference for these patients is to do a left superior cavopulmonary anastomosis (Glenn procedure), anastomosing the left superior vena cava to the left pulmonary artery. An alternative technique that has been reported is an intra-atrial baffle of pericardium, however, this is complicated by the location of the pulmonary veins.

Results of Operation

At the Children's Memorial Hospital between 1990 and 2009, 271 patients underwent surgical closure of an ostium secundum ASD. The median age at ASD closure was 3.3 years. All of these patients were approached through a median sternotomy with the use of cardiopulmonary bypass, aortic cross-clamping, and cold blood cardioplegia. In 50% of the cases, the defect was closed with a pericardial patch and in the other 50% direct suture closure was performed. However, since the advent of device closure, essentially all patients referred for surgery have required a patch. In this series, there were no deaths and no recurrences of the ASD. The mean hospital stay was 3.5 days. There have been multiple other series demonstrating outstanding surgical results of ASD closure in children (Table 16.1) [24,37–41]. In a large population-based study from Finland [42], the survival of children with a surgically closed ASD (812 patients) was comparable to that of the general population. In Murphy's [15] review from the Mayo Clinic, if the ASD was closed before the age of 25 years, there was no difference in actuarial survival at 27 years postoperatively from age-matched controls.

The results with sinus venosus defect are also very good. We have had no mortality from sinus venosus defect closure in 86 patients operated on between 1990 and 2009. In 54 patients that we recently reviewed [31], partial anomalous pulmonary venous connection was present in all but two patients; drainage was to the right atrium in eight patients (15%), the right atrial–superior vena cava junction in 17 patients (33%), and directly to the SVC in 27 patients (52%). Techniques utilized were single patch repair (24), two-patch repair (25), and Warden repair (5). The incidence of low atrial or junctional rhythm was 55% in the two-patch group, and 0 in the Warden group. Because of that finding we now use the Warden technique in all patients where a single patch repair is not achievable. Several other centers have reported no mortality and a very low incidence of sinoatrial node dysfunction using the Warden technique [43–46]. Superior vena cava stenosis and right pulmonary vein stenosis are also very rare with this technique. In the Mayo Clinic review, long-term survival of patients with a sinus venosus ASD was not different from age- and sex-matched populations [47].

Partial atrioventricular septal defect repair has a different set of possible complications than ostium secundum and sinus venosus repair. This is because though lacking a ventricular level communication, partial AVSDs share the same anatomic features of the scooped-out ventricular

septum, elongated left ventricular outflow tract (LVOT), and trifoliate left AV valve configuration characteristic of complete atrioventricular septal defects [48]. These include mitral valve insufficiency, atrioventricular block requiring pacemaker placement, and left ventricular outflow tract obstruction. Najm and colleagues [49] at the Hospital for Sick Children reported their results with 180 patients having repair of an ostium primum ASD. Mean age at repair was 4.6 years. Early mortality occurred in three patients (1.6%), two of whom were less than 1 year of age at time of repair. Actuarial survival was 98% at 10 years, with no late deaths. Reoperation was required in 17 of the 180 patients (9%), five of whom were in the infant group. Indications for reoperation were subaortic obstruction in five patients (3%), and left atrioventricular valve regurgitation in 12 patients (7%). Eleven patients underwent valve repair, one patient required valve replacement.

At Children's Memorial Hospital, we have operated on 66 patients with partial AVSD from 1990 to 2007. Median age at repair was 16 months, mean age was 2.3 years. There was no operative mortality. Two patients required a reoperation for mitral valve insufficiency, two patients required reoperation for subaortic stenosis, and one patient required a permanent pacemaker for third-degree AV block. Nunn reported 126 patients having partial AVSD repair, from 1983 to 2005. Median age at operation was 2.9 years. Two patients required reoperation on the mitral valve and eight patients required reoperation for subaortic stenosis [50].

Results of Transcatheter Closure

In the past 30 years, several percutaneous transcatheter techniques have been explored for closure of ASDs. Excellent initial results were described with the Clamshell occluder device (USCI Division of CR Bard Inc, Billerica, MA) [16]. On late follow-up, however, the device was taken off the market because of fractures of the struts of the device. More recently, the Amplatzer® device [16–18], a self-expanding wire mesh double-mushroom device, has been successfully employed. The HELEX device is a double disc occluder composed of an expanded PTFE membrane bonded to a single nitinol wire frame [20]. The Amplatzer® device and the HELEX® are now FDA-approved. With ongoing improvements in device construction and placement, they have become the technique of choice for closure of most small-to-medium size ostium secundum ASDs in older children.

Chan and colleagues [51] from the United Kingdom reported 100 ASD closures with the Amplatzer® device in a multicenter study. There were seven failures and one embolization requiring surgical removal. Occlusion rate at 3 months was 98.9%. Berger and associates [52] reported 200 patients undergoing placement of the Amplatzer® device with trivial residual shunts in only 1.9% of the patients. In a separate study, Berger and coworkers [53] compared Amplatzer® and surgical closure. Closure rates were identical, but the duration of hospital stay was less and there was less morbidity with the device. These conclusions are somewhat biased in that the surgical candidates had larger ASDs not suitable for the device. There are possible complications of device closure that the surgeon should be familiar with [41,54]. DiBardino reported 223 adverse events in an estimated 18333 implants (1.2%), resulting in 17 deaths (8%) and 152 surgical rescue operations (68%) [54]. Walther reported 15 reoperations on patients with an Amplatzer device – five for dislocation, five for neurologic events, and four for residual defect [41]. The most commonly reported complications are device malposition, dislocation, or embolization [41,54–56]. Another more serious complication is device erosion into the ascending aorta or the dome of the left atrium [41,54,57]. This tends to occur when the device is "oversized" because the ASD has deficient "rims" [58]. One of the ways to avoid this complication with the Amplatzer device is to not "oversize" the device to "make up for" a deficient aortic and/or superior rim. This complication occurred in 0.1% of patients tracked in the United States. We have had to operate on three patients at Children's Memorial Hospital after device closure. Two were for embolization (left atrium and mitral valve), and one for erosion into the dome of the left atrium causing a bloody pericardial effusion. Other reported complications include atrioventricular block [59], endocarditis [60], and anterior mitral valve perforation [61]. Another issue in the debate between surgical and device closure of ASD is cost. In developing countries, percutaneous occlusion costs were higher than those for surgical closure [62].

Results in Older Patients

The value of surgical closure of an ASD in an adult was previously controversial because of the higher operative risk in adults with multiple medical problems and questions regarding improvement in quality of life. Comparisons of medical therapy versus surgical therapy initially had mixed conclusions; however, recent series have found that surgical therapy has a better outcome [63]. Two studies [64,65] in the early 1990s suggested that surgical treatment is not of benefit to older patients with an ASD. Konstantinides and colleagues [66] evaluated patients diagnosed with ASD when they were more than 40 years of age. The surgical treatment group was comprised of 84 patients, and 95 patients were medically treated. Multivariate analysis revealed that surgical closure of the ASD significantly reduced mortality from all causes. The adjusted 10-year survival rate of surgically treated patients was 95% as compared with 84% for the medically treated patients. In addition, surgical treatment prevented functional deterioration

as measured by the New York Heart Association class. Both Vogel [67] and Gatzoulis [68] and their associates showed that surgical closure of an ASD in adults had a very low operative mortality, and was associated with an improved quality of life and a significant reduction in arrhythmia occurrences. Patients with ASD and atrial fibrillation should have a Cox-maze III procedure at the time of ASD closure [69,70]. Older patients require anticoagulation following ASD repair. Hawe and coworkers [71] observed postoperative embolism in 35 of 546 adults undergoing ASD closure. Coronary embolism has also been reported in adults following ASD repair [72]. We recommend anticoagulation with warfarin in all patients over the age of 35 who undergo ASD closure. This is then continued for 6 months following the procedure.

Scimitar Syndrome

Scimitar syndrome consists of a rare constellation of anomalies, the constant being total or partial anomalous pulmonary venous connection of the right lung to the inferior vena cava. On a chest radiograph, the gently curved vertical shape of this vein resembles a curved Turkish sword, or scimitar [73]. The other frequently associated anomalies include dextroposition of the heart, hypoplasia of the right lung and right pulmonary artery, and an anomalous systemic artery to the right lung from the abdominal aorta that penetrates the diaphragm. Up to 70% of patients with scimitar syndrome also have associated intracardiac defects, most commonly ASD [74].

Symptoms are related to the amount of left-to-right shunting from the anomalous vein, the degree of pulmonary hypertension, parenchymal lung disease, and associated intracardiac lesions. Patients tend to present with two distinct clinical profiles [75]. In the "adult" form the patient is usually only mildly symptomatic with exertional dyspnea and recurrent respiratory infections [76]. In the "infantile" form, patients present in the first few months of life with failure to thrive, cyanosis, respiratory distress, and congestive heart failure. Infants often have severe pulmonary hypertension. Chest radiograph shows a small right lung, displacement of the heart to the right, and the shadow of the anomalous vein. Electrocardiogram reveals right ventricular hypertrophy. Echocardiography should be able to establish the diagnosis, identify intracardiac lesions, and visualize the location of the anomalous vein [74]. Cardiac catheterization and angiography are diagnostic and identify the anomalous systemic artery from the descending aorta that penetrates the diaphragm and supplies blood to the right lower lobe (Figure 16.11) [5]. Cardiac catheterization is now also part of the therapeutic strategy for these patients. They can have the anomalous systemic artery embolized at the time of the catheterization [77].

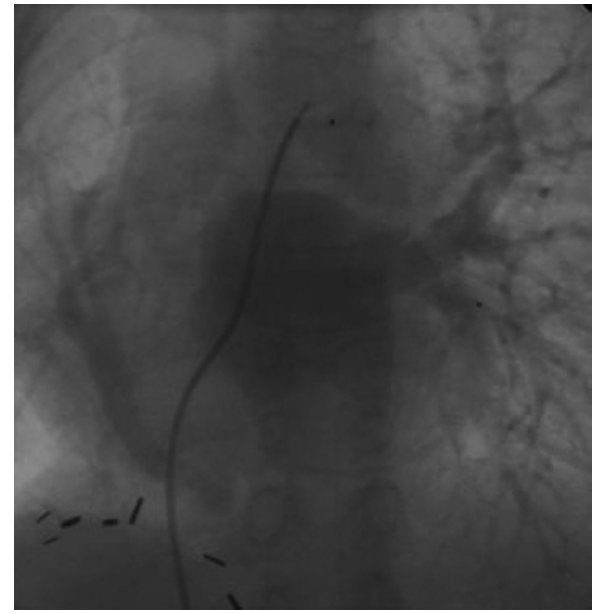

Figure 16.11 Scimitar syndrome. Levo-phase of a pulmonary angiogram. The left pulmonary veins drain normally to the left atrium. The right pulmonary veins drain to a vertical confluence that is directed toward the right diaphragm and enters the inferior vena cava. It is this vein that looks like a "scimitar."

Operative intervention is individualized and based on the degree of symptoms and findings at cardiac catheterization. In all instances, the systemic arterial supply to the lung is divided, if it was not occluded at the time of cardiac catheterization. Kirklin and colleagues [78] reported that the anomalous vein can either be anastomosed directly to the left atrium or an intracardiac patch can be used as a baffle to direct the flow from the anomalous vein to the left atrium through an atrial septal defect. Najm and coworkers [79] in Toronto reported 32 patients with scimitar syndrome seen over a 20-year time period. Nineteen were diagnosed in the first year of life. In 17 patients, the anomalous vein was baffled to the left atrium. Eight patients had postoperative evidence of pulmonary vein stenosis. Brown and colleagues [80] recently reported nine patients undergoing right thoracotomy with direct anastomosis of the scimitar vein to the left atrium without the use of cardiopulmonary bypass. All nine patients (mean age, 11.5 years) survived. That series was recently updated to 12 patients [81].

If inflammatory parenchymal changes are extensive, if the patient has persistent hemoptysis, or if there is marked hypoplasia of the right lung, pulmonary resection or pneumonectomy should be considered. Resection eliminates the left-to-right shunt as well as the lung infection. Huddleston and associates [82] reported 12 infants with scimitar syndrome. Primary pneumonectomy was performed in two patients, and three patients had a pneumonectomy after a

baffle procedure became occluded. Overall mortality in this critically ill infant group was 30%.

In general, results depend primarily on the degree of preoperative pulmonary hypertension and associated cardiac lesions. Older patients with minimal symptoms have an excellent prognosis, however, infants with cyanosis, failure to thrive, and severe pulmonary hypertension have a high mortality.

Conclusion

Atrial septal defect was the first congenital cardiac defect closed with an operation. It was the first congenital cardiac defect closed with cardiopulmonary bypass, and it was the first intracardiac lesion closed with a device in the catheterization laboratory. The history of ASD closure has exemplified the progress made in congenital heart surgery over the past 50 years. Ostium secundum defects are now primarily closed with transcatheter devices in the catheterization lab. Large ostium secundum defects are closed in the operating room with a pericardial patch with essentially no mortality or morbidity with a 50 year follow-up. Sinus venosus defects require attention to the associated partial anomalous pulmonary veins and are repaired with either a pericardial patch or with the Warden procedure. Partial atrioventricular septal defect is addressed with a pericardial patch and attention to the cleft in the left AV valve. The outcome with both surgery and transcatheter techniques is extraordinarily good and the vast majority of these patients have no residual hemodynamic sequelae and a normal life expectancy. Optimal outcomes depend on proper selection of surgical and transcatheter techniques tailored to the individual patient anatomy.

Definition and Prevalence

A ventricular septal defect (VSD) is a hole between the ventricles. Such holes can be located anywhere in the normal ventricular septum but can also exist at sites where, in the normal heart, there are no septal structures, such as directly beneath the leaflets of the pulmonary valve. They are characterized into anatomic types based on their location relative to the components of the right ventricle and their anatomic borders. The holes may vary in size, may be single or multiple, and may be associated with a number of other intracardiac and extracardiac anomalies. In this chapter, we discuss the management of isolated VSDs and those associated with persistent patency of the arterial duct (PDA), coarctation of the aorta, and acquired aortic insufficiency. Other associated major anomalies involving the ventricular outflow tracts, such as the defects seen in the setting of tetralogy of Fallot, double-outlet right ventricle, common arterial trunk (truncus arteriosus), and transposition, are discussed elsewhere in the appropriate chapters. Also in other chapters are discussions of those defects associated with atrioventricular anomalies and those with discordant atrioventricular connections.

Isolated VSD is the most commonly recognized congenital heart defect [1], excluding the aortic valve with two leaflets [2]. Ventricular septal defects occur in isolation at a rate of about 2 per 1000 live births, and account for about one-fifth of all forms of congenital heart disease [3]. When considered together, isolated VSDs and those associated with other major defects account for over half of the patients with congenitally malformed hearts.

Historical Perspectives

The clinical manifestations attributed to VSD were first described by Roger in 1879 [4]. Eisenmenger (1897) [5], when studying the heart of a 32-year-old cyanotic patient, noted the presence of a large VSD with an overriding aorta but in the absence of subpulmonary stenosis. It was much later that Abbott [6] and Selzer [7] formulated the pathophysiologic features of the VSD.

The era of surgical intervention began in 1952, when Muller and Dammann placed a band on the pulmonary trunk to limit the flow of blood to the lungs in a patient with a VSD [8]. The first operative repair was performed by Lillehei and associates in 1954 [9]. They used controlled cross-circulation with an adult acting as the pump oxygenator. The development of the heart–lung machine and cardiopulmonary bypass led rapidly to more widespread successful clinical results. DuShane and associates [10] had already shown, by 1956, that transventricular repair could be performed with an acceptable mortality rate, while Stirling and coworkers [11] showed that closure could be accomplished transatrially, thereby avoiding a ventriculotomy. In 1961, Kirklin and associates [12], and later Sigmann and associates [13], reported on the successful repair in infants, an approach which in the majority of cases obviated the need for palliative banding. Later reports by Okamoto (1969) [14] and Barratt-Boyes and colleagues (1976) [15] established the feasibility of repair in infants using deep hypothermia and circulatory arrest. Since that time, multiple refinements in methods of cardiopulmonary bypass and myocardial protection have allowed surgeons

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.
© 2013 Blackwell Publishing Ltd. Published 2013 by Blackwell Publishing Ltd.

the time to perform accurate closure without incremental risk to the patient [16]. These advances have resulted in excellent short- and long-term clinical results.

Embryology and Pathologic Anatomy

An interventricular communication is part of the circulatory pattern during the first 8 weeks of fetal life; the hole is bound by the atrioventricular endocardial cushions, the developing muscular ventricular septum, and the proximal ends of the endocardial cushions, or ridges, the latter structures separating the flow pathways in the developing ventricular outflow tract. Failure to close this embryonic communication is the reason for persistence of the most common type of VSD requiring surgical correction, the perimembranous variant. But VSDs due to inappropriate compaction of the muscular septum can result in defects in any part of the septum, while failure to muscularize the outflow ridges produces doubly committed defects. There are chromosomal, familial, and geographic influences on normal closure of the embryonic interventricular communication and normal formations of the ventricular septum and the subpulmonary infundibulum. There is variation in incidence for certain years, different seasons, and different geographic areas [17,18]. It is well known that Asian populations have a higher incidence of the defects that exist because of failure of formation of the subpulmonary infundibulum [19,20]. Children of patients with VSDs have a higher incidence of congenital heart disease [21], although not necessarily specifically for VSD [22]. There is also a higher incidence of VSDs in premature infants [23] although there is no correlation with birth order or maternal age.

As an isolated lesion, a VSD can occur in one of three main locations, albeit that subtypes of such defects have been defined and interpreted in different fashion by many authors [24–29]. Systems for naming the VSDs have developed based on varied embryologic and anatomic principles, and differences of opinion persist, although there is a move toward consensus. In this respect, nonetheless, it is important to agree on the locus of space identified as representing the defect. Consider, for example, the situation in which the aortic valvar orifice overrides the crest of the muscular ventricular septum (Figure 17.1). There are at least three loci that could reasonably be defined as the VSD. The direct cranial continuation of the long axis of the ventricular septum marks the plane of the anatomic interventricular communication, but this plane is limited cranially during ventricular diastole by the undersurface of the closed leaflets of the aortic valve. The surgeon would never place a patch to close this plane. A second plane represents the outflow tract from the left ventricle, and the surgeon would take great pains to ensure that this hole was unobstructed at the completion of the repair. It is, in fact, the entrance to the overriding aortic root that is the locus around which the surgeon places the patch to close the hole between the ventricles. It is, therefore, this view of the hole as seen from the right ventricle that we take to represent the VSD.

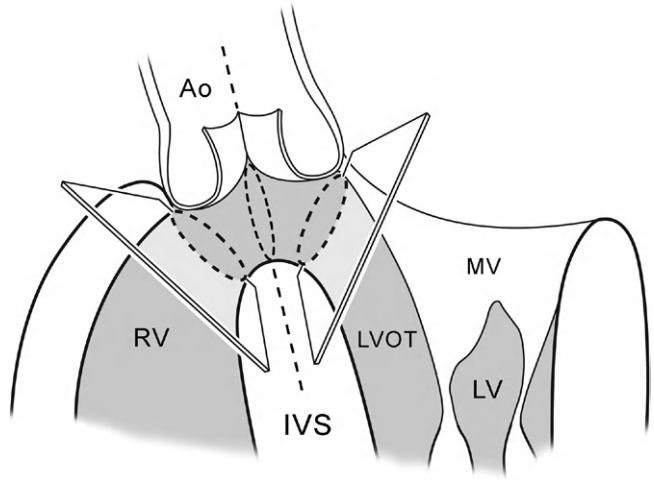

Figure 17.1 There are at least three potential loci that could reasonably be defined as the VSD. The direct cranial continuation of the long axis of the ventricular septum marks the plane of the anatomic interventricular communication, but this plane is limited cranially during ventricular diastole by the undersurface of the closed leaflets of the aortic valve. The surgeon would never place a patch to close this plane. A second plane represents the outflow tract from the left ventricle, and the surgeon would take great pains to ensure that this hole was unobstructed at the completion of the repair. It is, in fact, the entrance to the overriding aortic root that is the locus around which the surgeon places the patch to close the hole between the ventricles. It is, therefore, this view of the hole as seen from the right ventricle that we take to represent the VSD. (Ao, aorta; IVS, interventricular septum; MV, mitral valve; LV, left ventricle; LVOT, left ventricular outflow tract; RV, right ventricle.

When considering anatomic variants for the VSD, the initial, time-honored, surgical classification accounted for four types of defects (Figure 17.2) [3,30]. The type I defect, also referred to as doubly committed and juxta-arterial, conal, supracristal, infundibular, and subarterial, is the consequence of failure of formation of the muscular subpulmonary infundibulum. The phenotypic feature of the defect is the presence of fibrous continuity between the leaflets of the aortic and pulmonary valves in its cranial margin. In consequence of this feature, the superior rim has a direct relationship with the right coronary aortic sinus and the corresponding leaflet of the aortic valve. The inferior margin of the defect is usually muscular with the bar formed by fusion of the caudal limb of the septal band fusing with the musculature of the inner heart curve serving to protect the atrioventricular conduction axis. Defects of this type, however, can also extend to become adjacent to the remnant of the membranous septum and could then also be classified as the type II defect. Defects opening directly into the subpulmonary infundibulum can also, on occasion have exclusively muscular borders. While some authors might still identify such defects as being type

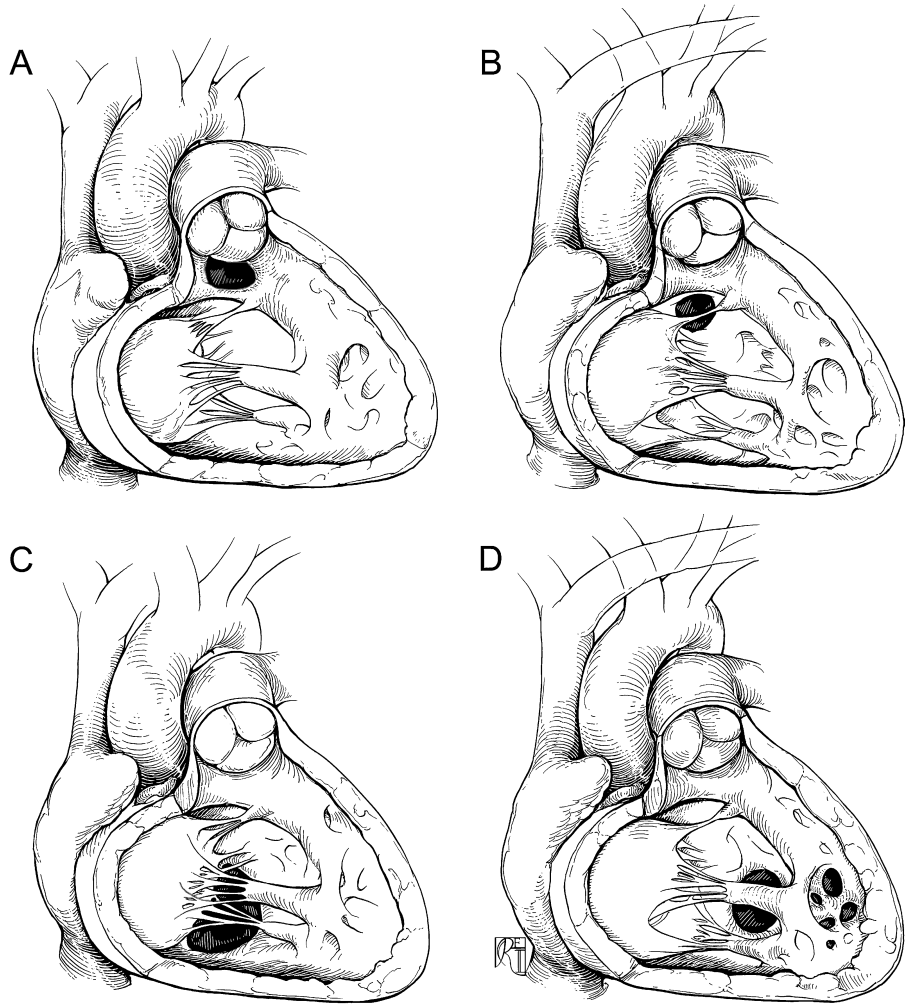

Figure 17.2 Classic anatomic types of VSD. **A,** Type I (conal, supracristal, infundibular, doubly committed, and juxta-arterial) VSD; **B,** Type II or perimembranous VSD; **C**, Type III VSD (atrioventricular canal type or inlet septum type); and **D**, Type IV VSD (single or multiple), also called muscular VSDs.

I in that they lack the phenotypic feature of fibrous continuity between the leaflets of the arterial valves, they are better defined as muscular outlet or muscular conal defects. In these defects also, the leaflets of the aortic valve can prolapse through the VSD and cause aortic insufficiency. In the presence of the muscular posteroinferior margin, the atrioventricular conduction axis is not in direct surgical proximity to the margins. Defects of this type account for less than one-tenth of isolated defects in Caucasian populations [16,31]. In contrast, reports from Asian countries show that the defects opening directly beneath the pulmonary valve are more frequent, accounting for up to one-third of all VSDs requiring surgical closure [32,33].

It is the type II VSD that is most frequently encountered at surgery [31]. It is the term perimembranous, in our opinion, that best describes this kind of defect, as the area of the defect is directly adjacent to the atrioventricular part of the membranous septum. This fibrous area, therefore, forms part of the perimeter of the VSD. These VSDs used to be described as being membranous. They exist because of failure to close the embryonic interventricular communication by appropriate formation of the membranous septum. A remnant of the interventricular part of the membranous septum, nonetheless, known as the membranous flap, is frequently found in the inferior and caudad margin of the defect. The defect, therefore, existing because of deficiency of the muscular margins of the defect, can open into various parts of the right ventricle according to the precise areas of the muscular deficiency [34]. Despite arguments as to the appropriateness of the term "perimembranous," common use trumps the best interpretations of ancient Greek and Latin. Current database assessments show that most surgeons now closing these VSDs describe them as being perimembranous. The VSDs are usually bordered cranially by the muscular subpulmonary infundibulum, often with malalignment of the muscular outlet septum, so

that they are directly related to the right and noncoronary leaflets of the aortic valve. The phenotypic feature of the defect, nonetheless, is fibrous continuity in the inferocaudad margin between the leaflets of the aortic and tricuspid valves (TVs), this area incorporating the atrioventricular component of the membranous septum. Because of this feature, the atrioventricular conduction axis penetrates directly through this border of the defect and is always at risk of damage during surgical closure.

The type III defects are also known as atrioventricular canal types, although this term is controversial. The feature of these defects is that they open to the inlet of the right ventricle, but they can take various anatomic forms (Figure 17.3). The true atrioventricular canal defect, as the name implies, has a common atrioventricular junction. These defects are atrioventricular rather than ventricular but with the bridging leaflets of the common atrioventricular valve attached to the underside of the atrial septum so that shunting is possible only at the ventricular level (Figure 17.3A). These VSDs, the rarest variant of atrioventricular septal defect with common atrioventricular junction, are associated with trifoliate left atrioventricular valves. They have the conduction axis arising from a posteroinferior atrioventricular node, as in all atrioventricular canal malformations. The more common defect described as being a type III VSD is no more than a perimembranous defect that opens predominantly to the inlet of the right ventricle (Figure 17.3B). These defects are shielded by the septal leaflet of the TV but retain fibrous continuity with both the noncoronary leaflet of the aortic valve and the leaflets of the mitral valve. They do not, however, possess a common atrioventricular canal. A third variant has also been described as being an atrioventricular canal defect. This is the defect associated with straddling of the leaflets of the TV and overriding of the right atrioventricular junction (Figure 17.3C). Such defects can also be considered perimembranous, in that they show fibrous continuity between the leaflets of the aortic, tricuspid, and mitral valves, but their phenotypic feature is malalignment between the atrial and muscular ventricular septal structures. Because of this, the atrioventricular node is deviated posteroinferiorly, being formed at the point of union between the muscular septum and the right atrioventricular junction. The node is no longer at the apex of the triangle of Koch and is at major risk during surgical closure of the defect. These VSDs again are not associated with a common atrioventricular canal. Some also include muscular defects opening to the inlet of the right ventricle in this group but on the basis of their phenotypic features, such VSDs with exclusively muscular borders should be considered as type IV defects (Figure 17.3D).

The various defects making up the type III VSDs have different embryologic origins. The perimembranous defects are the consequence of failure of proper formation of the muscular septum normally interposed between the ventricular inlets. The true atrioventricular canal defects, in contrast, reflect the failure to divide the atrioventricular canal into its right and left components, with the attachment of the bridging leaflets of the common valve serving to confine shunting at the ventricular level. The VSD associated with a straddling TV reflects inappropriate transfer of the developing right atrioventricular junction to the right ventricle. This defect is part of a spectrum leading to double-inlet left ventricle with right-sided incomplete right ventricle.

The phenotypic feature of the final type of defect, the type IV defect, is that, when viewed from the right ventricular aspect, it has exclusively muscular borders. Hence, they are also called muscular VSDs. They can be located in any part of the muscular ventricular septum and can be single or multiple. Some of the type I and type III defects, having exclusively muscular rims, should properly be defined as type IV defects. The muscular defects can be difficult to visualize and repair surgically, in part because their borders are often formed on different planes and take various shapes. When opening to the apical part of the right ventricle, they can also be difficult to reach. A particular subtype of muscular VSDs is the "Swiss-cheese" VSD. This defect can involve all components of the muscular septum, the morphologic characteristics suggesting failure of compaction during embryologic development [35,36]. Multiple, well formed muscular defects should be differentiated from the "Swiss-cheese" variant, as patients with the former type can undergo primary closure as opposed to banding of the pulmonary trunk, while those with the Swiss-cheese septum are better treated by banding.

A defect not included in the time-honored classification is the Gerbode defect. This is a direct communication between the left ventricle and the right atrium [37]. The first pathologic description was provided by Buhl in 1857 [38], and it was Kirby who performed the first surgical correction in 1956 [39]. Despite these antecedent reports, it was the report by Frank Gerbode and his associates in 1958 [40] that placed the moniker on this defect (Figure 17.4) [37,40].

In their description of five patients, four had a perimembranous VSD with an associated deficiency of the septal leaflet of the TV, thus permitting a shunt from left ventricle to right atrium (Figure 17.5) [37,40]. Their fifth patient, in contrast, exhibited a congenital deficiency of the atrioventricular component of the membranous septum (Figures 17.6, 17.7) [37,40]. It is this variant that is generally thought to represent the true Gerbode defect. Such true defects have been considered very rare, but at Children's Memorial Hospital over a period of 18 years, we encountered six patients with the true defect [37]. The patients had several diagnostic and therapeutic features in common,

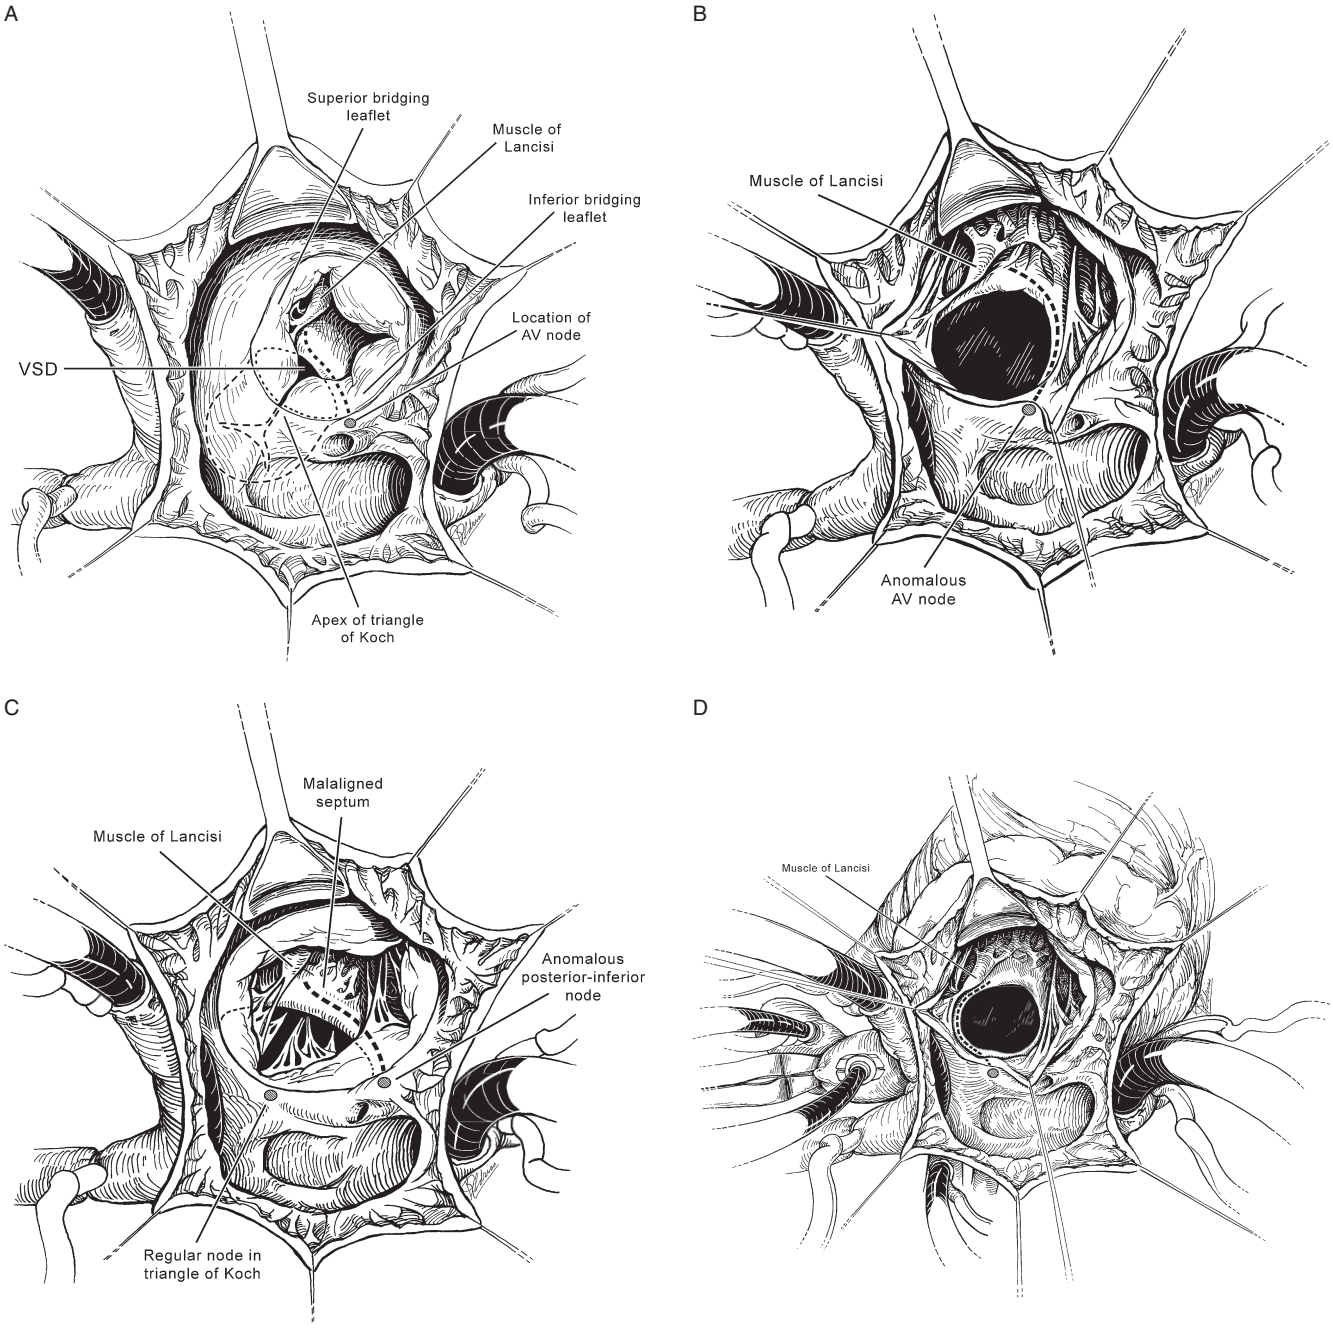

Figure 17.3 Composite representation of the various forms of inlet types of VSD, which have been identified historically as type III, atrioventricular canal type, and inlet VSDs. **A** shows an artists' view of a true atrioventricular canal defect. There is a common atrioventricular junction. These defects are basically atrioventricular rather than ventricular but with bridging leaflets of the common atrioventricular valve attached to the underside of the elongated atrial septum. The shunting therefore is possible only at the ventricular level. Note the location of the atrioventricular node, which conforms with the anatomy of complete atrioventricular septal defect and is not located within the triangle of Koch. **B** shows the more common inlet type of VSD, which is no more than a perimembranous defect that opens predominantly into the inlet of the right ventricle. The atrioventricular node and the conduction system is shown. **C** shows the lesion previously described as an "atrioventricular canal defect", but which has separate right and left atrioventricular junctions, and hence does not have an atrioventricular canal. The phenotypic feature of this defect is malalignment between the atrial septum and the muscular ventricular septum, associated with straddling and overriding of the tricuspid valve. Because of the septal malalignment, the ventricular septum inserts postero-inferiorly away from the crux of the heart. The feature underscores the grossly abnormal arrangement of the atrioventricular conduction axis, which arises from an anomalous atrioventricular node formed at the point where the muscular ventricular septum meets the atrioventricular junction. The regular atrioventricular node is present at the apex of the triangles of Koch, but because of the septal malalignment, is unable to make contact with the ventricular conduction tissues. **D** shows the defect with exclusively muscular borders that opens to the inlet of the right ventricle. This defect would correctly be classified as being muscular, but because of its position, and its exclusively muscular borders, it has a different relationship to the atrioventricular conduction axis when compared to the perimembranous defect that opens to the right ventricular inlet (B). Of great importance is the location of the conduction system, which proceeds superiorly around the defect as noted.

which enhanced their clinical management. The defect is usually diagnosed by echocardiography, which shows a high Doppler gradient from left ventricle to right atrium in association with an unusually dilated right atrium. The absence of tricuspid regurgitation distinguishes the true defect from the indirect forms. Spontaneous closure is very rare, so surgical closure is recommended and is associated with excellent results [37,41,42].

New Concepts of Nomenclature

Nowadays, many surgeons classify VSDs on the basis of the borders of the defect rather than the area they occupy relative to the components of the right ventricle, as it is recognition of the borders that provides the crucial information concerning the location of the atrioventricular conduction axis (Figure 17.8) [29,30,35,43]. According to the nature of the borders, all defects can then be placed into three rather than four groups. Perimembranous defects are bordered directly by fibrous continuity between the leaflets of the atrioventricular and arterial valves. Muscular defects are completely embedded in the septal musculature and have exclusively muscular rims when viewed from the right ventricle. Doubly committed and juxta-arterial defects are bordered directly by fibrous continuity between the leaflets of the aortic and pulmonary valves. The perimembranous and muscular defects are then subdivided into three additional subgroups, based on whether they mainly open into the inlet, apical trabecular, or outlet portions of the right ventricle.

Van Praagh and colleagues advocate a third system for nomenclature [34,44]. This system again includes four main types of VSDs, albeit with subtle differences from the time-honored groupings (Figure 17.9) [30,34,44]. In this system, VSDs are classified as being of atrioventricular canal, muscular, conoventricular, or conal types. Atrioventricular canal-type VSDs are those in the alleged atrioventricular canal portion of the muscular ventricular septum, being located beneath the TV and limited by the TV annulus. These defects, however, do not have a common atrioventricular junction but do have overriding of the orifice of the TV. Muscular VSDs have a rim totally made up of muscle and may occur anywhere in the muscular septum. Such muscular VSDs may be subdivided into anterior, midventricular, posterior, and apical types depending on their location in the muscular septum. Conoventricular defects can include defects of the membranous septum alone, but most involve more than just the membranous septum and are, therefore, termed paramembranous. Van Praagh *et al*. [34] use the term paramembranous and not perimembranous, arguing that these defects are beside the membranous septum and confluent with it. Such conoventricular defects include those with anterior malalignment of the conal septum, as seen in tetralogy of Fallot, and those

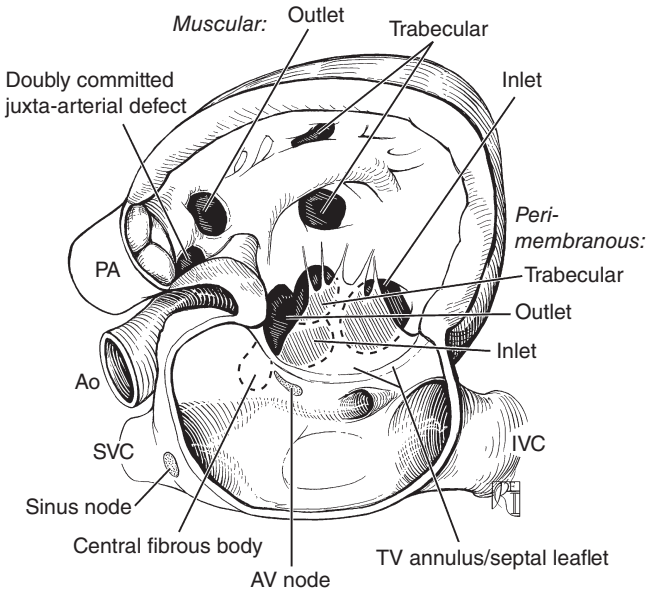

Figure 17.8 This drawing depicts the VSD nomenclature system advocated by the European school. VSDs are subdivided into three main types: perimembranous defects, muscular defects, and doubly committed juxta-arterial defects. (Ao, aorta; IVC, inferior vena cava; PA, pulmonary artery; SVC, superior vena cava.)

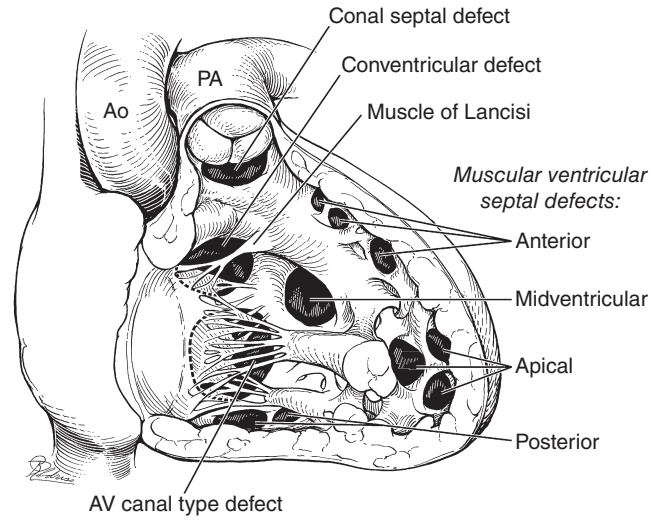

Figure 17.9 This diagram depicts the VSD nomenclature system advocated by Van Praagh. Ventricular septal defects are subdivided into four main types: conal, conoventricular, atrioventricular canal type, and muscular defects. (Ao, aorta; PA, pulmonary artery.)

with posterior malalignment, as seen in interrupted aortic arch. The conal septal defects result from a defect within the conal septum, being limited upstream by the muscular subpulmonary infundibulum and being surrounded by conal musculature.

Steps are currently in place to unify these various systems of nomenclature. Computer-generated images can now be used to demonstrate how the various previously described nomenclature systems can all coexist and be interrelated, providing that accurate phenotypes are provided for the defects as defined within the various systems [45].

Such a system that attempts to unify all the classifications may seem overly complex, but in reality, it is based on the existence of three types of interventricular communications: subarterial, perimembranous, and muscular. The myriad of other more detailed choices for coding is then manageable with the use of computer-generated coding and the hierarchical scheme as described by Jacobs and associates [45,46].

Thus, the basic hierarchy accounts simply for a VSD. The second level of the hierarchy divides the VSDs into the aforementioned main types. In the third level, each type of defect is modified according to its location relative to the components of the right ventricle. The fourth and fifth levels then provide further definitive descriptions for each subtype. These descriptors, which include malalignment between the atrial and ventricular septal structures, posterior or anterior malalignment of the muscular outlet septum, multiple VSDs, and so forth, thus account for multiple synonyms and appropriate systemic associations. Modern-day computer graphics, therefore, simplify the process of naming, as the more important issues are the location of the hole and the nature of its borders as seen from the right ventricle, rather than what it is called. The modern-day surgeon must be conversant with all classifications in order to describe, understand, and close the defects.

Pathophysiology

It is the size of the VSD, along with the pulmonary vascular resistance, which determines the magnitude of the left-to-right shunt. Other factors include ventricular compliance and obstructions to pulmonary or aortic outflows. The physiologic effects are age-dependent, being related early in life to pulmonary vascular resistance and later in life to the degree of narrowing and eventual closure of the VSD. For example, at birth pulmonary vascular resistance is predictably high and usually blunts the potential left-to-right shunt to the extent that the diagnosis often may go unrecognized. Within weeks to months, the pulmonary vascular resistance falls, resulting in an increasing left-to-right shunt and audible murmur. When shunting is excessive, congestive heart failure develops manifested by dyspnea, poor feeding, frequent upper respiratory infections, and failure to thrive. In these patients, pulmonary vascular changes may begin to develop as early as the first months of life with pulmonary arteriolar thickening [47]. Typically, after 2–3 years, these changes may progress resulting in irreversible pulmonary vascular obstructive disease. In later stages, pulmonary vascular resistance may exceed systemic vascular resistance resulting in reversal of the shunt, cyanosis, and eventual death.

Children with restrictive defects and decreased left-to-right shunting usually remain asymptomatic with little or no medical therapy. They may improve symptomatically as the relative size of the VSD decreases. This leads to a clinical dilemma concerning the most prudent time for reference for surgical closure. Although the progression of pulmonary vascular disease is variable, it is generally agreed that irreversible pulmonary vascular disease will not occur before 1–2 years of age.

Natural History

The clinical course of patients born with a VSD is quite variable, depending to a large degree on the size of the defect, the magnitude of the left-to-right shunt, and the pulmonary vascular resistance. Most VSDs are restrictive, being less than 0.5 cm diameter. They frequently become smaller or undergo spontaneous closure during the first year of life, obviating the need for surgical closure in the majority of cases [48–51]. The mechanisms of spontaneous closure include fibrosis of the margins induced by hemodynamic changes; adherence of the septal leaflet of the TV to the defect, often forming a tricuspid tissue pouch; and muscular hypertrophy, which occurs most commonly with muscular defects [52]. The incidence of spontaneous closure is highest during the first year of life but continues to a lesser degree up to about 5 years, after which spontaneous closure is rare. An undesirable mechanism of spontaneous occlusion is prolapse of an aortic valvar leaflet into the defect, oftentimes causing aortic insufficiency. This is an indication for prompt surgical repair, albeit that it is preferable to identify the defects associated with this potential complication and close them before its development.

In patients with larger VSDs, symptoms develop soon after birth concomitant with the fall in the elevated neonatal pulmonary vascular resistance. Congestive heart failure, manifested by dyspnea, repeated pulmonary infections, hepatomegaly, sweating, and failure to thrive, usually responds to medical therapy but may persist. Increased pulmonary vascular resistance secondary to hypertensive pulmonary vascular disease worsens with increasing age [53–55]. Patients are at risk of developing irreversible pulmonary vascular disease after 1–2 years of age. This process

may lead to the Eisenmenger syndrome, which is characterized by greater pulmonary than systemic vascular resistance, reversal of the ventricular shunt with resultant cyanosis, and eventual right ventricular failure. Although some patients show increased pulmonary vascular tone in the first year of life, the Eisenmenger syndrome typically takes much longer to develop, appearing most frequently in the second and third decade of life and typically leading to death by the age of 40 [56].

Some children with isolated defects develop subpulmonic stenosis due to right ventricular infundibular hypertrophy, producing physiology similar to tetralogy of Fallot. Because the pulmonary arteriolar beds have been protected from the high ventricular pressures, these patients are not at risk for pulmonary vascular destructive disease, in much the same way as if the patient had undergone palliative banding of the pulmonary trunk.

Bacterial endocarditis is a rare complication and occurs at a rate of approximately 0.3% per year for each patient with a VSD [57–61]. Its development is indicated by fever, bacteremia, and recurrent pulmonary infections. The locus of infection is usually the septal leaflet of the TV, which may result in an altered systolic murmur and localized vegetations identifiable by echocardiography. Antibiotic treatment is usually effective in controlling the active infection. After such an episode, closure of the VSD, regardless of its size, and TV repair are indicated. Prophylactic closure of restrictive VSDs in the absence of traditional indications for closure remains controversial. This is because of the small incidence of endocarditis compared with the small, but nevertheless present, risk of morbidity and mortality from surgical closure, as well as emotional and cosmetic considerations.

Ventricular septal defects are often associated with other lesions that develop because of their anatomic and hemodynamic characteristics. Prolapse of the leaflets of the aortic valve occurs most frequently with the defects opening directly into the outlet of the right ventricle, be these defects doubly committed and juxta-arterial, muscular outlet, or perimembranous defects opening to the right ventricular outlet with malalignment of the muscular outlet septum. Either the right or noncoronary leaflets of the aortic valve can be involved. With advancing age, untreated prolapse of the aortic valvar leaflets results, first, in a decreased left-to-right shunt because the involved leaflet often prolapses into the defect and reduces the shunt and, second, worsening aortic insufficiency. Early surgical closure may prevent the development of aortic insufficiency in those patients who initially had prolapse without insufficiency. If aortic insufficiency is present, repair can be performed at the time of surgical closure. Chronic turbulence through the VSD can also lead to bacterial endocarditis, which most often affects the septal leaflet of the TV [58].

Diagnosis

Patients with restrictive VSDs are generally diagnosed by the discovery of a loud holosystolic murmur heard best at the left sternal border, rarely accompanied by a hyperactive precordium and a ventricular bulge. The intensity of the murmur may vary significantly and can be inversely related to the size of the defect. The smaller its size, the louder the murmur. As the pulmonary vascular resistance rises, the murmur becomes shorter, softer, and limited to the early part of systole. It may disappear entirely, leaving a loud second heart sound due to closure of the pulmonary valve and indicative of severe pulmonary hypertension. The liver may be enlarged, and the neck veins can be distended.

Changes in chest X-ray are relative to the size of the left-to-right shunt. They include varying degrees of increased pulmonary vascularity and cardiomegaly with biventricular enlargement (Figure 17.10) [30]. The electrocardiogram may be normal or may show right, left, or combined ventricular hypertrophy.

Cross-sectional echocardiography, coupled with Doppler interrogation, now permits cardiologists not only to diagnose the presence of VSDs, but also to establish their phenotype. Multiple views help determine the location and size of the VSD, its borders, the morphology of the ventricular outflow tracts, the involvement of the aortic valve, and the proximity to the tension apparatus of the atrioventricular valves (Figure 17.11) [30]. This technique, however,

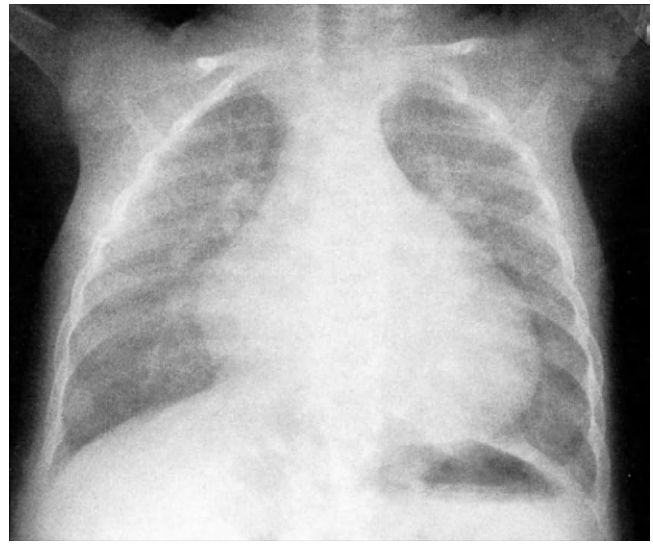

Figure 17.10 Chest roentgenograph of a patient with a large VSD showing cardiomegaly and increased pulmonary vascularity due to the large left-to-right shunt.

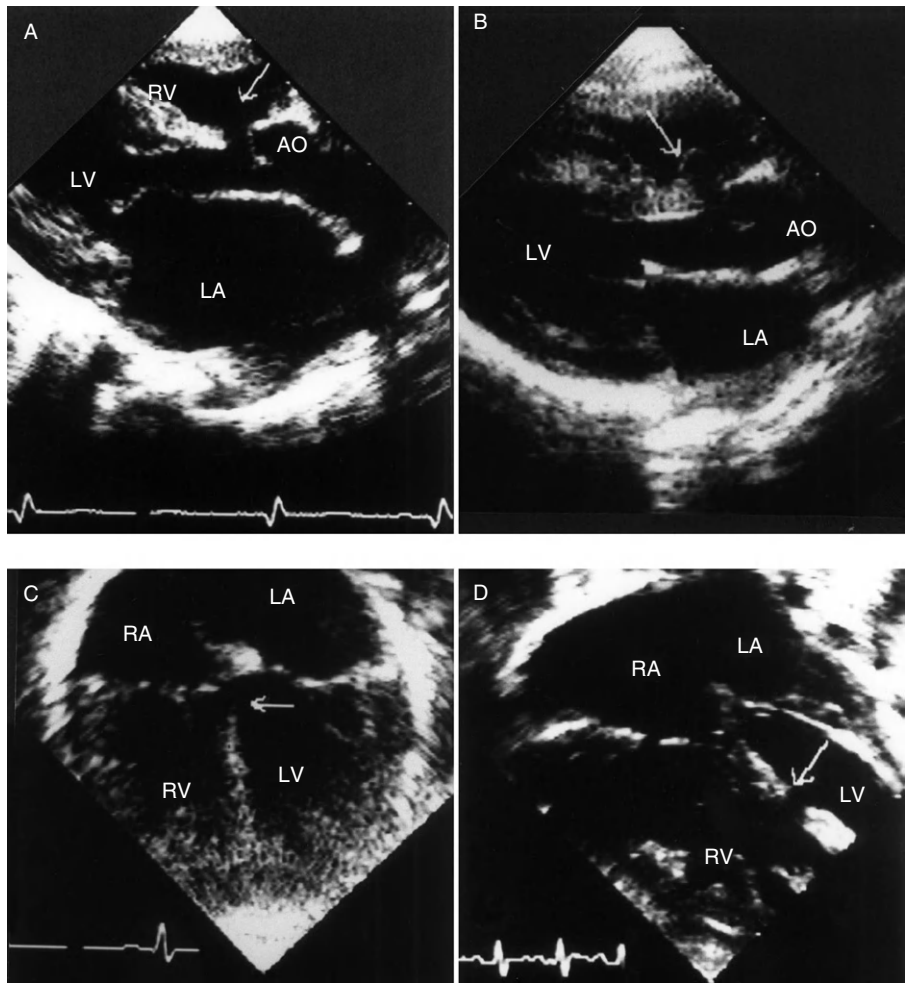

Figure 17.11 Echocardiographic views showing examples of the various types of VSDs. **A,** Parasternal long-axis view showing a doubly committed and juxta-arterial VSD. Arrow indicates the VSD with the right coronary leaflet of the aortic valve prolapsing into the defect. **B,** Parasternal long-axis view showing a perimembranous VSD. Arrow indicates tricuspid pouch (accessory tricuspid tissue). **C,** Apical four-chamber view showing a so-called atrioventricular canal type VSD (inlet VSD). Arrow indicates the position of the VSD in relation to the mitral and tricuspid valves at the inlet portion of the right ventricle. Note that the patient does not have a common atrioventricular canal. **D,** Apical four-chamber view showing a midmuscular VSD. Arrow indicates the position of the VSD. does not provide other important information that is determined by cardiac catheterization, such as quantification of ratio of systemic and pulmonary flows, the pulmonary arterial pressure, and accurate identification of multiple defects (Figure 17.12) [30] (see Chapter 4, *Preoperative Diagnostic Evaluation*). The current diagnostic trend, nonetheless, is away from cardiac catheterization, with greater reliance on echocardiographic and Doppler interrogation. The reason for this change is based on surgical trends toward earlier closure. For instance, a 3–6-month-old infant with a demonstrated large VSD and related symptoms almost assuredly has elevated pulmonary arterial pressures and a large left-to-right shunt. Moreover, the chance of irreversible pulmonary vascular disease approaches zero. Consequently, cardiac catheterization, while technically informative, does not impact on the decision to advocate surgical closure in light of the current advances in echocardiographic techniques. On the other hand, a child or young adult with a large VSD may have increased pulmonary vascular resistance, which cannot accurately be determined by echocardiography. In these circumstances cardiac catheterization is required to measure pulmonary arterial pressure, to calculate pulmonary vascular resistance, and to determine the response of the pulmonary arteries to vasodilators, all of which will influence the decision regarding surgical closure.

Medical Management

Medical management is directed at the pathophysiologic consequences of the left-to-right shunt, the management of increased pulmonary vascular resistance, and prophylactic antibiotic administration for endocarditis.

Infants with congestive heart failure often respond to digitalis, diuretic therapy, and afterload reduction. Supplemental nutritional support may be necessary because of poor feeding and failure to thrive. Optimal antibiotic therapy will be required for recurrent pulmonary infections. These supportive measures often allow delay of surgical treatment and may promote spontaneous restriction or closure of the VSD. When these measures are not effective, surgical closure should be undertaken. Occasionally, a patient may require assisted ventilation and inotropic support to treat decompensated congestive heart failure as a bridge to surgical therapy. Under these conditions, a thorough evaluation should be undertaken to determine causes for the decompensation, such as subaortic stenosis, coarctation, persistent PDA, or infection.

Older patients with pulmonary hypertension and elevated pulmonary vascular resistance require cardiac catheterization to determine the pulmonary arterial pressure, along with the response to inspired oxygen and other vasodilators such as amrinone, isoproterenol, nitroglycerin, nitroprusside, inhaled nitric oxide, and prostaglandin E1. An increase in left-to-right shunting and/or a decrease in the mean pulmonary arterial pressure are considered responses favoring VSD closure. These same agents can be administered postoperatively to promote resolution of reversible pulmonary hypertension.

Patient Selection

The selection of patients for VSD closure centers around the size and type of the defect as determined by echocardiography and/or cardiac catheterization, the natural history, the intervening symptoms caused by the VSD, and complicating factors.

Patients with Large Ventricular Septal Defects

Infants with large VSDs and severe, intractable congestive heart failure should undergo surgical closure at any time during the first 3 months of life. If, however, these patients respond to medical therapy, then conservative follow-up is warranted up to about 6 months of age. Spontaneous closure of large VSDs becomes less probable after this time (Figure 17.13) [16,30,48,51,62], while the incidence of progressive pulmonary vascular obstructive disease increases. Closure should be undertaken at this time, especially if the pulmonary vascular resistance is high, greater than 4 units/m^2 [2,62] or if the ratio of pulmonary to systemic flows exceeds 2:1.

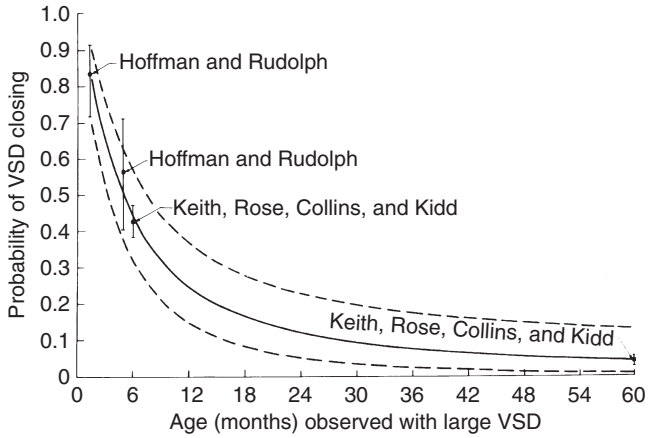

Figure 17.13 Probability of eventual spontaneous closure of a large VSD according to the age at which the patient is observed. The broken lines enclose the 70% CLs around the solid probability line. The specific ratios, with the 70% CLs reported by Hoffman and Rudolph [62] (1966) and Keith and associates [51] (1971), are shown centered on the mean or assumed ages of patients in their reports ($p < 0.001$). (Reproduced with permission from Blackstone *et al.* [48].)

Older patients with large VSDs occasionally present with varying degrees of established pulmonary vascular obstructive disease. Predictably, these patients have a history of some antecedent clinical improvement due to the decreased left-to-right shunt in response to the increased pulmonary vascular resistance. Patients with a dominant right-to-left shunt and calculated pulmonary vascular resistance higher than 8 units/m^2 and who show no response to pulmonary arterial vasodilatation are not considered candidates for surgical closure. Some centers have depended on lung biopsy to evaluate the degree of pulmonary vascular changes, but this has now fallen from favor [63–65]. There has been limited experience with VSD closure and single- or double-lung transplantation for those patients with progressive pulmonary vascular disease. The results of this therapy are discussed in Chapter 43, *Heart, Lung and Heart-lung Transplantation in Children*.

Patients with Small Defects

Infants shown by echocardiography and physical examination to have small VSDs require little or no medical therapy. They are followed with the expectation that the VSDs may get smaller and/or undergo spontaneous closure. After the first year of life, asymptomatic patients with small perimembranous or muscular defects can be re-evaluated on a timely basis for physiologic and anatomic signs that would suggest indications for surgical closure. Recent data

have led to questions regarding the validity of historical indications for surgical closure [66]. The proposed, more liberal indications are any evidence of aortic valvar prolapse (even without regurgitation), a history of prior endocarditis, and any evidence of ventricular dilation, even if the left-to-right shunt is less than 2:1. A review from our institution from 1980 to 1991 revealed 141 patients with a Qp/Qs ratio of less than 2:1 who had undergone surgical closure for one or more of the above indications [66]. There were no operative or late deaths, no instances of heart block, and no reoperations for residual shunting. Transatrial or transpulmonary repair was feasible in all. These data, although presently mildly controversial, suggest that the surgical risk of closing a restrictive VSD permitting a high-velocity turbulent jet is less than the combined lifetime risk of bacterial endocarditis, aortic valvar prolapse that may lead to aortic insufficiency, and tricuspid regurgitation [67,68].

Patients with Defects Opening Directly Beneath the Pulmonary Valve (Conal Ventricular Septal Defects)

These patients have a high probability of developing aortic valvar prolapse and aortic insufficiency, especially after 5 years of age (Figure 17.14) [30,69]. Early surgical intervention may control or prevent the progression of aortic insufficiency [69–75]. Because of the known natural history and the impact of surgery, all doubly committed and juxta-arterial defects (conal VSDs) should be closed regardless of the magnitude of the left-to-right shunt.

Surgical Considerations

Preoperative demonstration of the location of the VSD determines the options available with regard to the cardiac incisions needed for exposure, avoidance of injury to the conduction pathways, and the operative technique needed to secure closure when part of the perimeter of the defect is formed by the leaflets of the atrioventricular or arterial valves.

In general, there are five operative approaches for VSD closure: right atrial, transpulmonary, transaortic, right ventricular, and left ventricular. Mixed and multiple VSDs, or those that have extensive involvement of more than one region of the septum, may require a combined approach.

Right Atrial Approach

This surgical approach (Figure 17.15) [30] is the most frequently used and is usually applicable to perimembranous defects, all those opening to the inlet of the right ventricle, most muscular defects, and the Gerbode types. Closure of muscular defects is usually first attempted through the right atrium. With some types, nonetheless, such as those opening at the right ventricular apex or the Swiss-cheese variant, a limited left apical ventricular incision may be required.

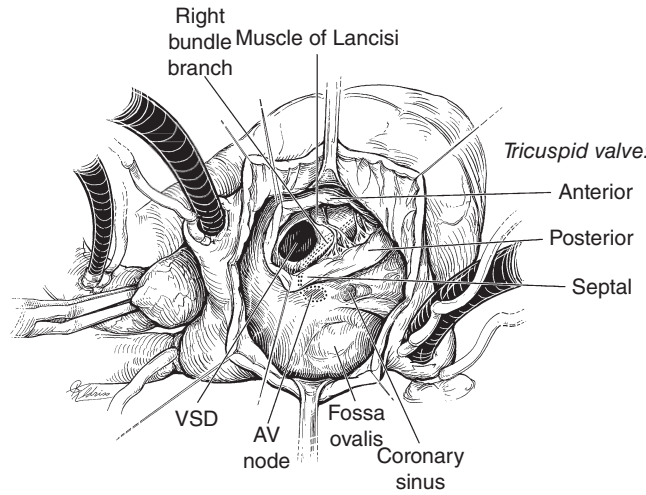

Figure 17.15 Right atrial approach for VSD closure after aortobicaval cannulation and aortic cross-clamp with cardioplegia. The tricuspid valvar leaflets are retracted to expose the VSD and the important surrounding structures. Interrupted pledget-supported sutures can be placed on the right ventricular side of the septum while avoiding injury to the aortic valve, the tricuspid valve leaflets, and the conduction system. (Ao, aorta; AV, atrioventricular; VSD, ventricular septal defect.)

In addition to the general tenets regarding the cavitary incision and the conduct of extracorporeal circulation, many established techniques may be helpful in facilitating exposure with these different approaches during surgical VSD closure. The use of aortic cross-clamping, cardioplegia, hypothermia, and a left ventricular vent are important not only to protect the myocardium and provide a relatively bloodless intracardiac surgical field but also to relax the myocardium in order to optimize exposure. The view through the tricuspid valvar orifice may not be sufficient to effect complete and simultaneous exposure of all areas and the extent of the defect. When the heart is relaxed, changing the direction and tension of retractors will permit viewing the lesion one sector at a time.

It is usual to close the defect with 5-0 double-armed sutures, with buttressing pledgets, placed 2–3 mm away from its edge on the right ventricular side, permitting a wider contact area between the patch and the myocardium, helping to avoid injury to the conduction bundle that often runs near the crest of the defect, usually on the left ventricular side. Frequently the defects in the perimembranous area may be covered by the septal leaflet of the TV and may not be visualized immediately. This occurs particularly in those cases when the cordal attachments of the TV to the edges of the defect are short and tight, or when there is formation of a pouch by redundant or accessory valvar tissue. In these instances, a clue to the location may be a depression in the TV tissue being sucked into the defect by the action of the left ventricular vent. At times, the surgeon may be misled to believe that a small opening in the valvar tissue represents the total extent of the VSD (Figures 17.16, 17.17) [30,76]. In this circumstance, there may be a temptation to use simple direct closure with a suture, thus leaving the defect open behind the leaflet. This may result in residual shunting through another unrecognized open part of the defect. In order to avoid this pitfall, the hinge of the tricuspid valvar leaflets should be opened in a radial fashion (Figure 17.18) [30], thus exposing the true perimeter of the defect, which should always be closed with a patch.

When incising the TV, it is essential to proceed carefully from the free edge toward an area 3–4 m from the annulus, gradually increasing the size of the opening in the leaflet depending on the needed exposure. The incision should be made meticulously, keeping the leaflets of the aortic valve constantly in view, in part because of their proximity on the upper rim but also because the aortic valvar leaflets may have prolapsed to varying degrees in this area. Radial incision of the TV has been shown to have minimal long-term influence on valvar function, validating the use of this technique [76]. Some authors prefer a circumferential inci-

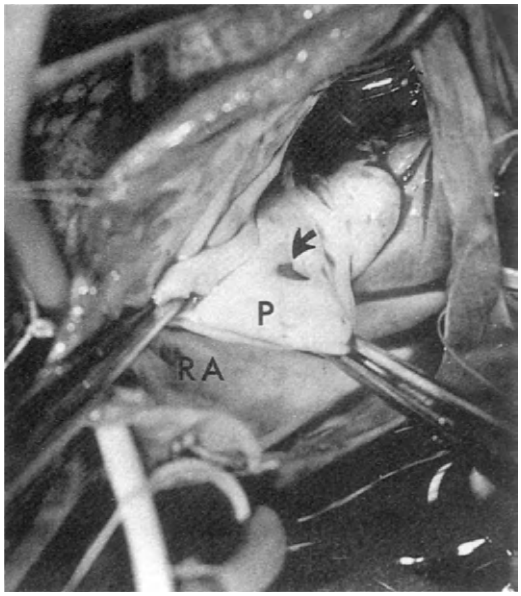

Figure 17.16 Operative photograph showing the right atrium opened to expose a tricuspid pouch, which is pulled with forceps to show a single orifice defect (black arrow). (P, tricuspid pouch; RA, right atrium.) (Reproduced with permission from Idriss *et al.* [76].)

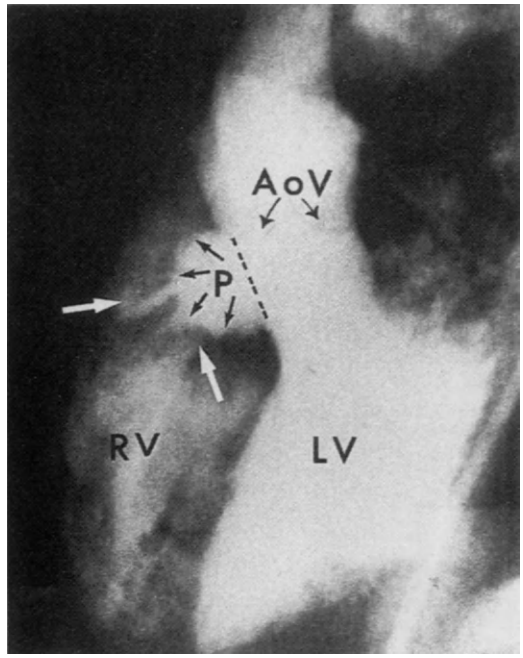

Figure 17.17 Left ventricular angiogram in diastole of a tricuspid pouch with multiple small jets (white arrows). The dotted line delineates the true ventricular defect. Note the proximity of the defect to the aortic valve. (AoV, aortic valve; LV, left ventricle; P, tricuspid pouch; RV, right ventricle.) (Reproduced with permission from Idriss *et al.* [76].)

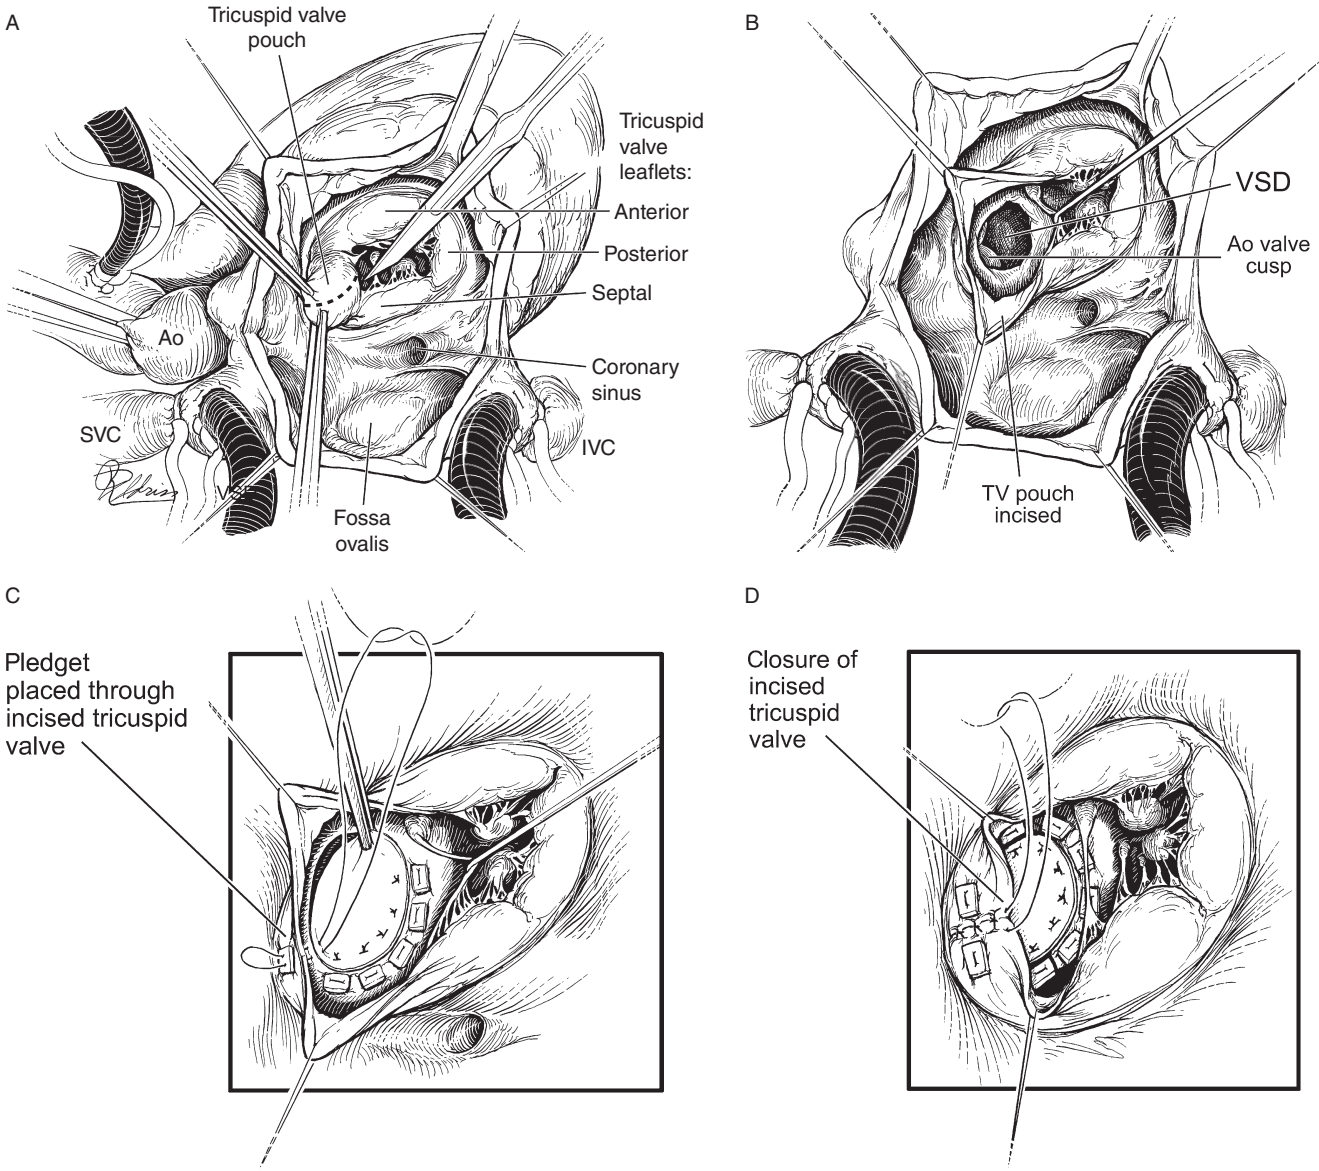

Figure 17.18 A, Tricuspid valve pouch exposed through a right atrial incision and retracted with sutures. The dotted line outlines the proposed incision site. **B,** The tricuspid valve pouch has been incised toward the annulus and retracted exposing the actual extent of the VSD; **C**, Pledget placed through incised tricuspid valve; **D**, Completed VSD closure showing repair of the incised tricuspid valve. (Ao, aorta; SVC, superior vena cava; IVC, inferior vena cava.)

sion for VSD exposure [77–80]. We have used such a circumferential incision to expose large perimembranous VSDs opening primarily to the inlet of the right ventricle (Figures 17.19–17.24) [81].

To avoid injury to the conduction system, the sutures should be placed superficially and carefully along the inferior and posterior margins of the defect beginning from the area of insertion of the muscle of Lancisi and continuing to the annulus of the TV near the region of the apex of the triangle of Koch (Figure 17.25) [30]. At this junction, buttressed sutures should be placed from the right atrium inward through the septal leaflet of the TV, keeping the needle about 1–2 mm away from the annulus. This suturing technique is continued superiorly until the transitional area, where the superior edge of the VSD begins to be formed by muscle of the outlet septum. Here, the risk of injury to the conduction system is minimal, while the hazard of damage to the aortic valve is increased. It may be tempting to place the sutures through the membranous flap, which represents the remnant of the interventricular part of the membranous septum, often found in the posteroinferior angle of the defect. We do not recommend this technique because of the possibility of injury to the conduction system. We also avoid the temptation to place sutures

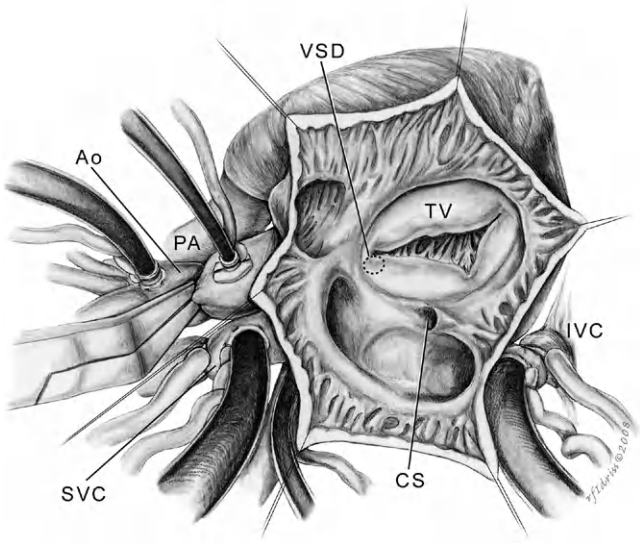

Figure 17.19 A perimembranous ventricular septal defect (circular dotted line) is represented behind the septal leaflet of the tricuspid valve that oftentimes extends toward the anterior leaflet. When complex chordal attachments are present, retraction and optimal exposure may result in chordal disruption and tricuspid insufficiency. It is for these reasons that a circumferential incision is performed to visualize the ventricular septal defect. (Ao, aorta; CS, coronary sinus; IVC, inferior vena cava; PA, pulmonary artery; SVC, superior vena cava; TV, tricuspid valve; VSD, ventricular septal defect.) (Reproduced with permission from Mavroudis *et al.* [81].)

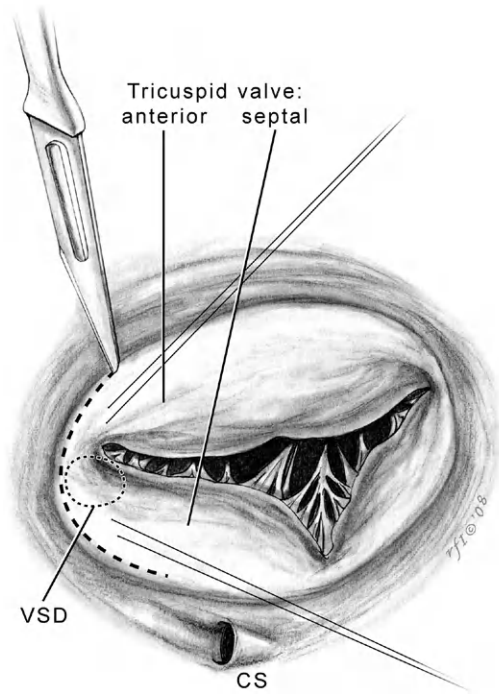

Figure 17.20 The circumferential incision (dashed line) is performed to detach that portion of the tricuspid valve in order to optimally expose the ventricular septal defect, thereby avoiding the possibility of chordal rupture. Great care is taken to avoid injury to the subtended aortic valve leaflets, which are in close proximity to the projected tricuspid incision. Oftentimes, a dose of antegrade cardioplegia can help in identifying the aortic leaflets through this approach. (CS, coronary sinus; VSD, ventricular septal defect.) (Reproduced with permission from Mavroudis *et al.* [81].)

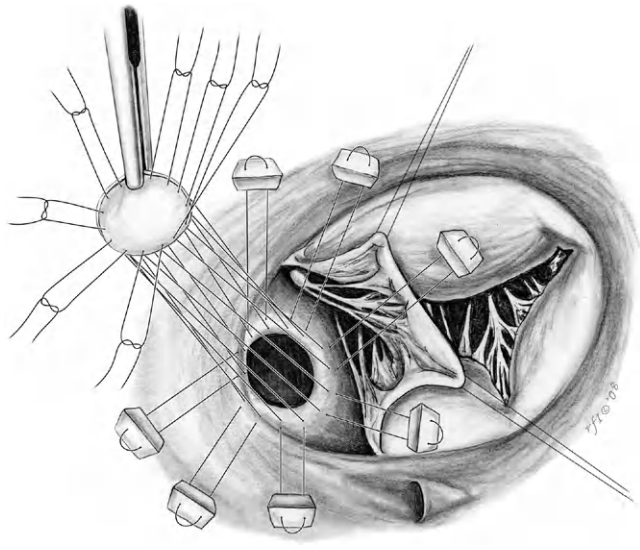

Figure 17.21 The tricuspid valve is retracted, which results in excellent exposure. Pledgeted sutures are place around the edges of the defect with special care to avoid injury to the tricuspid valve, the aortic valve, and the conduction system. At least two pledgeted sutures are placed through the tricuspid annulus from the right atrial cavity to anchor the polytetrafluoroethylene patch. These sutures are then placed through the patch, which can be tied in place, thereby closing the ventricular septal defect. (Reproduced with permission from Mavroudis *et al.* [81].)

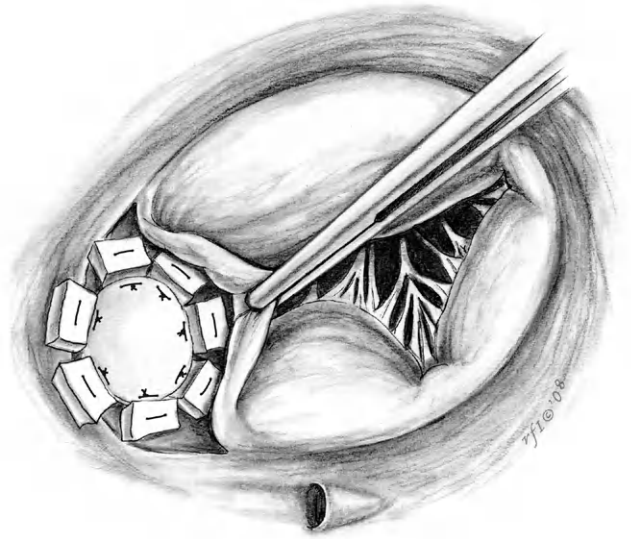

Figure 17.22 The closure of the ventricular septal defect is completed showing the tied pledgeted sutures anchoring the polytetrafluoroethylene patch in place. (Reproduced with permission from Mavroudis *et al.* [81].)

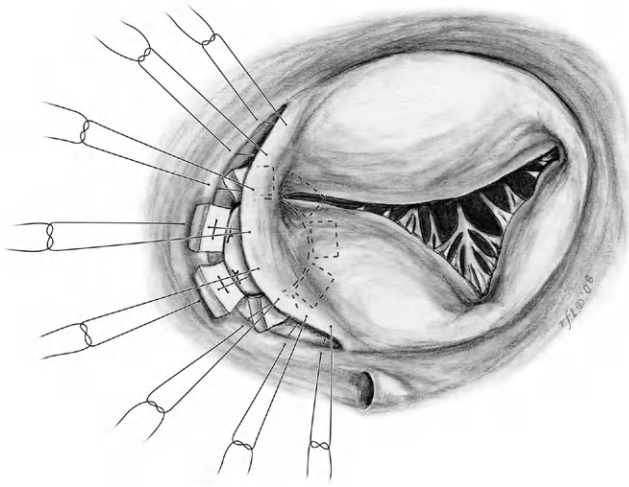

Figure 17.23 The tricuspid valve is reattached using the interrupted suture technique, which theoretically has the advantage of allowing annular growth. (Reproduced with permission from Mavroudis *et al*. [81].)

through any fibrous accretions on the crest of the muscular septum, because in our experience such tissue lacks holding qualities.

Transpulmonary Arterial Approach

This technique is usually used for repair of the doubly committed and juxta-arterial defects (conal VSDs) or for muscular defects opening in the subpulmonary area (Figure 17.26) [30]. The techniques for bypass and myocardial

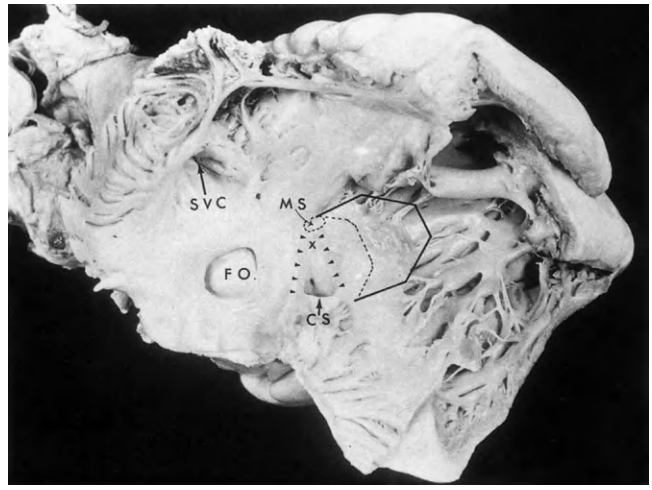

Figure 17.25 Preserved gross specimen showing the right atrium and right ventricle after an atrioventricular transannular incision for exposure. The solid and dotted lines show the inlet portion of the interventricular septum. The black triangles along with the coronary sinus (CS) mark the borders of the triangle of Koch in which lie the atrioventricular node and the bundle of His (X). (FO, foramen ovale; MS, membranous septum; SVC, superior vena cava.)

Figure 17.26 Preserved gross specimen showing a doubly committed juxta-arterial VSD with aortic valve prolapse. The left ventricle and aorta have been opened. The VSD is intimately related to the aortic valve and the right coronary cusp (RC) of the aortic valve is prolapsing into the defect. (Ao, aorta; MV_A, mitral valve anterior leaflet; NC, noncoronary cusp.)

preservation are the same as for the right atrial approach. Exposure is accomplished through a vertical incision in the pulmonary trunk (Figure 17.27) [30]. These defects are closed using a patch, which helps support the prolapsing leaflets of the aortic valve, preventing continued downward pressure on the leaflets. Complete closure of the defect eliminates the Venturi effect that initially pulls the aortic leaflet into the VSD. A particularly treacherous situation may exist should the prolapsing leaflet partially occlude the defect. In this circumstance, the defect itself may appear small and seem amenable to direct suture. It is important to recognize this pitfall, avoiding injury to the aortic valvar leaflet by using an appropriately sized patch and placing the sutures around the true perimeter of the defect rather than the small false opening (Figure 17.27) [30].

The superior aspect of these defects is formed by fibrous continuity between the leaflets of the aortic and pulmonary

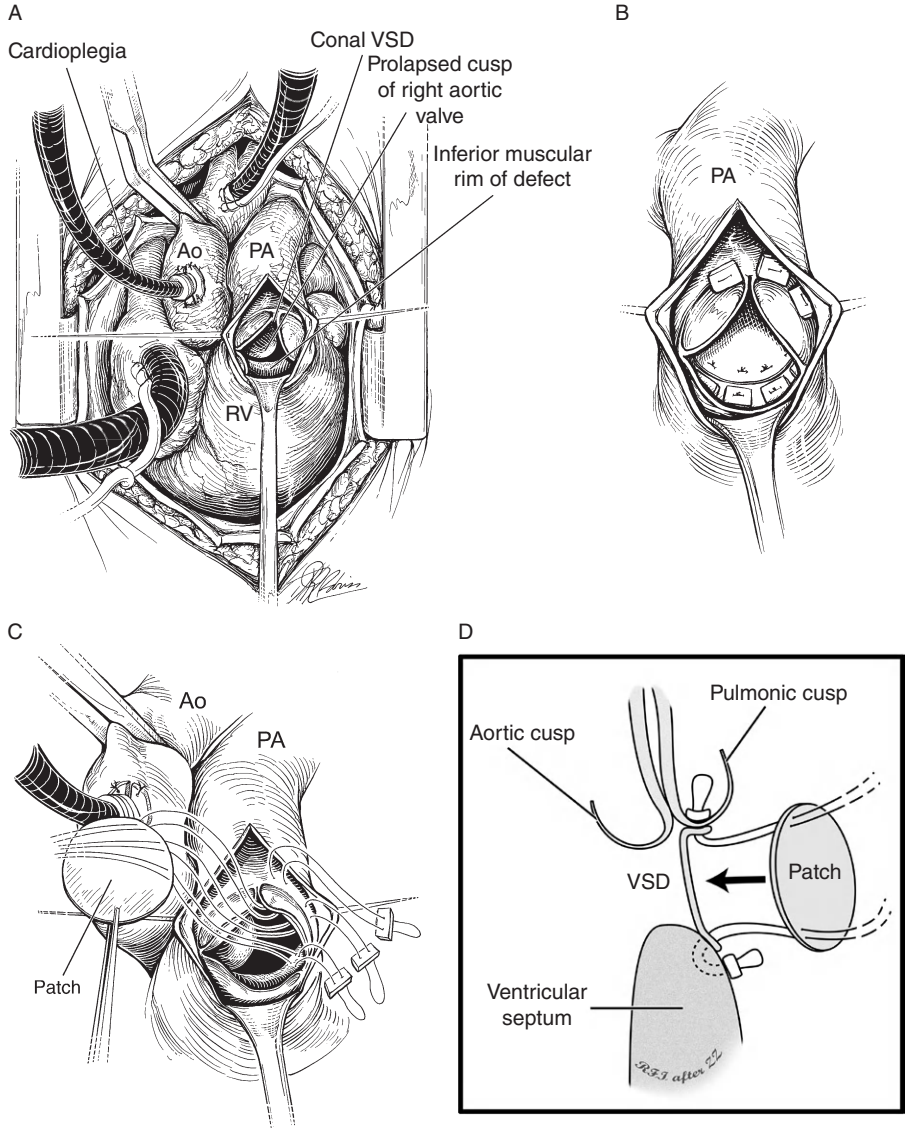

Figure 17.27 A, Operative view of the doubly committed and juxta-arterial (conal) VSD after cardiopulmonary bypass, aortic cross-clamping, and cardioplegic arrest have been established. The exposure is through the longitudinally opened pulmonary artery showing the right cusp of the aortic valve prolapsing into the defect and partially occluding it. **B,** Interrupted pledget-supported sutures are placed circumferentially around the defect and then through a PTFE. **C,** Anterior projection shows that at the superior portion of the defect, the sutures are placed through the base of the pulmonary valve leaflets because there is no muscular septum between the leaflets of the aortic and pulmonic valves. **D,** Lateral projection showing the relationship of the sutures to the pulmonary valve. (Ao, aorta; RV, right ventricle; PA, pulmonary artery; PTFE, polytetrafluoroethylene.)

valves, but the fibrous margin is frequently unsuitable for anchorage of sutures. In this circumstance, a few sutures must be anchored through the base of the leaflets of the pulmonic valve at their junction with the valvar sinuses where the small pledgets will rest against the arterial wall, decreasing the chances of the sutures tearing the thin valvar tissue (Figure 17.27C) [30]. Some have advocated a combined transaortic and transpulmonary approach for concomitant surgical repair of aortic insufficiency [82].

The patch should not interfere with the function of the pulmonary valve and should provide support to the previously prolapsed leaflets of the aortic valve (Figure 17.27D) [30]. The pulmonary trunk is closed primarily.

Transaortic Approach

Closure of VSDs via an aortic incision (Figure 17.28) [30] is usually performed when there is need for concomitant correction of associated lesions, such as aortic valvoplasty for prolapsed leaflets or for relief of valvar or subvalvar stenosis. An obliquely curved incision is made, starting on the anterior aspect of the ascending aorta at a level above the center of the right coronary aortic sinus. The surgeon should keep in mind that orifices of the coronary arteries may occasionally arise high in the aortic sinuses or above the sinotubular junction and could be injured by the aortic incision. The incision is carried inferiorly and to the right under direct vision toward the center of the noncoronary aortic sinus. The incision may be extended as needed transversely toward the left. Alternatively, the aorta can be transected 1–2 mm above the sinotubular junction. This maneuver permits anterior mobilization of the proximal aorta, thus maximizing the transaortic view. The aortic valvar leaflets are retracted carefully to expose the defect. Often there is absence of a superior muscular or fibrous rim to the defect, making placement of sutures difficult. In this situation, mattress sutures buttressed with pledgets may be taken through the aortic wall from the inside of the aortic valvar sinuses. This exposure has also been used for the subaortic VSDs encountered in the setting of double-outlet right ventricle [83].

Right Ventricular Approach

This incision (Figure 17.29) [30] is now infrequently used for closure of isolated VSDs, as the majority can safely be

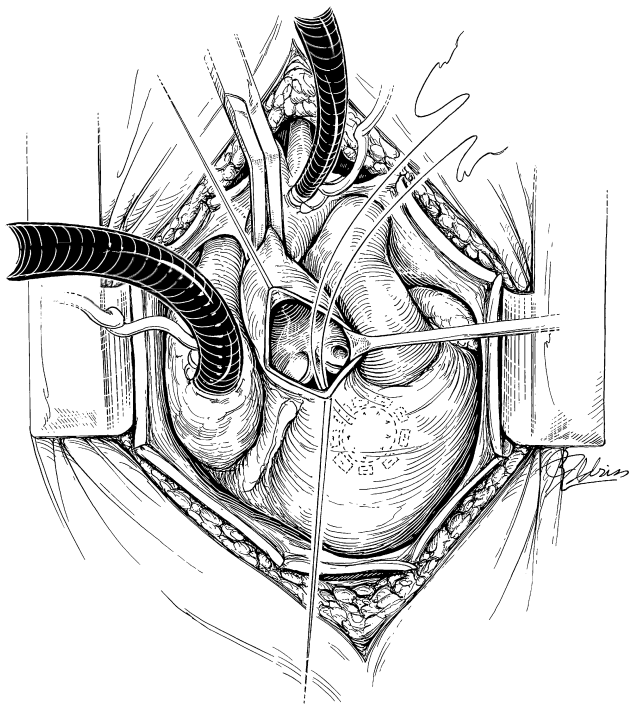

Figure 17.28 Transaortic approach to VSD closure can be applied if the VSD is subarterial and if other indications warrant intra-aortic exposure. Because of the increased risk of heart block, most surgeons prefer the other approaches for VSD closure.

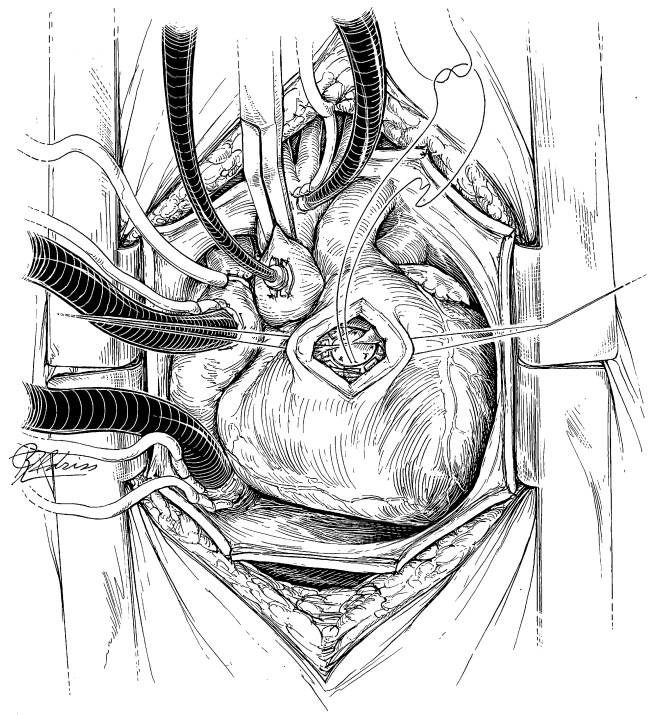

Figure 17.29 Diagram of VSD closure through a right ventriculotomy using aortobicaval cannulation, aortic cross-clamp with cardioplegia, and interrupted pledget-supported sutures.

approached through the right atrial, transpulmonary, or transaortic routes. Should the incision be required, it can be transverse or vertical. The transverse incision may have the advantage of limiting injury to the myocytes aggregated in circular fashion in the subpulmonary infundibulum, albeit that the exposure may be restricted. It is also inadequate when it proves necessary to enlarge the infundibulum with a patch.

The vertical incision should be limited to the infundibular area. Under direct vision, it is usually started in the middle of the anterior infundibular wall between traction sutures and extended upward in the direction of the pulmonary trunk or downward toward the apical component of the right ventricle.

The epicardial distribution of the coronary arteries should be established before beginning the ventriculotomy, in particular the origin of the left anterior descending artery from the main left coronary artery. On occasion, this artery arises as a branch of the right coronary artery and crosses the infundibular wall. At other times, there can be dual supply, with one branch originating from the left coronary artery and the other as an extension of a large conal artery arising from the right coronary artery. In either of these situations, a ventriculotomy is dangerous and should be avoided because of the possibility of injury to the myocardium supplied by the left anterior descending coronary artery. Infrequently, these arteries crossing the infundibulum are intramyocardial and may not clearly be seen. The coronary arterial distribution may also be obscured by adhesions resulting from previous surgery.

The indications for right ventricular incisions include inaccessibility from the right atrium or pulmonary trunk, the presence of a defect opening directly into the infundibular area, optimization of exposure in the presence of obstructive infundibular muscle bundles, and difficulty exposing the inferior margin of an outlet defect. A ventricular incision may optimize exposure in the presence of abnormal and obstructive infundibular muscle bundles that may require resection. Oftentimes these muscle bundles cannot be excised adequately from a right atrial incision, especially when enlargement of the infundibulum with a patch is deemed necessary. A ventricular incision may also be necessary should difficulty be encountered in exposing the inferior margin of an outlet defect due to absence of the subpulmonary infundibulum. A small infundibular incision will help in securing the patch to the inferior border of the VSD. At times this may be accomplished through the right atrium without ventriculotomy.

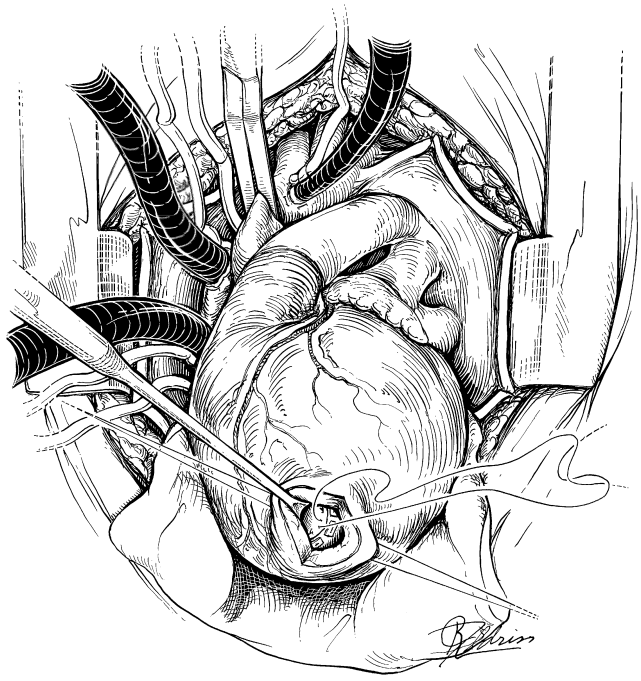

Figure 17.30 Diagram of left ventricular exposure for an apical muscular VSD using aortobicaval cannulation, aortic cross-clamp with cardioplegia, and interrupted pledget-supported sutures. Care is taken to limit the left ventriculotomy to the apex away from the converging coronary arteries. Midmuscular VSDs, on the other hand, are best approached through a right atriotomy to avoid left ventricular dysfunction, which is associated with larger and higher left ventriculotomies.

Left Ventricular Approach

This approach (Figure 17.30) [30] is rarely used. It is limited to closure of certain types of apical muscular defects, particularly those with multiple sieve-like perforations. These defects may be easier to patch from the left ventricular side because of the relatively smooth septum, unlike the right ventricle with its coarse trabeculations and attachments of papillary muscles. The muscular defects, when viewed from the right side, may be hidden or divided by the ventricular trabeculations, thus appearing as multiple openings on the right side, but having a single opening when seen from the left side of the septum.

There are two types of left ventricular incisions. The more frequently employed vertical incision [84] starts in the relatively avascular left ventricular apical area and requires limited extension superiorly. The alternative is to make a transverse incision [85]. In either case, attention to the distribution of the coronary arteries is essential to minimize injury. Left ventricular incisions, except for the small apical incisions that are well tolerated, should be avoided whenever possible to minimize the possibility of associated significant long-term ventricular dysfunction [86].

Relationship of the Conduction Pathways to Different Types of Ventricular Septal Defects

The relationship of the atrioventricular bundle to isolated VSDs was determined by the early work of Lev [87], Truex and Bishof [88], and more recently by Kurosawa and Becker [89], and Milo and colleagues [90]. These contributions enhanced surgical knowledge and awareness of the location of the pathways for atrioventricular conduction, and decreased the incidence of intraoperative injury. Damage to the atrioventricular node, the penetrating bundle, or its right or left branches may result from a suturing needle, from snaring by the suture material, by fibrosis, from hemorrhage, or by anoxic insult. Direct pressure and trauma from rough handling of surgical instruments may also contribute to the occurrence of atrioventricular and intraventricular conduction disturbances [91,92].

When the intracardiac anatomy is viewed through the most commonly used right atrial approach, the location of the atrioventricular node is indicated by the apex of the triangle of Koch (Figure 17.25) [30]. This location does not vary appreciably with the different types of isolated VSDs, aside from the VSD associated with straddling and overriding of the TV. The surgeon can identify the area by the depression or concavity felt by palpation above the coronary sinus and between it and the attachment of the septal leaflet of the TV. From the apex of the triangle, the atrioventricular bundle penetrates the central fibrous body to reach the crest of the muscular ventricular septum. There are variations, however, in the course of the conduction bundle, its depth within the ventricular myocardium, and its relationship to the septal crest.

Avoiding Conduction Injury During Closure of Different Types of Ventricular Septal Defects

Defects Having a Muscular Posteroinferior Rim

Such muscular rims are found in muscular outlet VSDs and in the majority of doubly committed and juxta-arterial VSDs. In the presence of such a muscular rim, the conduction bundle is usually at a safe distance from the margin of the defect. Although the sutures for closure of the defect can be placed with minimal fear of injury to conduction axis, conduction disturbances can occur due to careless introduction of instruments, such as a suction tip, into the right ventricle. In some large VSDs, however, with minimal formation of the caudad limb of the septal band, the inferior rim of the defect may be very close to the bundle of His.

Perimembranous Ventricular Septal Defects

The major danger area for all perimembranous VSDs, apart from those associated with straddling and overriding of the TV, is the inferior and posterior region of the defect as seen from the right atrium through the tricuspid valvar orifice. The region is generally between the area of the medial papillary muscle of the conus (Lancisi) and the corner where the defect meets the tricuspid annulus, near the remnant of the membranous septum. In the type of defects that have some extension toward the inlet of the right ventricle, the medial papillary muscle may be more anterior and superior in location than usual.

Inlet Ventricular Septal Defects

In the VSDs opening to the inlet of the right ventricle, the medial papillary muscle is usually located more superiorly in relation to the edge of the defect. A consistent guide to the location of the penetrating bundle remains the apical area of the triangle of Koch. From this point the common bundle courses around the inferior aspect of the defect. This type of defect can be distinguished from the muscular inlet type by absence of a muscular ridge in the inlet (Figure 17.3).

Muscular Ventricular Septal Defects

Muscular VSDs opening to the apical part of the right ventricle are unrelated directly to the conduction bundles, and those opening to the outlet are protected from the conduction axis by the caudad limb of the septal band. For muscular defects opening to the inlet of the right ventricle, the conduction axis is found anterosuperiorly relative to the defect (Figure 17.3).

Gerbode Ventricular Septal Defects

The rare left-ventricular-to-right atrial defects located in the atrioventricular portion of the atrial septum are at less risk to the conduction system during closure [40]. Some perimembranous defects, however, may simulate the LV-to-RA defects by shunting through an opening in the TV septal leaflets and have the same risk of injury to the conduction system as other perimembranous VSDs.

The Conduction System and the Transaortic approach

In the normal heart, the nonbranching part of the atrioventricular bundle passes under the fibrous triangle interposed between the noncoronary and right coronary leaflets of the aortic valve. In the presence of a VSD, however, the bundle can be located near the left corner and left inferior border of the defect, close to the junction of the central fibrous body, the remnant of the membranous septum and the mitral valve, and directly beneath the noncoronary leaflet of the aortic valve. Hence, the area extending from under the noncoronary leaflet toward the zone of apposition with the right coronary leaflet and extending toward the middle of the right coronary leaflet should be considered a danger

zone with regard to the possibility of surgical injury to the conduction system.

Surgical Management of Ventricular Septal Defects with Associated Lesions

Patent Ductus Arteriosus

Closure of persistent PDA should not present a significant technical difficulty at the time of repair of an associated VSD. Early in the history of surgical management of this combination, correction was performed in two stages. First, ligation of the patent duct coupled with banding of the pulmonary trunk was performed early in infancy, followed at an older age by a second-stage definitive closure of the VSD, debanding of the pulmonary trunk, and arterioplasty.

This early approach has been generally abandoned in favor of a single-stage repair. Infrequently, the two-stage approach is indicated in small sick infants with severe ventricular failure due to multiple muscular or Swiss-cheese VSDs, which may present significant technical difficulties with incomplete closure and unsatisfactory results when primary repair is attempted.

The PDA is easily isolated through the median sternotomy. After opening the pericardium, dissection along the pulmonary trunk carried distally leads to the duct, which is situated in the space near the pulmonary arterial bifurcation between the left pulmonary artery and the aorta.

Several precautionary steps should be taken. During dissection to expose the patent duct, the surgeon should be cognizant at all times of the intimate relationship with the recurrent laryngeal nerve. Hugging too close to the aortic wall during dissection at the aortoductal junction or too close to the sometimes very friable ductal wall should be avoided. The surgeon should carefully clarify the margins of the duct and its aortic and pulmonary relationship before passing an instrument or a ligature around it in order to prevent the possibility of accidental ligation of the left pulmonary artery.

The duct itself should be ligated before initiation of bypass whenever feasible, or exposed enough to be readily closed as soon as bypass is started. Presence of a large open duct during extracorporeal circulation will produce a steal from the aorta into the lower-resistance pulmonary circulation, causing difficulties in maintaining perfusion pressure and possibly causing pulmonary congestion and hemorrhage.

Ventricular Septal Defect with Aortic Insufficiency

Aortic insufficiency (AI) is known to be associated with either the doubly committed subarterial VSDs or perimembranous VSDs opening to the outlet of the right ventricle [69,93–96].

In general, it is the right coronary leaflet of the aortic valve that prolapses into the VSD when the defect is doubly committed (conal VSDs), while the noncoronary leaflet is prolapsed with perimembranous VSDs. At times, the right coronary leaflet near its zone of apposition with the noncoronary leaflet, as well as the noncoronary leaflet itself, protrudes into the defect. The left coronary leaflet is rarely involved [97].

Concomitant repair of the prolapsing leaflet during closure of the VSD depends on the extent of prolapse and the severity of aortic regurgitation. In patients with aortic prolapse and/or mild aortic insufficiency, closing the defect with a patch at a relatively early age has the effect of treating the prolapse by supporting the leaflet and eliminating the windsock or Venturi effect through the open VSD.

In patients with moderate-to-severe aortic regurgitation, consideration should be given to performing an aortic valvoplasty, especially in the older child with long-standing prolapse and a markedly distorted and stretched aortic valvar leaflet. Transaortic exposure is usually employed for aortic valvoplasty, while the VSD itself can be closed through either the transaortic or right atrial approach. Yacoub [98] has advocated a transaortic approach to repair the prolapsing leaflet and suggests closing the VSD using sutures but without inserting a patch. The principles of repair center on reefing of the redundant aortic leaflet and approximation of the inferior rim of the VSD with the hinge of the leaflet from the valvar sinus.

In the presence of moderate-to-severe aortic valve regurgitation, there is a large steal of blood flow from the aortic cannula to the left ventricle during bypass. This will tend to diminish the effectiveness of extracorporeal circulation, distend the left ventricle, and interfere with myocardial perfusion. Left ventricular distention becomes especially severe when the heart fibrillates. Important and rapid sequential steps need to be taken on initiation of bypass to prevent this situation.

On initiation of bypass and positioning of a left ventricular vent, the aorta is cross-clamped and opened. General body cooling is simultaneously begun with cold cardioplegia directly injected into the orifices of the coronary arteries. Alternatively or in combination, retrograde cardioplegia may also be employed. The left ventricular outflow tract is explored to evaluate the location of the VSD, and to determine if closure can be performed through the aorta, or in combination with another type of intracardiac exposure.

Aortic valvar competence is achieved by making the length of the stretched free margin of the prolapsed leaflet equal to that of the adjacent normal leaflets. The center of all three leaflets is approximated through the corresponding body of Arantius with a temporary suture that allows accurate comparison of the opposing three leaflets and helps determine the extent of the needed plication.

Shortening and anchoring of the prolonged leaflet can be accomplished by reefing, plication, or by closing part of the zone of apposition with the adjacent leaflets [97–103]. Although coaptation of the repaired valve may appear quite satisfactory at termination of the procedure, there is a tendency for disruption, continued stretching, and recurrence of regurgitation, particularly in those with long-standing prolapse. The technique of shortening the leaflet and fixing the folded portion of the redundant leaflet to the aortic wall between buttressed sutures [97] provides a relatively secure repair (Figure 17.31) [30]. Often more than one technical maneuver will be needed to accomplish successful and stable correction.

In extreme cases, where the aortic valve has been badly distorted and damaged with fibrosis, calcifications, and hemodynamic changes, replacement may be the only satisfactory solution. Under these circumstances, the surgeon may elect to implant a prosthetic or biologic valve. We believe that early repair [69] of the doubly committed (conal, subarterial) or perimembranous VSDs should be undertaken whenever a prolapsing aortic leaflet is identified, even before the onset of aortic regurgitation, and even though the left-to-right shunt may be hemodynamically small. This treatment policy will prevent progression to the more extreme stages of valvar distortion that necessitate eventual replacement of the aortic valve.

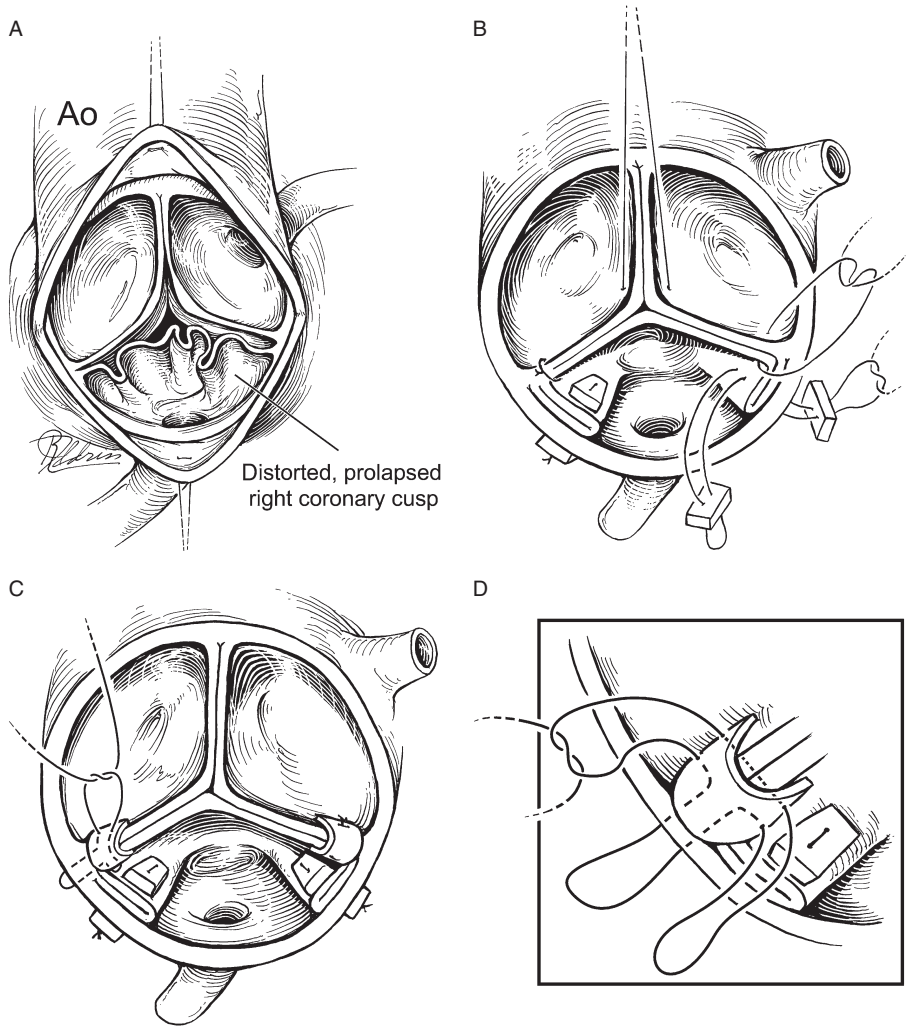

Figure 17.31 Diagram of aortic valve repair. **A**, Elongated free margin of prolapsed right leaflet. **B**, Suture in corpora arantii allowing accurate comparison with apposing leaflets to determine extent of plication. Suture at commisure to maintain correct leaflet length. **C**, Fold of excess valve securely sandwiched against aortic wall by pledget-supported mattress sutures. **D**, Commisure reinforced with hood of pericardium.

Ventricular Septal Defects with Coarctation of the Aorta

Coarctation of the aorta is often associated with VSDs, albeit with varying incidence in reported series. In one study at the Hospital for Sick Children [104] in London, a VSD was found in one-sixth of a cohort of infants and children operated for repair of coarctation, with similar findings reported from the Royal Brompton Hospital, also in London [105]. A study of 100 autopsied specimens from subjects with coarctation of the aorta revealed that patients under 6 months of age with coarctation and VSD frequently had associated tubular hypoplasia of the aortic arch [106].

The morphology of the VSDs associated with coarctation of the aorta has been the focus of several autopsy studies [107,108] and echocardiographic investigations [109]. These showed that the outlet septum could be deviated rightward with aortic overriding or leftward alignment to narrow the subaortic area. In the majority of cases studied, narrowing of the left ventricular outflow tract was present due to hypertrophic muscle bundles, anomalous attachments of the mitral or TVs, septal bulges, or fibrous ridges. These findings give credence to the hypothesis that coarctation of the aorta is induced by a compromise of flow to the ascending aorta during fetal life. When coarctation is associated with a VSD, the surgeon may be faced with more complex problems, and there are several options for surgical management.

One option is to repair the coarctation only. This is applicable when the VSD is small and likely to close spontaneously, or if it is moderate in size and can be managed medically [110,111]. This option has limited applicability to patients with hemodynamically insignificant defects. Although some success can be attained in medical management of infants with more significant VSDs after repair of coarctation of the aorta, it is difficult to select the patient in advance.

Another option, repair of the coarctation and banding the pulmonary trunk [112,113], has been used extensively in infants with large left-to-right shunts and severe heart failure. The surgical approach is through a left thoracotomy incision. The coarctation is repaired and the pulmonary trunk is then banded. There is a trend toward avoiding banding because of several disadvantages. Scarring of the pulmonary trunk may necessitate extensive arterioplasty at the time of debanding, leaving the child subject to restenosis. Obstruction to the right ventricle, in cases where the VSD is spontaneously becoming smaller while waiting for the second-stage repair, is especially dangerous if there is recurrence of the coarctation, or if it is associated with narrowing of the left ventricular outflow tract. This situation results in obstruction to the outflow from both the left and right ventricles, which often leads to significant heart failure.

Still another option is to perform concomitant repair of both lesions using two incisions [114]. The coarctation is repaired first through a left thoracotomy, followed by repair of the VSD through the standard median sternotomy. The clinical results with this approach have been excellent. The proponents of this approach cite better exposure for repair of the coarctation with the left thoracotomy, avoidance of circulatory arrest that is necessary to adequately repair the coarctation from the front, and the excellent tolerance infants have for the double incision.

Simultaneous repair of the VSD and coarctation can also be achieved through a median sternotomy. Historically, this method produced suboptimal results [15,16,19,110]. Recent experience, however, has been more favorable, now making the combined approach the procedure of choice [115–120]. The procedure can be performed with deep hypothermia and circulatory arrest. While cooling the infant, extensive dissection of the great vessels and descending aorta is performed that permits coarctectomy and extended end-to-end anastomosis. This maneuver also corrects the frequent problem of hypoplasia of the transverse aortic arch. Most surgeons prefer to perform the coarctectomy and extended end-to-end anastomosis during a brief period lasting from 15 to 20 minutes of deep hypothermia circulatory arrest, followed by closure of the VSD once cardiopulmonary bypass is re-established [121]. Others [122,123] have used low-flow perfusion via the brachiocephalic artery to achieve the same results. There are similar differences in the technique used to close the VSD. While some surgeons prefer to repair the coarctation and close the VSD during one period of deep hypothermia and circulatory arrest, most, having repaired the coarctation, have used perfusion to close the VSD. This method is in keeping with recent trends to limit, as much as possible, the period of circulatory arrest when there are reasonable alternatives [124–127].

Complications

Complications of closure of VSDs are generally related to injury to the anatomic structures, inadequate exposure, and the conduct of cardiopulmonary bypass.

The anatomic structures that are at risk during VSD closure are the conduction system and the leaflets of the tricuspid and aortic valves. Transient arrhythmias are not uncommon after closure and can be associated with close contact with the atrioventricular node and His bundle during administration of cardioplegia. Right bundle branch block, not usually found in patients undergoing transatrial closure, is a frequent finding in those undergoing transventricular closure. This is not related to subsequent serious conduction disturbances [128,129]. Complete heart block requiring a pacemaker should now be avoidable, albeit often reported in 1–2% of cases [130]. Injury to the aortic

valve can occur during closure due to inappropriate incision of the TV, placement of sutures, or both. These problems can result in aortic insufficiency. Hemolysis has also been reported in these circumstances with the insufficient aortic jet striking the VSD patch [131]. Tricuspid insufficiency can occur if the cords are foreshortened by the VSD patch. If severe, the aortic and/or tricuspid valvar defects should be repaired.

Incomplete closure can be due to inadequate exposure, disruption of sutures placed in immature or diseased myocardium, and bacterial endocarditis. This complication occurs in less than 5% of cases, and reoperation is indicated if the residual left-to-right shunt is greater than 1.5 to 1. The introduction [132] and routine use of intraoperative epicardial and, later, transesophageal echocardiography has given the surgeon the capability visually to evaluate the closure and to intervene, if necessary, to close residual or undiagnosed defects. Intraoperative echocardiography has been instrumental in decreasing the incidence of residual shunts and has been shown to be cost effective despite the increased resources that are necessary for its routine use [133–135].

Complications related to the conduct of cardiopulmonary bypass are usually the result of deep hypothermia and circulatory arrest. The incidence of neurologic complications is directly related to the period required for circulatory arrest. While some have noted few deleterious neurologic and developmental effects with deep hypothermia and circulatory arrest [136,137], others [124–127, 138–140] have noted significant motor and intellectual abnormalities not generally seen in those who had continuous cardiopulmonary bypass. We prefer continuous cardiopulmonary bypass whenever possible, even in babies weighing 2 kg or less, with short periods of very low flow, using hypothermic circulatory arrest only when absolutely necessary.

Results

Operative mortality for VSD closure has decreased considerably over the past two decades because of improved techniques of cardiopulmonary bypass, myocardial preservation, and postoperative care. In older patients with uncomplicated VSDs the mortality should now approach zero [66]. Mortality in infants, which had been higher [141,142] due to the severity of the left-to-right shunt and their size, has steadily improved allowing surgeons to perform cardiopulmonary bypass safely and close VSDs successfully in premature infants weighing as little as 700 g [143].

Over a span of 14 years, from 1990 to 2004, we closed isolated defects in 358 infants and children at Children's Memorial Hospital, Chicago. These numbers include patients with an atrial septal defect and/or a persistent PDA. The classification of the VSD at the time of surgery and corresponding percentages are shown in Table 17.1. None of our patients died. Heart block occurred in seven patients (1.9%). In six of these, the patients had Down syndrome with inlet VSDs. There were no residual VSDs. Postoperative complications are shown in Table 17.2. These results are consistent with other published series [144,145] and underline the current effectiveness of surgical closure in infants and children.

Transcatheter/Transventricular Device Closure

The introduction of transcatheter closure of atrial and ventricular septal defects has been associated with therapeutic controversies comparing catheter and surgical techniques [146–154]. The development of VSD occluders has undergone many iterations that have resulted in improved delivery systems and higher rates of complete closure [146–154]. Device closure of VSDs has been applied to muscular [155–158] and perimembranous [146–154] subtypes, with the

Table 17.1 Surgical classification of VSD (1990–2004), Children's Memorial Hospital.

Type	Patients	%
Perimembranous (type II, paramembranous, Conoventricular)	284	79
Doubly committed juxta-arterial (type I, subarterial, supracristal, conal septal defect, infundibular)	34	9
Muscular	16	4
Atrioventricular septal defect with exclusively ventricular shunting (type III, inlet, atrioventricular canal type)	12	3
Multiple defects	12	3
Direct Gerbode defect	6	1.7
TOTAL	358	

Table 17.2 Complications of VSD closure during the period from 1990 to 2004 at Children's Memorial Hospital.

Type	Patients	%
Death	0	0
Heart block requiring pacemaker	7*	1.9
Reoperation for bleeding	4	1.0
Significant residual shunting	0	0

*6 of 7 had Down syndrome.

devices delivered either by transcutaneous or perventricular techniques [158].

Perhaps the least controversial therapeutic application of transcutaneous or perventricular closure is in patients with muscular VSDs. Apical and anterior muscular defects can be difficult to visualize by surgical techniques owing to obstructing trabeculations and uncertainty regarding the detection of the margins. Self-centering devices have been used effectively in these situations, because identification is enhanced by flow velocity and absence of confounding trabeculations on the left ventricular side. In addition to effective identification, transcatheter or perventricular techniques allow closure without cardiopulmonary bypass or aortic cross-clamping. Disadvantages of this technique are unwanted disruption of atrioventricular tendinous cords, device embolization, hemolytic anemia, and the yet to be determined long-term effects of a large metallic mass in the heart. In particular, heart block for closure of muscular VSDs is rare. Open surgical closure, on the other hand, has the distinct advantage of avoidance of cannulation of the femoral vessels and allows the surgeon to address other hemodynamic problems such as additional VSDs, a significant atrial septal defect, or coarctation of the aorta.

Significant controversy exists with transcatheter closure of perimembranous defects compared with open surgical techniques. During the development and clinical application of transcatheter closure, significant problems were encountered such as aortic insufficiency, hemolytic anemia, tricuspid regurgitation, device embolization, endocarditis [159], and complete heart block. In particular, the incidence of complete heart block requiring a pacemaker has been reported to be 5.7% [146] and as high as 22% [160], which compares unfavorably to surgical closure and ideally should now be zero. The impact of life-long pacer therapy for children undergoing transcatheter closure cannot be overemphasized, as this enduring complication can be associated with pacer-induced cardiomyopathy and an abbreviated life span.

The difficulty with transcatheter closure of perimembranous VSDs is the basic anatomy relative to the conduction system. Most self-centering devices are firm and by necessity hug the left ventricular lip of the VSD, exactly the location of the bundle of His. This fact will always challenge transcatheter techniques, as complete heart block can occur acutely or remotely and potentially result in sudden death. At the present time, most clinicians consider the rate of complete heart block following transcatheter closure of perimembranous VSDs to be unacceptable [160].

Conclusions

In summary, the results of operative closure of VSD are very good. The risk of mortality for all patients including those with pulmonary arterial hypertension is less than 1%. The risk of major morbidity, atrioventricular block requiring a pacemaker, emergent reoperation, and significant residual shunting are all approximately 1%. Thus over 96% of patients have excellent outcomes when surgeons have used the surgical techniques outlined in this chapter.

CHAPTER 18

Atrioventricular Canal Defects

Carl L. Backer[1] and Constantine Mavroudis[2]

[1]Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Chicago, IL, USA
[2]Florida Hospital for Children, Orlando, FL, USA

The atrioventricular canal defects, also referred to as atrioventricular septal defects or endocardial cushion defects encompass a wide spectrum of anatomic findings. The pathognomonic feature of this group of hearts is a *common atrioventricular junction* [1]. The complete atrioventricular canal defect consists of a large ventricular septal defect beneath the plane of the atrioventricular (AV) valves, an atrial septal defect immediately superior to the plane of the AV valves, and instead of two AV valve orifices, a single or common AV valve orifice. Atrioventricular canal defects account for 4% of all congenital cardiac malformations and over half of the cardiac defects seen in children with trisomy 21 [2,3]. There can be varying degrees of incomplete development of the septal tissue surrounding the AV valve, along with varying degrees of abnormalities of the AV valves themselves, leading to the broad classification of partial, intermediate, and complete AV canal defects [4].

The first successful repair of a complete atrioventricular canal defect was reported by Lillehei and colleagues in 1955, using cross-circulation and direct suture of the atrial rim of the septal defect to the crest of the ventricular septum [5]. The early experience with surgical correction of complete atrioventricular canal had a high mortality and a high incidence of complications such as complete AV block, residual AV valve insufficiency, and subaortic stenosis. Developments in the understanding of the precise anatomic details of this lesion and refinements in operative technique have led to substantial improvement in patient outcome [6]. A significant advance occurred in 1958 when Maurice Lev described the location of the bundle of His in patients with complete AV canal [7]. This understanding resulted in a significant reduction in the incidence of postoperative heart block. In 1962, James Maloney and Frank Gerbode independently described a single-patch technique suspending the AV valve tissue to a single patch that closed both the atrial and ventricular septal defects [8,9]. Giancarlo Rastelli and colleagues at the Mayo Clinic described a classification system of complete atrioventricular canal in 1966 that emphasized the heterogeneity of this lesion and the different approaches required by different anatomic findings [10]. The two-patch technique was first reported by George Trusler in 1975 [11]. This technique employed a Dacron patch to close the ventricular septal defect component, suturing the valve leaflets to the crest of the ventricular septal defect patch, closing the left AV valve zone of apposition, and using a pericardial patch to close the atrial septal defect component. Most recently, Ben Wilcox from the University of North Carolina at Chapel Hill [12] and Graham Nunn from Sydney Children's Hospital [13] have reported a technique of repair that does not use a patch for the ventricular septal defect closure. Congenital heart surgeons should be familiar with all techniques and in point of fact, different anatomic morphology in different patients often lends itself to one of these three techniques.

Historically, pulmonary artery banding played a role in the management of infants with atrioventricular canal who presented early with severe congestive heart failure. However, this strategy of an initial pulmonary artery band followed later by complete repair has been abandoned by most centers. Pulmonary artery banding often results in an increase in AV valve insufficiency and hence does not ameliorate the congestive heart failure [14]. Improvements in neonatal and infant techniques of cardiopulmonary bypass, anesthesia, and postoperative intensive care unit medical management have allowed earlier repair of atrioventricular canal defects with, in nearly all instances, improvement in outcome by earlier date of operation. Most centers currently recommend complete repair of atrioventricular canal defects at the age of 3–5 months.

Pathology and Anatomy

Atrioventricular canal defect represents a spectrum of cardiac anomalies subdivided into partial, intermediate, and complete atrioventricular canal [4,15–17]. Partial atrioventricular canal (also referred to as partial atrioventricular septal defect) has an atrial septal defect adjacent to the AV valves along with a trifoliate left AV valve leading to varying degrees of left AV valve insufficiency (Figure 18.1) [17]. The atrial septal defect is a crescent-shaped defect in the inferior portion of the atrial septum immediately adjacent to the AV valves. Complete atrioventricular canal defect (also known as complete atrioventricular septal defect) has both an atrial septal defect and a defect in the ventricular septum below the common AV valve (Figure 18.2) [17]. In complete atrioventricular canal defect there is a common AV valve that bridges both the right and left sides of the heart, creating superior (anterior) and inferior (posterior) bridging leaflets. These patients always have a "bare area" at the crest of the ventricular septum. Intermediate atrioventricular canal (also known as transitional atrioventricular canal) is "intermediate" between the partial and complete lesions: there are two distinct left and right AV valve orifices, an atrial septal defect adjacent to the AV valves, and a ventricular septal defect below the AV valves [18]. The ventricular septal defect in these patients is usually in the inlet septum, and there is *no* "bare area" at the crest of the ventricular septal defect. These anatomic variations are merely different phenotypic expressions of the same underlying genotype.

The Rastelli classification (Figure 18.3) [4] describes three types of complete atrioventricular canal based on the morphology of the anterior (superior) bridging leaflet, its degree of bridging, and its chordal attachments [10]. The Rastelli classification does *not* relate to the anatomy of the posterior common leaflet or inferior bridging leaflet. In a Rastelli type A defect, the common superior (anterior) bridging leaflet is effectively split in two "halves" at the septum. The left superior leaflet is entirely over the left ventricle and the right superior leaflet is similarly entirely over the right ventricle. This division of the common anterior leaflet into left and right components is caused by extensive attachment of the superior bridging leaflet to the crest of the ventricular septum by chordae tendineae. This morphologic finding effectively divides the anterior common AV valve into right and left components for the surgeon at the time of reconstruction. The anterior common leaflet is "divided and attached." Rastelli type B is quite rare and describes an anomalous papillary muscle attachment from the right side of the ventricular septum to the left side of the common anterior bridging leaflet. In Rastelli type C defects, there is marked bridging of the ventricular

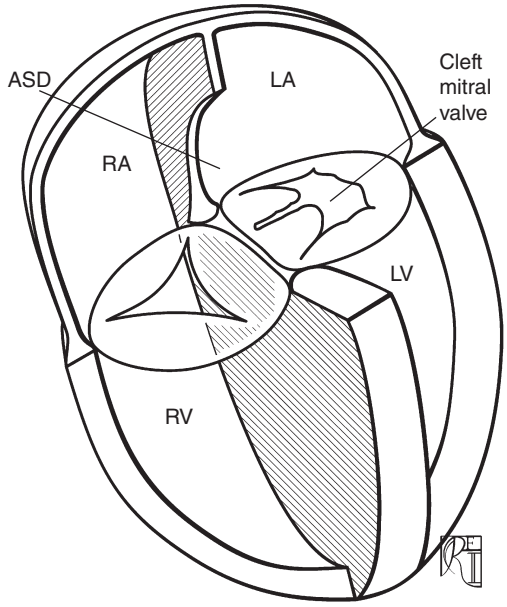

Figure 18.1 Partial AV canal defect. There is an atrial septal defect (ASD) immediately adjacent to the right AV valve and the left AV valve is trifoliate. (LA, RA, left, right atrium; LV, RV, left, right ventricle.)

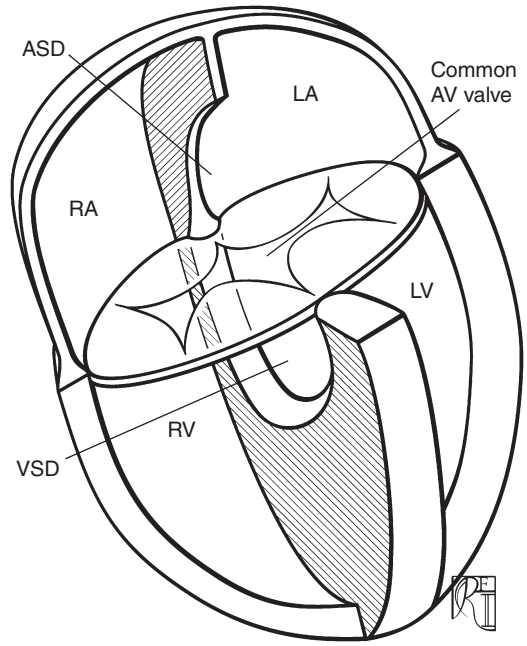

Figure 18.2 Complete AV canal defect. There is a common (single) AV valve with an atrial septal defect (ASD) "above" and a large ventricular septal defect (VSD) "below." There is a common atrioventricular junction. (LA, RA, left, right atrium; LV, RV, left, right ventricle.)

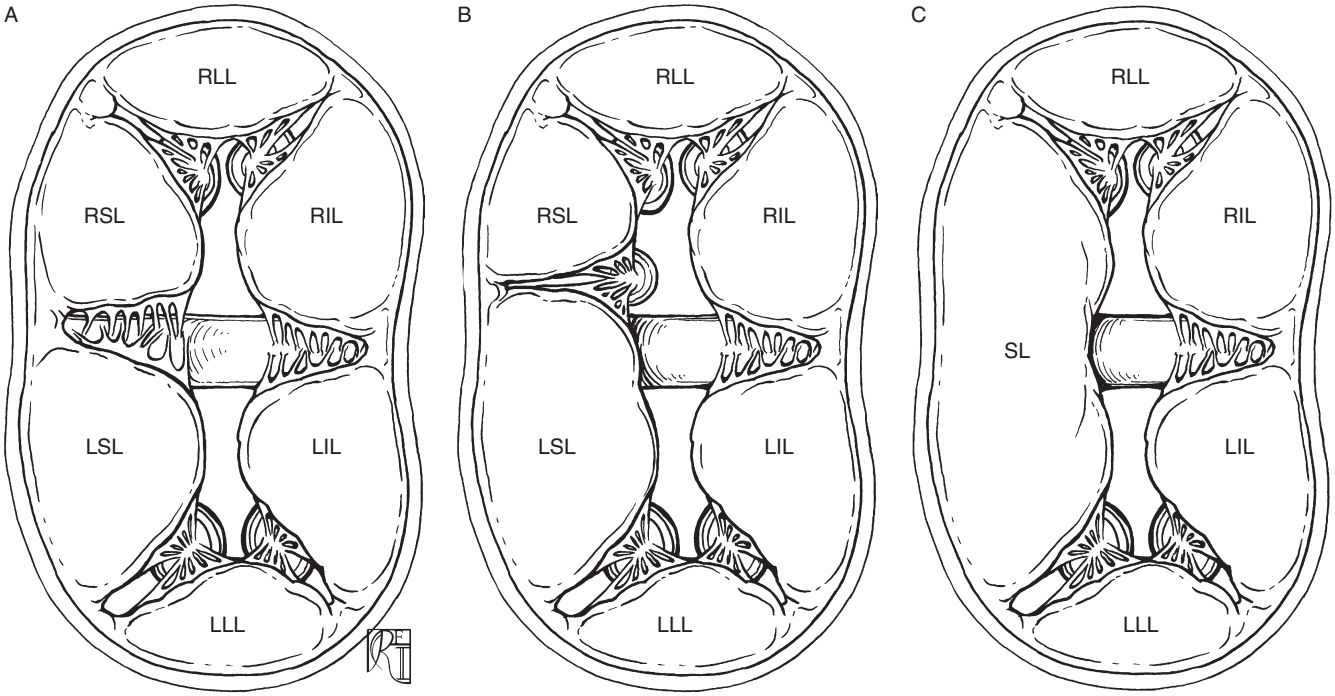

Figure 18.3 Rastelli classification. **A,** In a Rastelli type A defect, the common superior (anterior) bridging leaflet is effectively split in two at the septum; the left superior (anterior) leaflet (LSL) is entirely over the left ventricle, and the right superior (anterior) leaflet (RSL) is similarly entirely over the right ventricle. **B,** Rastelli type B is rare and involves anomalous papillary muscle attachment from the right side of the ventricular septum to the left side of the common superior (anterior) bridging leaflet. **C,** In Rastelli type C defects there is marked bridging of the ventricular septum by the superior (anterior) bridging leaflet (SL). The superior (anterior) bridging leaflet is generally not divided and floats without chordal attachment to the crest of the ventricular septum. The posterior common leaflet may be divided (as shown), or undivided, but nearly always is well attached (as shown). (LIL, RIL, left, right inferior (posterior) leaflets; LLL, RLL, left, right lateral leaflets). (Reproduced with permission from Jacobs *et al.* [4].)

septum by the anterior (superior) bridging leaflet. The anterior (superior) bridging leaflet is *not* divided and floats freely over the ventricular septum without chordal attachment to the crest of the ventricular septum. The anterior common leaflet is "not divided and not attached." In our series of AV canal patients, the Rastelli classification breakdown in 110 patients was Rastelli A, 76 patients (69%), Rastelli B, 10 patients (9%), and Rastelli C, 24 patients (22%) [19].

There is a definite association of complete atrioventricular canal and other conotruncal anomalies, particularly tetralogy of Fallot, double-outlet right ventricle, and transposition of the great arteries. The most common conotruncal anomaly associated with atrioventricular canal defect is tetralogy of Fallot. It is encountered in 6% of cases of atrioventricular canal [20]. The pathophysiology in these patients is dictated by the degree of right ventricular outflow tract obstruction, which causes varying degrees of cyanosis. Congestive heart failure is infrequent in these patients because of the restricted pulmonary blood flow. Double-outlet right ventricle in association with complete atrioventricular canal is also rare (34 of 507 pathology specimens – 6%), and transposition of the great arteries is even rarer (17 of 507 specimens – 3%) [20]. Other anomalies associated with complete atrioventricular canal defect are patent ductus arteriosus (10%), persistent left superior vena cava (3%), and left ventricular outflow tract obstruction (3%) from discrete subaortic stenosis or redundant AV valve tissue.

Deficiencies in the atrioventricular septum in patients with AV canal defects result in displacement of the atrioventricular conduction tissue (Figure 18.4) [7,21,22]. The AV node is more posterior and inferior (near the coronary sinus ostium) than normal. The bundle of His usually courses along the inferior rim of the ventricular septal defect and therefore the bundle branches arise more inferiorly. It is this displacement of the AV node that causes the northwest axis on electrocardiogram.

Hemodynamics/Natural History

Patients with an atrioventricular canal defect initially have excessive pulmonary blood flow resulting from left-to-right shunting at the atrial and ventricular levels. If there

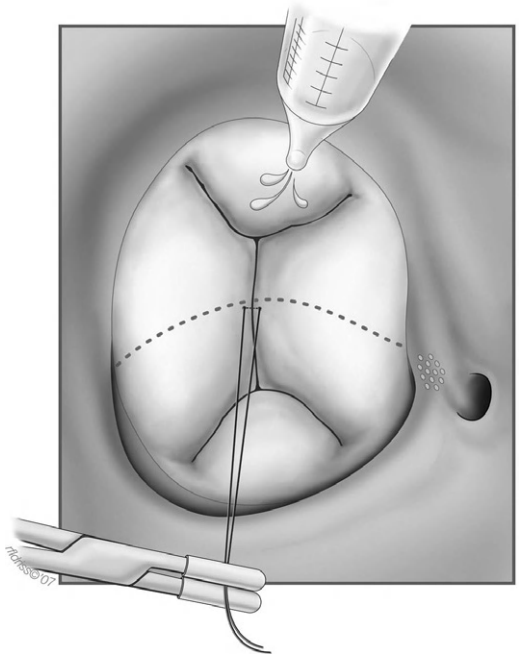

Figure 18.4 This is an illustration of a common atrioventricular valve in a patient with complete AV canal defect. The coronary sinus and the AV node are identified. The dotted line indicates where the AV valve will be divided into right and left components. (Reproduced with permission from Backer *et al.* [22].)

is no interventricular communication, the hemodynamics are similar to those of a large atrial septal defect, with increased right ventricular stroke volume. As the AV valve insufficiency through the left AV valve increases over time these patients may develop a larger left-to-right shunt. In some cases, the regurgitation from the left AV valve proceeds directly into the right atrium. These patients develop progressive cardiomegaly and congestive heart failure that is definitely more significant than in a patient with an atrial septal defect without left AV valve insufficiency.

In patients with a complete atrioventricular canal defect, the large left-to-right shunt causes right ventricular and pulmonary artery pressures to be the same as the systemic pressure. These patients have significant pulmonary hypertension from birth which is unrelenting until they have complete intracardiac repair. These patients can have a relatively rapid progression of their pulmonary vascular disease [23]. Trisomy 21 appears to be associated with accelerated development of pulmonary hypertension [24]. Within a few months of birth the pulmonary vascular resistance is frequently significantly elevated. In our series of AV canal patients, the mean PVR (u/m^2) at 0–3 months was 2.1 ± 0.9, at 4–6 months was 4.0 ± 2.6, and at 7–17 months was 5.7 ± 3.0 [19]. The pulmonary hypertension and congestive heart failure is compounded by the presence of AV valve insufficiency, which increases the ventricular volume overload. It is the rapid elevation of pulmonary vascular resistance and progression of pulmonary vascular obstructive disease that makes early repair of complete atrioventricular canal defects so important.

Diagnosis

Patients with a complete atrioventricular canal defect typically have all the classic symptoms of congestive heart failure in infants. This includes frequent upper respiratory tract infections, poor feeding and inadequate weight gain, and sweating with feeds. On physical examination, these patients will have tachycardia, tachypnea, dyspnea, and hepatomegaly. On cardiac examination the precordium is hyperactive and if there is significant AV valve insufficiency a loud systolic murmur will be present. Chest X-ray will demonstrate cardiomegaly with biventricular enlargement and increased pulmonary vascular markings. Electrocardiographic findings include biventricular hypertrophy, a prolonged P-R interval, and a characteristic northwest or leftward and superior axis.

Two-dimensional echocardiography with Doppler color interrogation has become the standard for diagnosis of atrioventricular canal defects [25,26]. Two-dimensional echocardiography can identify and characterize valvular abnormalities, atrial and ventricular septal defect morphology, and associated anomalies (e.g., left superior vena cava, patent ductus arteriosus, left ventricular outflow tract obstruction). Color flow Doppler imaging provides accurate information regarding the degree of interatrial and interventricular shunting and assessment of AV valve insufficiency. It is more and more frequent now for the diagnosis of complete atrioventricular valve defect to be made on a prenatal ultrasound. Cardiac catheterization was previously frequently used to evaluate patients with complete atrioventricular canal defects. However, because most of these patients are known to have systemic pulmonary artery pressures, the use of cardiac catheterization is now more frequently limited to those patients presenting late in life where there can be a question as to whether or not the pulmonary vascular resistance has elevated to a point where repair is no longer indicated. In our practice, the most common indication for cardiac catheterization is as noted above or to evaluate other associated defects such as tetralogy of Fallot and double-outlet right ventricle. The characteristic "goose neck" deformity is seen in both the partial and complete forms of atrioventricular canal (Figure 18.5) [27]. This is caused by the "unwedging" of the aorta [1].

Indications and Timing of Operation

In patients with a partial atrioventricular canal defect, surgical repair is usually performed electively between 1 and

4 years of age [28,29]. Exceptions to this may occur if there is significant mitral valve regurgitation or hypoplastic left-sided cardiac structures (coarctation of the aorta, abnormal mitral valve, subaortic stenosis) [30]. Patients with complete atrioventricular canal defect usually present with congestive heart failure within the first 1–3 months of infancy. These children should be operated on between the ages of 3 and 5 months [19,31]. Failure to perform the operation until after 6–9 months of age can be associated with the risk of developing elevated pulmonary vascular resistance that is not reversible. Although in most surgical series patients with associated tetralogy of Fallot and significant right ventricular outflow tract stenosis were initially palliated with a preliminary modified Blalock–Taussig shunt, several authors [32–34] have advocated early primary repair.

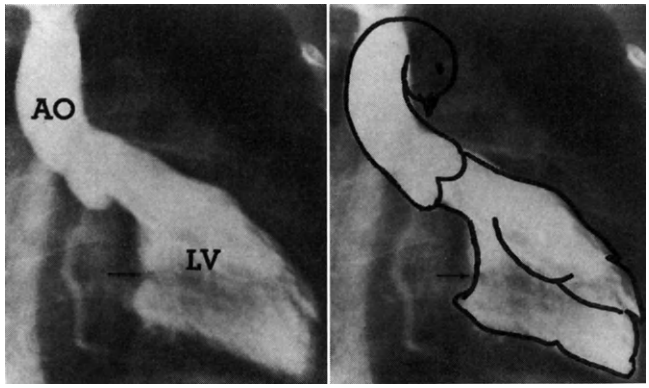

Figure 18.5 Frontal view of a left ventriculogram of a patient with a partial AV canal defect showing a goose-neck deformity. The left ventricular outflow tract is elongated and narrowed. The arrows point to the left AV valve zone of apposition. (Reproduced from Park [27].)

Operative Management and Results

As mentioned in the introduction, pulmonary artery banding was previously used for many patients with a complete atrioventricular canal defect [14,35]. The problem with pulmonary artery banding is that it often makes the left AV valve insufficiency worse and does not result in effective palliation. Most centers have now adopted early primary repair as the procedure of choice. Pulmonary artery banding is only used in exceptional cases where the use of cardiopulmonary bypass must be avoided (cerebrovascular accident, sepsis, etc.). Closure of the partial atrioventricular canal defect is reviewed in Chapter 16, *Atrial Septal Defect, Partial Anomalous Pulmonary Venous Connection, and Scimitar Syndrome*.

The principles of operative management of complete atrioventricular canal defect include closure of the atrial septal defect, closure of the ventricular septal defect, creation of two nonstenotic, competent AV valves, and avoidance of damage to the AV node and bundle of His. Repair of complete atrioventricular canal defects has been described using single-patch, two-patch, and modified single-patch techniques (Figure 18.6) [17]. The method of cardiopulmonary bypass is similar for the different techniques. We have routinely used continuous cardiopulmonary bypass with moderate hypothermia (28–32 °C) and intermittent antegrade cold blood cardioplegia for myocardial protection. In many cases we cannulate the superior

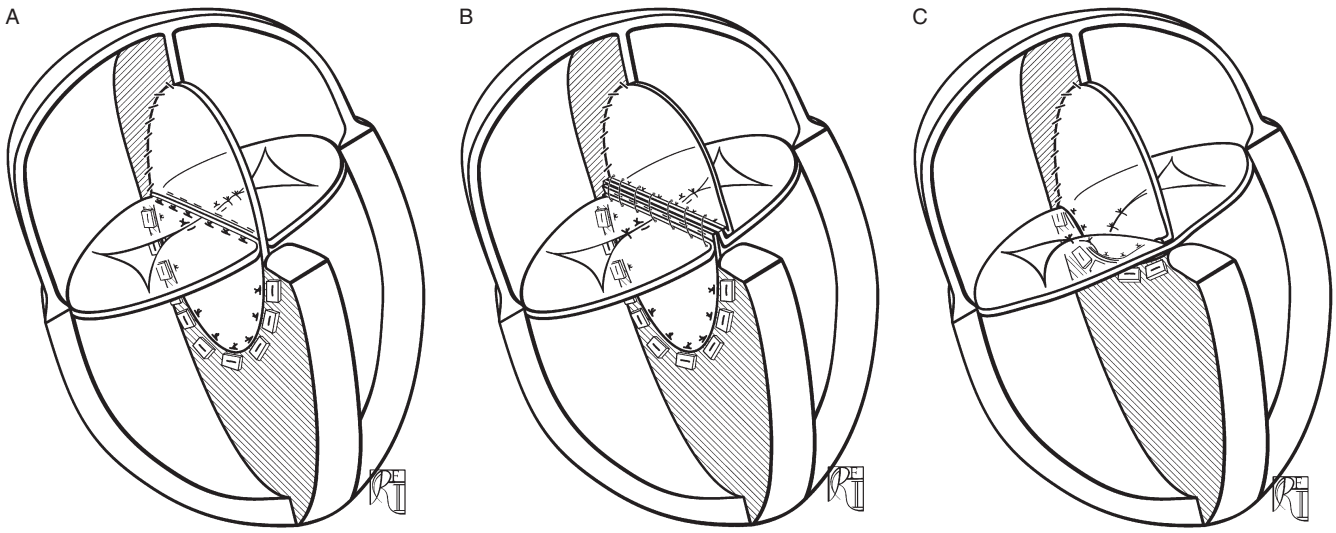

Figure 18.6 Schematic three-dimensional reconstruction of the three different surgical techniques: single-patch (**A**), two-patch (**B**), and modified single-patch (**C**).

vena cava directly with a right angle cannula to improve exposure within the right atrium. We have used a vent placed in the right superior pulmonary vein after beginning cardiopulmonary bypass. This vent can be pulled back into the atrium during the time of the left-sided AV valve repair. It is then reinserted into the left ventricle as the atrial septal defect is closed and the right-sided AV valve repair is performed. We have emphasized a long, medial atriotomy (parallel to the right coronary artery) that extends to a point medial to the inferior vena cava. This offers excellent exposure of the defect to facilitate the repair (Figure 18.7) [17]. Some surgeons are using both antegrade and retrograde cardioplegia [36]. Other centers use deep hypothermia and circulatory arrest, particularly for the younger and smaller infants. We and others use transesophageal echocardiographic assessment for all cases of AV canal [37].

One of the keys to successful repair of atrioventricular canal defects using any technique is a careful inspection of the intracardiac anatomy. This includes an assessment of the right and left ventricular size, the size and shape of the atrial and ventricular septal defect components, the number and location of papillary muscles, and the arrangement of the chordal structures including their attachment to the ventricular septum. The ventricular chambers should be gently filled with cold saline prior to the procedure to float the AV valve leaflets to their closed position. Floating the valvar leaflets with saline helps to identify the line of apposition between the anterior and posterior common leaflets (Figure 18.4) [22]. Careful inspection of the leaflet tissue identifies the line that divides the valves into the right and left components. Some techniques employ division of the common AV valves, some do not.

Single-Patch Technique

The single-patch technique has been described using a pericardial, polytetrafluoroethylene (PTFE), or Dacron patch. The pericardial patch is most commonly used, especially for smaller infants, but carries some risk of aneurysm development at the ventricular level [38]. This can be corrected by fixing the patch in glutaraldehyde. The Dacron patch, although somewhat more malleable than PTFE, runs the risk of postoperative hemolysis should the jet of mitral or tricuspid valve insufficiency strike the Dacron. The patch dimensions are determined by the size and shape of the ventricular septal defect, the distance between the anterior and posterior margins of the AV valve annulus, and the dimensions of the atrial septal defect. This repair is started by floating the AV valve leaflets into the closed position. The line of apposition of the anterior and posterior common leaflets is noted and an imaginary line demarcating the tricuspid and mitral valve components is created by marking the coaptation of the anterior and posterior common leaflets with a horizontal mattress suture (Figure 18.8) [17]. The crest of the ventricular septum is then

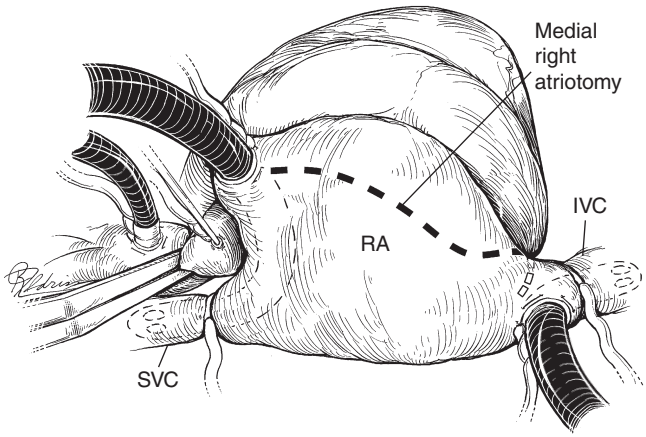

Figure 18.7 Atrial incision. Aortic and bicaval venous cannulation has been accomplished. The aorta has been cross-clamped and cold blood cardioplegia is being administered. The caval tapes have been snared. The dotted line indicates the medial right atrial incision. This incision extends from the right atrial appendage parallel to the right AV groove and the right coronary artery. Note the most inferior extent of the incision which is between the inferior vena cava (IVC) and the right coronary artery and coronary sinus. This incision allows excellent mobilization of the ventricle and resultant exposure of the AV valves. (RA, right atrium; SVC, superior vena cava.)

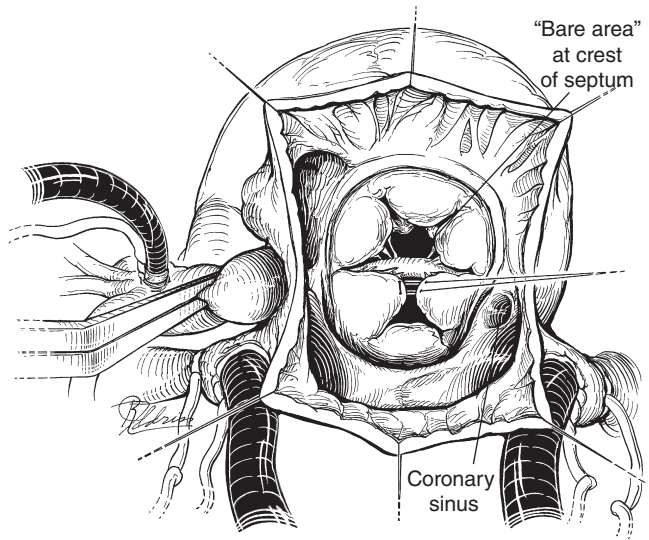

Figure 18.8 Single-patch technique in a Rastelli type A patient. Long medial atriotomy facilitates exposure. The zone of apposition of the superior and inferior bridging components of the left AV valve is approximated with a horizontal mattress suture. This defines the portion of the valve that will become the left AV valve.

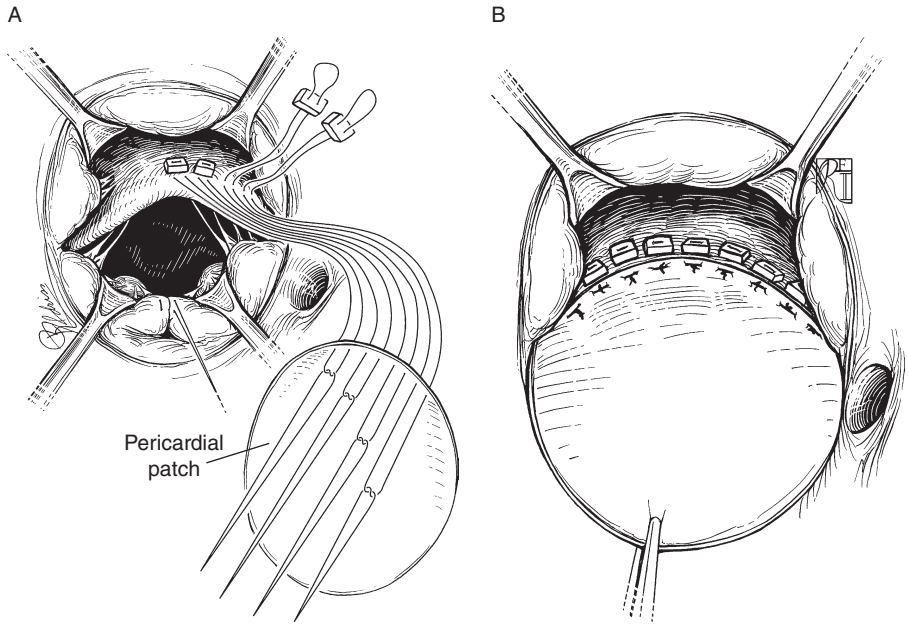

Figure 18.9 A, Pledget-supported horizontal mattress sutures are inserted on the right side of the ventricular septum and passed through the base of the pericardial patch. **B,** The patch is lowered down to the septum and these sutures are then tied.

sutured to the inferior aspect of the patch with multiple interrupted horizontal mattress sutures (Figure 18.9) [17]. It may be necessary to weave the patch carefully around chordal structures. The leftward components of the common AV valve tissue are then secured to the patch in the appropriate plane with multiple interrupted mattress sutures. This may require division of the common AV valve. The left AV valve zone of apposition closure is illustrated in Figure 18.10 [17]. Whenever possible, these same sutures can be used to anchor the right AV valve components to the patch (Figure 18.11) [17]. The atrial portion of the defect is then closed by suturing the superior rim of the patch to the lower rim of the atrial septal defect (Figure 18.12) [17]. Care is taken to avoid injuring the conduction system and the bundle of His by carrying this suture line into the left atrium adjacent to the mitral valve in the region of the coronary sinus. Superficial bites are taken in this region. Some authors recommend displacing the coronary sinus into the left atrium by carrying the suture line of the atrial septal defect up and around the coronary sinus. Both techniques have a similar (low) incidence of complete atrioventricular heart block [19].

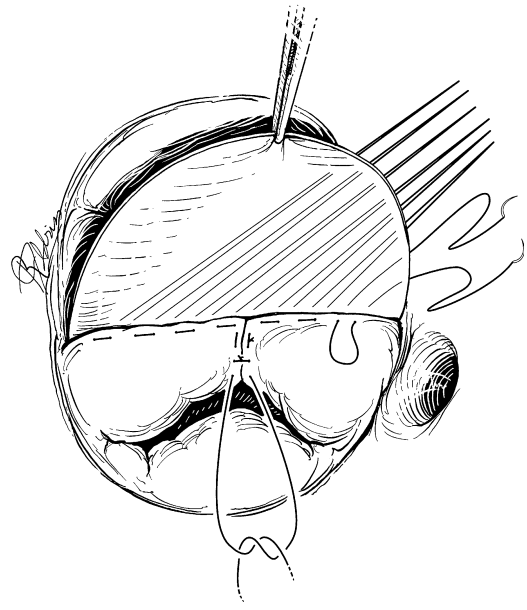

Figure 18.10 The patch has now been reflected anteriorly and a row of horizontal mattress sutures attaches the left AV valve tissue to the patch at the appropriate level. The zone of apposition of the left AV valve becomes apparent as shown and can be closed as indicated.

Two-Patch Technique

The two-patch repair, as first described by George Trusler [11], uses a patch of Dacron or PTFE to close the ventricular septal defect. The valve leaflets are sutured to the top of the ventricular septal defect patch. The left AV valve zone

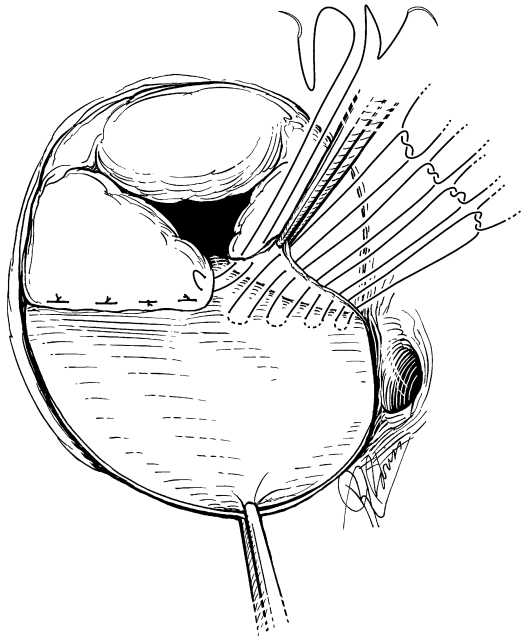

Figure 18.11 The sutures that pass through the left AV valve and through the patch are now passed through the edge of the right-sided AV valve. These sutures, once tied, anchor the valves to the patch at an appropriate height above the ventricular crest.

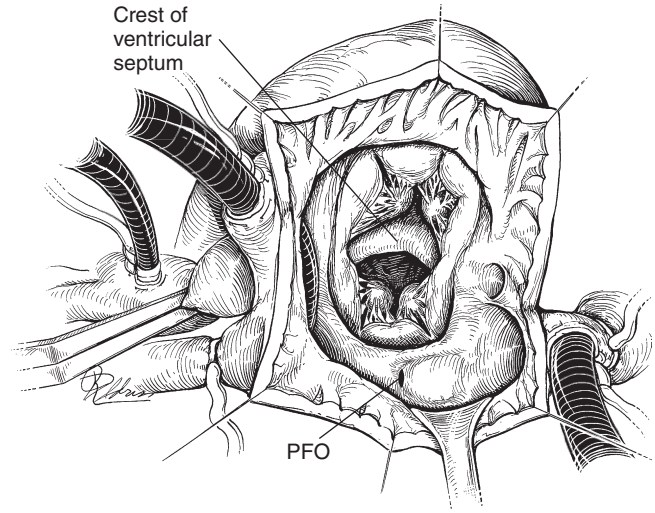

Figure 18.13 Two-patch technique. Exposure of atrioventricular canal defect, Rastelli type A. The right atrium has been opened with the medial atriotomy and stay sutures have been placed. The pertinent anatomic findings are a single common AV valve and the "bare" area at the crest of the ventricular septum that divides the right and left ventricles. In this particular patient there is a patent foramen ovale (PFO). Spatial relationships are demonstrated in Figure 18.14.

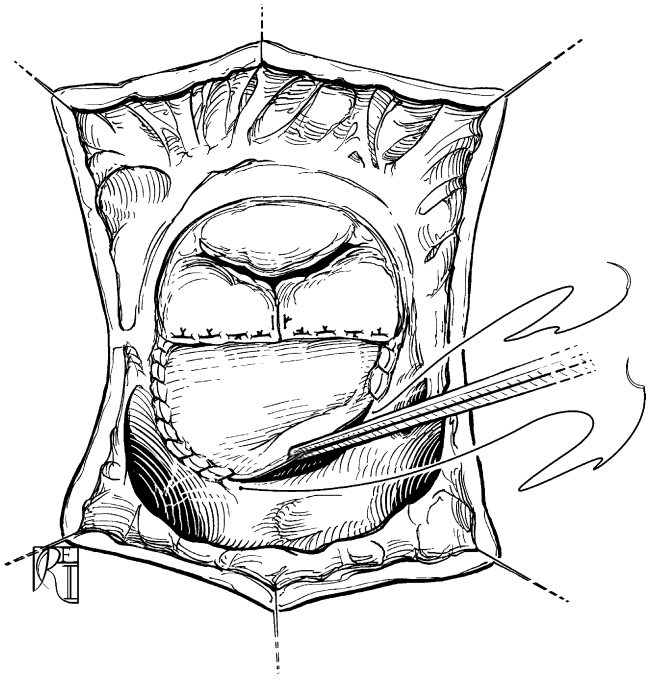

Figure 18.12 The single-patch closure technique is completed by using the pericardial patch to close the atrial septal component of the AV canal with a running suture technique.

of apposition is sutured closed, and a separate pericardial patch is used to close the atrial septal defect. Again, exposure is obtained through a long medial atriotomy (Figure 18.13) [17]. The distance between the superior aspect of what will become the left AV valve and the crest of the ventricular septum (extent of the ventricular septal defect) is assessed to accurately fashion a PTFE patch for the ventricular septal defect component (Figure 18.14) [17]. This will place the AV valves at the proper height above the septum and theoretically prevent subaortic stenosis. The ventricular component of the atrioventricular canal defect is closed with a PTFE patch anchored with interrupted pledget-supported sutures (Figure 18.15) [17]. These sutures are placed on the right ventricular side of the septum to avoid the left bundle and the AV node. In some cases the posterior common leaflet must be divided to fully expose the ventricular septal defect. The left AV valve is then suspended from the PTFE patch after approximating the left superior and inferior leaflets centrally (Figure 18.16) [17]. The left AV valve is sandwiched between the ventricular (PTFE) and atrial (pericardial) patches, as a buttressing measure to prevent sutures from cutting through the valve leaflets, thereby minimizing the chance of valve dehiscence (Figure 18.17) [17,39]. The zone of apposition of the left AV valve created between the left superior and left inferior leaflets is closed with simple interrupted polypropylene sutures (Figure 18.18) [17]. This closure is carried to the insertion site of the first order chordae tendineae at the free

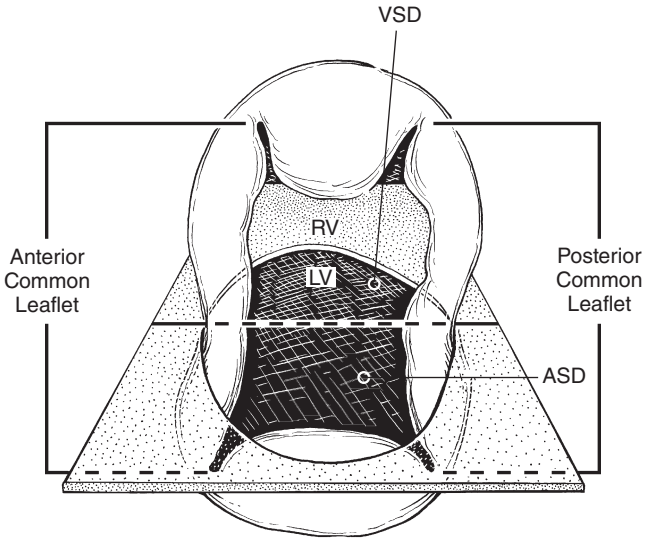

Figure 18.14 A schematic representation of the three-dimensional relationship of the ventricular and atrial septal defects and their location in regard to the AV valve tissue is an important concept to grasp. The imaginary line spatially divides the ventricular septal defect from the atrial septal defect. Standard surgical nomenclature refers to the anterior and posterior common AV valve leaflets as illustrated.

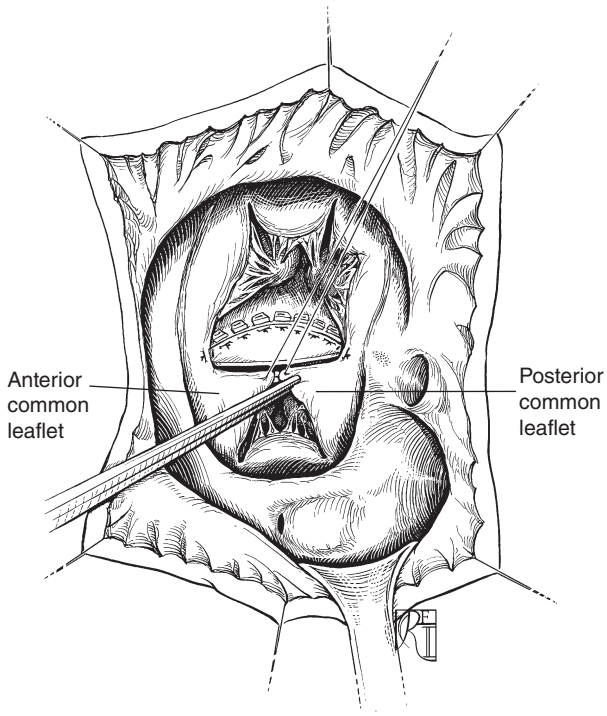

Figure 18.16 The anterior and posterior common leaflets have been brought together in the midline above the crest of the ventricular septal defect patch that has now been tied in place. This sets up the attachment of the left AV valve to the crest of the ventricular septal defect patch and also the location for the zone of apposition closure.

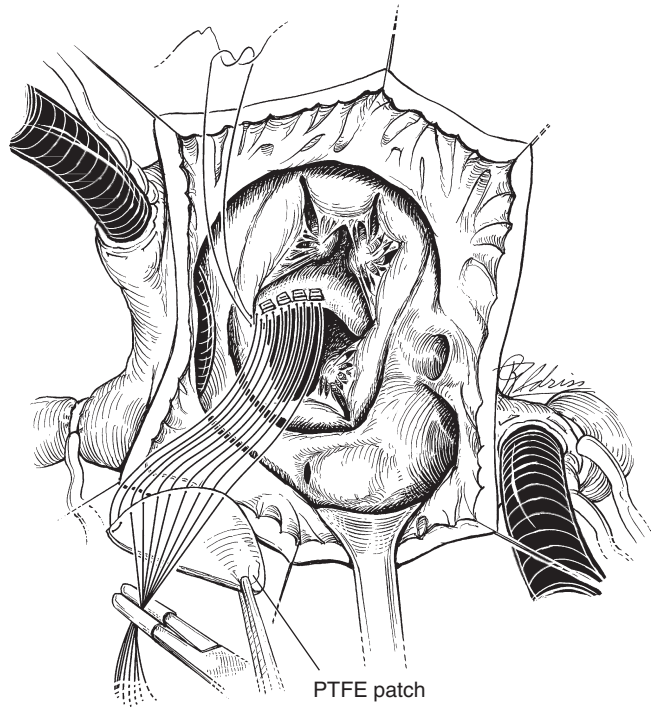

Figure 18.15 Ventricular septal defect closure; two-patch technique. A series of pledget-supported sutures are being placed on the crest of the ventricular septum and then passed through a polytetrafluoroethylene (PTFE) patch. Sutures are placed on the right ventricular side of the septum. A separate horizontal mattress suture at the very corner of the patch passes underneath the anterior common leaflet into the atrium to anchor the corner of the ventricular septal defect patch. The ventricular septal defect patch is cut in a crescent shape with a flat top where the AV valve tissue will be suspended to the patch.

edge of the left AV valve leaflet. Competency of the left-sided AV valve is assessed by irrigating the left ventricle with sterile saline solution through a bulb syringe (Figure 18.19) [17]. An autologous pericardial patch is used to close the atrial septal defect (Figure 18.20) [17]. We have used a running polypropylene suture to anchor the atrial septal defect patch (Figure 18.21) [17]. Care is taken in the area of the AV node to place superficial sutures that extend close to the left-sided AV valve and thus away from the conduction system. The coronary sinus is kept on the right atrial side of the patch. The right AV valve is repaired in a similar fashion to the left-sided AV valve by closing the zone of apposition between the right superior and inferior leaflets (Figure 18.22) [17] and approximating the valve edge to the atrial septal defect patch (Figure 18.23) [17]. This valve is also irrigated with saline to assess competency.

We currently employ intraoperative transesophageal echocardiography in all patients with a partial, intermediate, or complete atrioventricular canal defect. Transesophageal

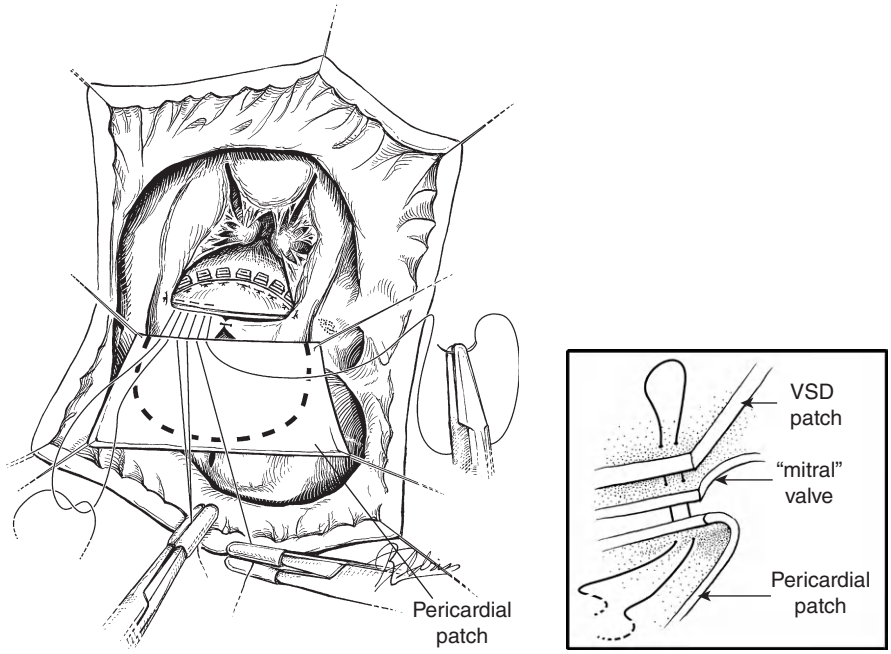

Figure 18.17 Atrial septal defect closure. Separate horizontal mattress sutures of polypropylene are passed through the crest of the ventricular septal defect patch, through the left AV valve leaflet tissue, and then through the pericardial patch that had previously been harvested. The small inset shows how the left AV valve is sandwiched between the ventricular septal defect patch of PTFE and the pericardial atrial septal defect patch. This reduces the incidence of valve dehiscence following the procedure.

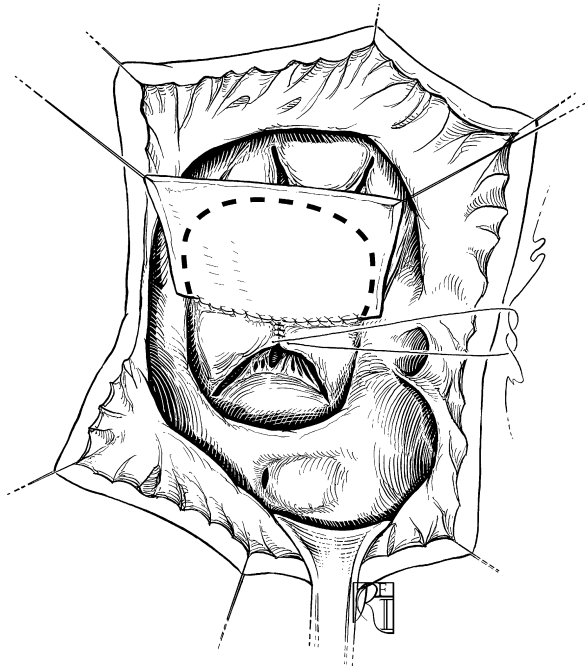

Figure 18.18 Left AV valve zone of apposition closure. The pericardial patch has been reflected anteriorly and separate interrupted polypropylene sutures have been placed to close the "zone of apposition" between the anterior and posterior common leaflets. The extent of this closure is to the insertion of the primary chordae at the edge of the left AV valve leaflet.

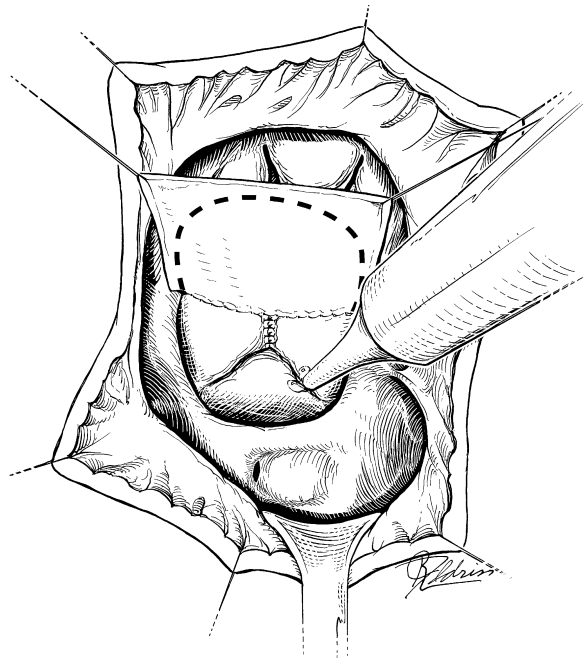

Figure 18.19 Valve assessment. The reconstructed left AV valve is tested intraoperatively with a bulb syringe. The bulb syringe is passed into the ventricle and cold saline is injected. As the ventricle fills and the valve becomes competent, the bulb syringe is removed. As the ventricle recoils against the cold saline, left AV valve insufficiency can be assessed. Often, a small residual jet can be eliminated by an additional suture in the zone of apposition.

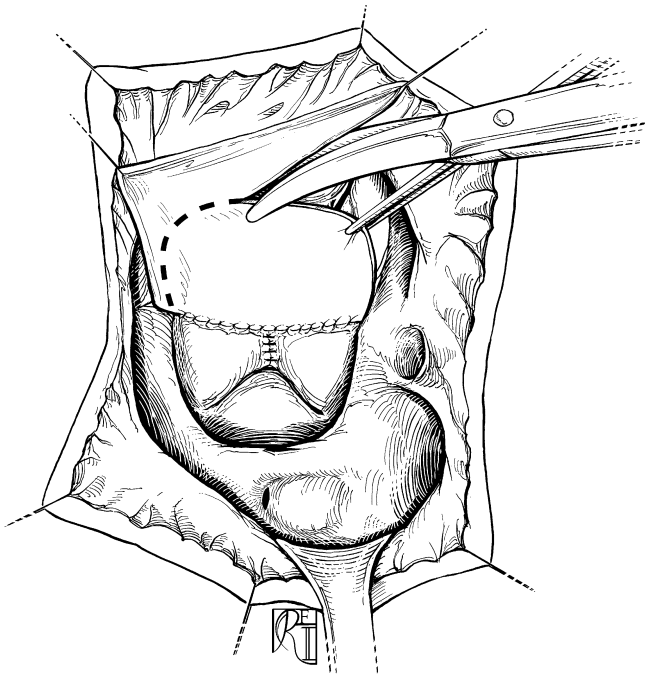

Figure 18.20 Atrial septal defect closure. The pericardial patch is being trimmed to an appropriate shape to approximate the extent of the atrial component of the defect.

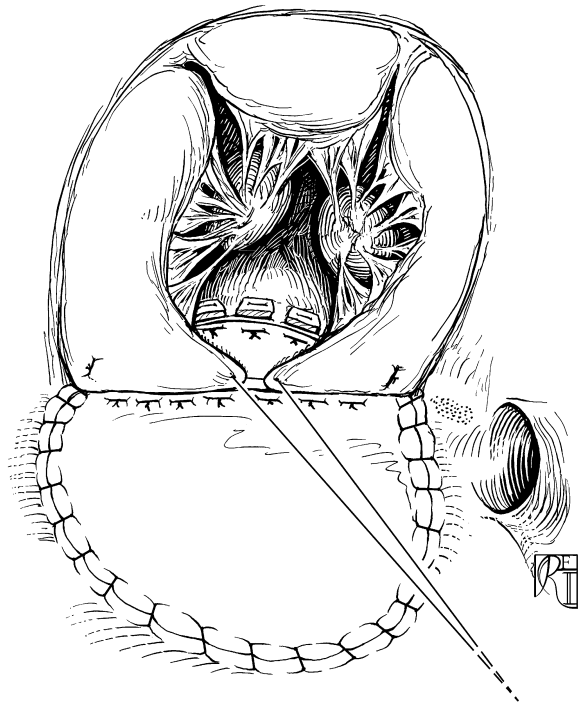

Figure 18.22 Right AV valve repair. The right AV valve is reconstructed by first approximating the anterior and posterior leaflets in the midline.

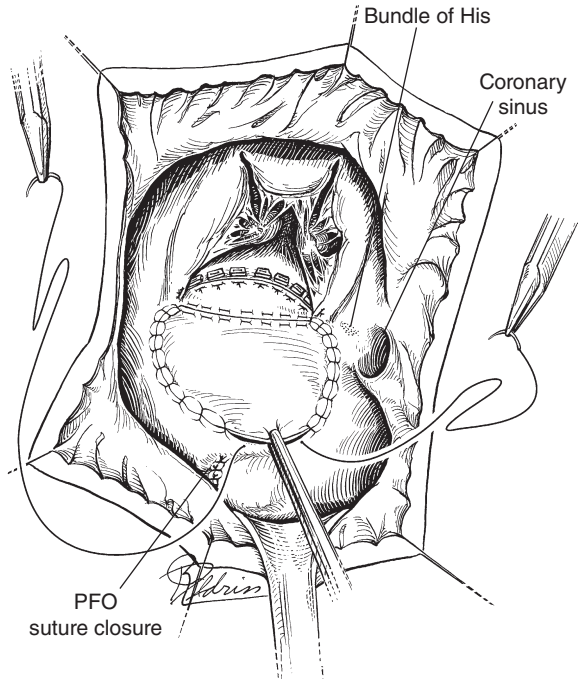

Figure 18.21 Two separate suture lines are used to complete the atrial septal defect closure. Each begins at the corner of the ventricular septal defect patch (running polypropylene). In the region of the bundle of His, the suturing is carried down into the left atrium immediately adjacent to the left AV valve in an effort to avoid creating heart block. Prior to completing the suture lines and tying the knot, the left side of the heart is de-aired.

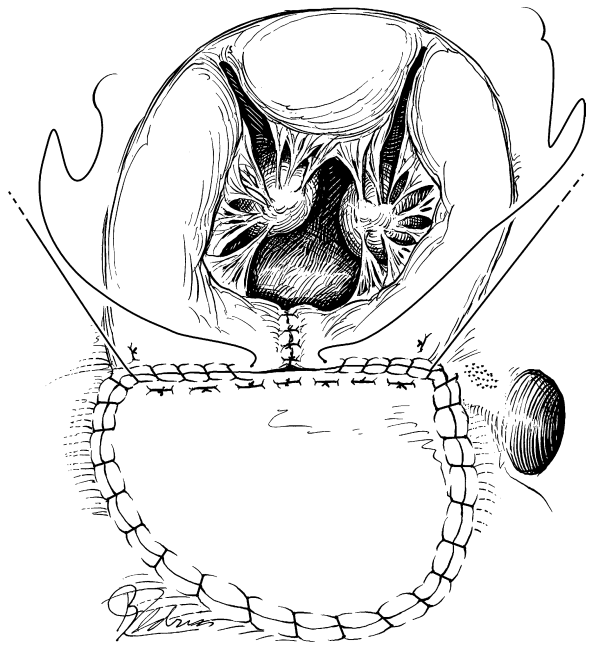

Figure 18.23 Right AV valve repair. The right AV valve is sutured to the confluence of the ventricular septal defect patch and the atrial septal defect pericardial patch. The right AV valve is irrigated with cold saline to see if there is any evidence of insufficiency that may be amenable to further suturing of the zone of apposition.

echocardiography is used to evaluate the preoperative anatomy, particularly the right and left ventricular sizes, the anatomy of the common AV valve, straddling or other unusual chordal issues, and the extent of preoperative AV valve insufficiency. Postoperatively, the transesophageal echocardiography can be used to evaluate for residual ventricular septal defect, residual atrial septal defect, subaortic stenosis, and right and left AV valve insufficiency or stenosis. All of these can be potential indications for an immediate re-repair of the noted abnormality.

Modified Single-Patch Technique

We perform this operation with continuous cardiopulmonary bypass, moderate hypothermia, and multi-dose cold blood antegrade cardioplegia. The ventricular septal defect is closed by placing a series of pledget-supported 5-0 sutures on the right side of the crest of the interventricular septum (Figure 18.24) [17]. These sutures are then passed sequentially through the anterior and posterior common leaflets at a site predetermined to separate the right and left AV valves. The visualization of the division of the valve leaflets into right and left components is facilitated by insufflating the ventricles with cold saline and marking the midportion of the valves with a prolene suture (Figure 18.4) [22]. In most cases, we begin with the central suture and then progress first toward the AV node and then toward the aortic valve. When in doubt, we "give" valve tissue to the left AV valve. After all the sutures are placed through the leaflets, Nunn advocates passing them through a thin strip of Dacron, aiming to reduce the length of the septal crest sufficiently to create an increased central coaptation of the anterior and posterior leaflet components [13]. We have *not* incorporated the use of a Dacron strip in our patients having the modified single-patch technique. The sutures are then placed through the edge of a patch of autologous pericardium (Figure 18.25) [17]. These sutures are then tied, effectively eliminating the VSD and converting the remaining pathology to that of a partial AV canal. Now the zone of apposition of the left AV valve component created by apposition of the anterior and posterior common leaflets is closed (Figure 18.26) [17]. Closure of the zone of apposition is to the point where chordal attachments from the papillary muscles reach the free edges of the leaflet. The reconstructed valve is tested for competence with saline irrigation. The atrial component of the AV canal defect is then closed with the pericardial patch (Figure 18.27) [17]. This is performed with a running monofilament suture that follows the edge of the defect except in the region of the AV node. Here the suture line skirts down into the left atrium adjacent to the mitral annulus and close to the mitral leaflet tissue until a point lateral to the triangle of Koch is reached. The suture line then crosses up to the edge of the remaining atrial septum allowing the coronary sinus to normally drain into the right atrium. Separate secundum atrial septal defects are either covered by the same patch or sutured closed directly or closed with a separate pericardial patch if they are large and remote from the AV canal defect.

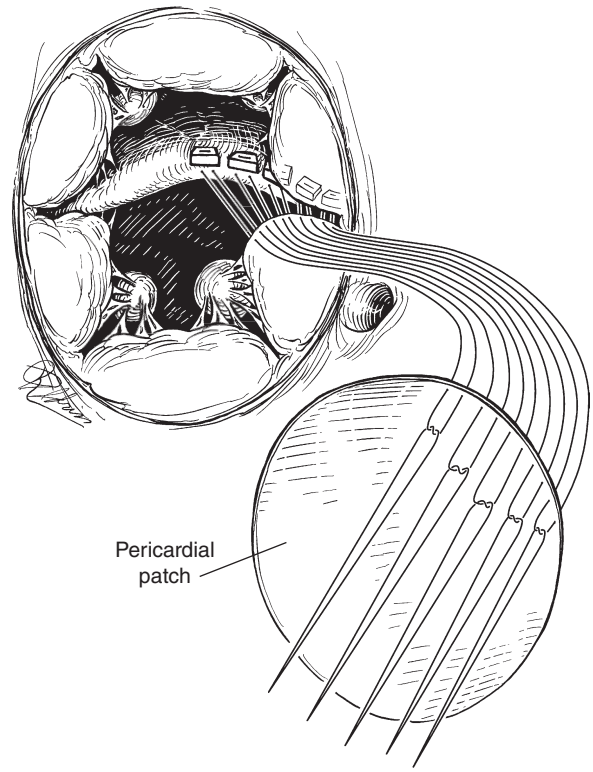

Figure 18.24 Modified single-patch technique in a Rastelli type A patient. A series of pledget-supported sutures are placed on the right ventricular side of the crest of the ventricular septum. The sutures are passed through the left AV valve component of the common AV valve, and then through the pericardial patch.

AV Canal with Tetralogy of Fallot

The presence of tetralogy of Fallot imposes some modifications in the technique used for atrioventricular canal repair. Most surgeons prefer to use a double-patch technique for these patients, and the patch needs to be wider near the subaortic area to allow enough redundancy at the anterosuperior end of the ventricular septal defect and thus avoid left ventricular outflow tract obstruction. With the two-patch technique, the ventricular septal defect patch is

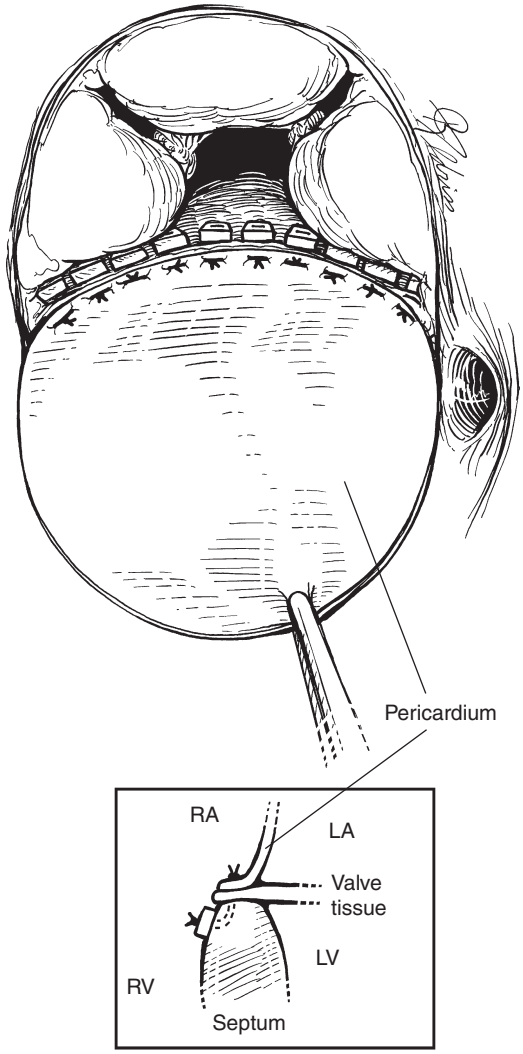

Figure 18.25 The sutures have now been tied, eliminating the ventricular septal defect by approximating the left AV valve to the crest of the ventricular septal defect between the pledgets and the pericardial patch. Inset shows the relationship between the pledget-supported suture, the left AV valve, and the pericardial patch. (LA, RA, left, right atrium; LV, RV, left, right ventricle.)

"comma"-shaped. The VSD component in these patients is frequently very large. The current trend in these patients is to avoid palliation and repair the patients primarily with a transatrial/transpulmonary approach [40]. Palliation with a shunt is reserved for severely cyanotic neonates and patients with small pulmonary arteries [41]. Palliation with a shunt will result in volume loading of the ventricles and the potential (desirable in this case) for annular dilation making partitioning of the common AV valve easier [42]. The review by Najm and associates would suggest that primary repair does have the best results [33].

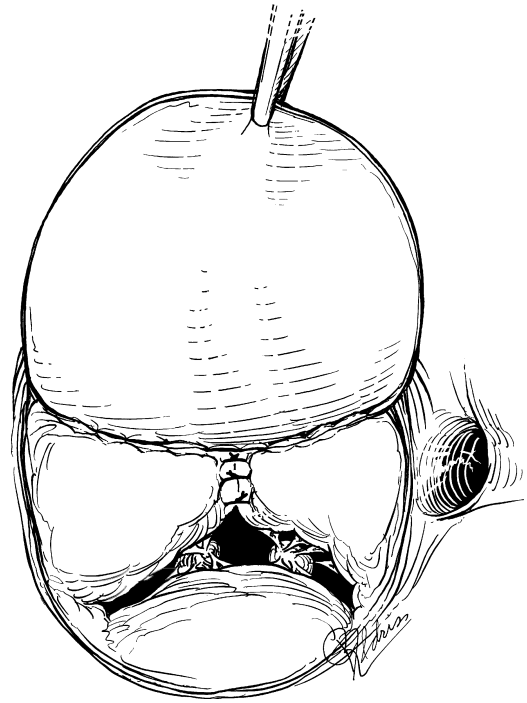

Figure 18.26 The pericardial patch is reflected anteriorly and the zone of apposition of the left AV valve is being closed.

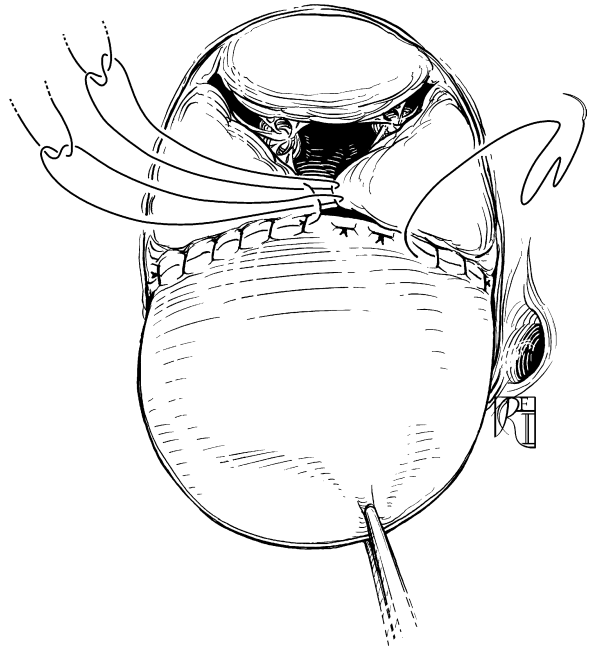

Figure 18.27 Right AV valve reconstruction and pericardial patch closure of ASD. The anterior and posterior common leaflet portion that is to become the right AV valve is sutured to the confluence of the pericardial patch, left AV valve tissue, and crest of the VSD. The interrupted sutures in the center are closing the right AV valve zone of apposition.

Results

The results of the three main techniques described above can be best evaluated by examining the operative mortality and the reoperation rates for mitral insufficiency, pacemaker, left ventricular outflow tract obstruction, and residual atrial or ventricular septal defect. A comparison summary of selected recent series of AV canal repairs is shown in Table 18.1 [12,19,43–54]. In comparing the results of these series one must keep in mind the fact that some of the results have an era effect. The modified single-patch technique has been more frequently applied in the recent era as compared to the two-patch technique and classic single-patch technique where the results go back, in some cases, nearly 20 years. Despite that era effect we believe that the modified single-patch technique offers distinct advantages over the other techniques. In comparing operative mortality the modified single-patch technique at 2% was less than the two-patch technique at 3.5%, and the single-patch technique at 4.8%. This may be partially reflected by the era effect as I mentioned previously, but I believe it is also a tribute to the ease with which the modified single-patch technique can be performed. The modified single-patch technique has been shown to have shorter cross-clamp and cardioplegia times than the other techniques. In our comparison the mean cross-clamp time was shorter by 26 minutes and the mean cardiopulmonary bypass time was shorter by 29 minutes [45]. Another reason the mortality rate may be lower in the patients with the modified single-patch technique is that this operation lends itself well to the smaller infant. In our series the mean age at the time of repair has dropped from 6 months to under 4 months. Operating on these babies earlier in life, prior to the progression of pulmonary vascular disease and atrioventricular valve insufficiency is advantageous.

It is the reoperation rate for left AV valve insufficiency that has the most dramatically different outcome when comparing the three techniques. The modified single-patch technique reoperation rate was 2%, the two-patch technique was 7.2%, and the classic single-patch technique was 9.7%. This has always been the "Achilles' heel" of complete AV canal repair. In his landmark review of a single surgeon's experience of over 25 years using the single-patch technique, Fred Crawford stated, "Unfortunately what has not improved and what continues to be the limiting factor of this procedure, especially insofar as long-term results are concerned, is left atrioventricular valve competence" [52]. Crawford collected 13 operative series reported from 1997 to 2006 and examined the incidence of reoperation for left AV valve regurgitation. He found that the incidence of reoperation ranged from 3.5–19.7% and was in fact remarkably constant at approximately 7–8%. Kanani and associates recently stated the following in a review of mechanisms for late incompetence of the left AV valve after repair of

Table 18.1 A comparison summary of selected recent series of AV canal repairs. (NS, not stated.)

Author	Number of patients	Operative mortality	Late mortality	Left AV valve reoperation	Heart block

atrioventricular valve defect, "Mortality following repair of atrioventricular septal defects has fallen dramatically in the last four decades, but reoperation for late regugitation across the left atrioventricular valve has remained disconcertingly stagnant" [55].

This problem of reoperation of the left AV valve after AV canal repair is we believe addressed and altered significantly by the modified single-patch technique. This may be the single most important reason why the modified single-patch technique is now our operation of choice for patients with complete AV canal defect. There are several reasons for this improvement in outcome. The modified single-patch technique, because of its simplicity, is well suited for repair in the young infant. In Nunn's series the median age of patients at operation was 63 days, just over 2 months [45]. In our series the mean age is 4 months [46]. Dr Lacour-Gayet and colleagues have reported the importance of operating on these patients at 2–4 months of age [47]. This avoids the complications of pulmonary vascular obstructive disease and progressive dilatation of the common AV junction leading to regurgitation across the left AV valve.

Another explanation for the success of the modified single-patch technique is that the complexity of the repair is considerably reduced by avoiding the VSD patch. When this patch is placed it has the potential to be too short, too wide, too tall, or too long. Any one of these combinations can affect the coaptation of the left AV valve. This exact sizing of the ventricular patch is avoided with the modified single-patch technique. A third explanation for the success of the modified single-patch technique is that it is performed without dividing the AV valve leaflets. When the leaflets are divided, they must be reapproximated to the top of the VSD patch or to the midportion of the classic single patch. The very act of splitting the common leaflet and reattaching the left and right components by necessity sacrifices valve tissue. Although this may not be significant in older children, it becomes important in infants in whom the sacrificed valve tissue comprises a greater portion of the whole. Moreover, the potential for patch disruption of the reattached mitral and tricuspid components is avoided if the common leaflets are not split [56].

Fortuna and colleagues at the Hospital for Sick Children in Toronto reviewed their results with the two-patch technique in 209 children [51]. They demonstrated that division of the bridging leaflets obligates a portion of the leaflet tissue to the repair whether using one or two patches. This loss of leaflet tissue may lead to distortion of the remaining valve tissue and an increase in tension on the zone of apposition closure, leading to the potential for valve regurgitation and increased risk of valve dehiscence. They concluded that the division of the bridging leaflets is a risk factor for AV valve regurgitation during the first year after repair. In contrast, preservation of the bridging leaflet integrity improves valve competency, decreases the need for future reoperation, and eliminates some causes of operative mortality.

One possible complication of the modified single-patch technique is the potential for left ventricular outflow tract obstruction in the patient with a very large ventricular component or "scoop." Adachi and colleagues have shown that in addition to the VSD size, the degree of anterosuperior extension of the VSD is also important in assessing the risk of late left ventricular outflow tract obstruction [57]. This "potential" complication does not seem to be a major clinical problem. In Nunn's recent review he applied the modified single-patch technique sequentially to all patients regardless of VSD size (n = 128) [43]. The long-term follow-up of the modified single-patch technique in Nunn's series would appear to refute and to answer the question regarding the possible risk of late left ventricular outflow tract obstruction. Nunn now has 26 patients with more than 10–15 years of follow-up, and no patient has required reoperation for left ventricular outflow tract obstruction. Similarly in our own series, no patient has developed significant left ventricular outflow tract obstruction, a finding replicated in the series from Jonas [44]. In fact, the synthetic material placed in the two-patch technique in the left ventricular outflow tract may encourage fibrotic obstruction in the naturally narrow left ventricular outflow tract. It may also contribute to increased rigidity in the posterior wall of the left ventricle outlet by its very presence, and in doing so may promote turbulence on the left ventricular outflow tract during systolic contraction in a manner similar to that seen in asymmetric septal hypertrophy. We have elected not to apply the modified single-patch technique only in the unusual case when the ventricular septal defect is >12 mm in diameter as measured from the crest of the VSD to the level of the common AV valve during end diastole by transesophageal echocardiogram [58].

It would appear that all three techniques have a very low risk of third-degree atrioventricular heart block. In the modified single-patch technique we have not seen a patient with heart block at our institution. In over 200 total reported patients there was only one incidence noted of complete heart block. In the two-patch technique and the classic single-patch technique the incidence as reported in the literature is 2–2.5%. Again, the removal of the rigid PTFE or Dacron patch from the VSD closure portion of the repair may lend itself to a lower incidence of AV block, although this would be difficult to demonstrate statistically with its low overall incidence.

In summary, the modified single-patch technique, which was first performed in a significant amount of patients beginning in the mid-1990s is now in our opinion the procedure of choice for atrioventricular canal repair. The operative mortality rate is very low (<2%), the late mortality rate is very low (<1%), and the incidence of left AV valve reoperation is very low at 2%; significantly lower than any

reported repairs with the classic single-patch or two-patch techniques. The modified single-patch technique has results that are superior to the classic two-patch technique and can be applied in very young infants (2–3 months of age). This facilitates AV canal repair before progression of pulmonary hypertension, AV valve dilatation, and AV valve insufficiency.

Risk Factors

Age at Operation

It was previously thought that delaying operation until a later age would increase operative survival. This in fact is incorrect, and earlier age at operation, particularly operating on these patients at less than 6 months of age, is associated with increased survival based primarily on decreased incidence of significant postoperative pulmonary hypertension. [19,48,59]. In the recent series from Michigan [59], the median age at operation for complete atrioventricular canal was 4.8 months.

Preoperative AV Valve Incompetence

The presence of severe preoperative left AV valve regurgitation, and its contribution to the development of pulmonary hypertension and changes in pulmonary vascular resistance is a significant factor in increased risk of hospital death after repair.

Double Orifice Left AV Valve

Approximately 5% of patients with complete atrioventricular canal or partial atrioventricular canal will have a double orifice left AV valve [60]. The left AV valve component will have two separate orifices. These orifices are typically abnormal holes in essentially normal leaflets, not abnormal fibrous bridges or adhesions across commissures. The key to repair is not dividing the tissue bridging between these two orifices as this will cause severe valvar insufficiency. This can be an area of preoperative assessment confusion as the orifice can be assessed as "too small," not considering the fact that there are actually two orifices for the left AV valve.

Zone of Apposition

The nomenclature of the left AV valve has changed dramatically as our understanding of this valve has increased. We formerly referred to the area between the superior and inferior bridging leaflets as the "mitral valve cleft." Professor Robert Anderson in particular has demonstrated for us that the left AV valve in these patients is not anatomically a mitral valve. The surgical approximation of the superior and inferior bridging leaflets is really bringing together what should more accurately be called, "the zone of apposition" [61]. In the late 1970s and early 1980s some surgeons believed that this valve should be treated as a trifoliate valve and that the superior and inferior bridging leaflets should not be joined. However, not closing the zone of apposition is associated with an increased incidence of late left AV valve insufficiency [54,62]. Now, almost all surgeons approximate the zone of apposition at the time of partial or complete atrioventricular septal defect repair. We have been routinely closing the zone of apposition since 1985.

Trisomy 21

In many series the presence of trisomy 21 has been associated with redundant AV valve tissue available for reconstruction. This helps to decrease the incidence of significant postoperative AV valve insufficiency and has been associated with a better outcome as far as reducing the incidence of left AV valve reoperation [31]. The great majority of patients with atrioventricular canal (86% in our series) will have trisomy 21. In a recent article from Masuda and colleagues, the incidence of reoperation on the left AV valve was 4% in the trisomy 21 group and 15% in the non-trisomy 21 group [63]. In another recent review, the presence of trisomy 21 was protective of the need for reoperation [64].

Postoperative Management

We routinely manage our postoperative complete atrioventricular canal patients with paralysis, sedation, and hyperventilation. This helps to avoid pulmonary hypertensive crises and optimizes cardiac output in the critical first 24–48 hours postoperatively. Factors that are known to trigger pulmonary hypertensive crisis such as hypoxia, hypercapnia, acidosis, pain, and hypothermia, are minimized by this strategy. The sedation and paralysis is continued usually for a minimum of 24 hours, often 48 hours, and sometimes 72 hours, depending on the age of the patient and the expected degree of pulmonary hypertension. Studying the pulmonary artery pressures of these patients postoperatively in the operating room, many of them after a good repair have essentially normal pulmonary artery pressures with the use of the above strategies. However, we would treat patients who have any evidence of residual pulmonary hypertension with inhaled nitric oxide [65]. Cardiac output in these patients is optimized by routine administration of low-dose dopamine (2.5–5 μg/kg/min) and low-dose dobutamine (2.5–5 μg/kg/min). In addition, we have used milrinone (0.5–0.7 μg/kg/min), a phosphodiesterase inhibitor, in all patients.

Conclusion

Atrioventricular canal defects represent a spectrum of intracardiac anomalies. The pathognomonic feature is a common atrioventricular junction. This ranges from a partial atrioventricular canal (atrial septal defect, trifoliate

left AV valve) to intermediate atrioventricular canal (atrial septal defect, trifoliate left AV valve, ventricular septal defect beneath two separate AV valve orifices), to complete atrioventricular canal (atrial and ventricular septal defects and a common AV valve). The complete atrioventricular canal defects are divided into three categories, Rastelli A, B, and C. Patients with partial atrioventricular canal defects are treated much like patients with a large atrial septal defect and can be operated on electively between the ages of 1 and 4 years. Patients with a complete atrioventricular canal defect should undergo operative repair before 6 months of age. Surgical techniques currently employed for complete atrioventricular canal include the single-patch technique, the two-patch technique, and the modified single-patch technique. In the current era, repair is facilitated by the use of intraoperative transesophageal echocardiography in all patients. Postoperative management centers on proactive management of pulmonary hypertension. The most common late complication is residual or recurrent left AV valve insufficiency. Long-term survival and functional outcome are excellent for most of those patients. Our current operation of choice for the great majority of patients with complete atrioventricular canal defect is the modified single-patch technique.

CHAPTER 19

Truncus Arteriosus

Constantine Mavroudis[1] and Carl L. Backer[2]

[1]Florida Hospital for Children, Orlando, FL, USA
[2]Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Chicago, IL, USA

Truncus arteriosus is a congenital malformation in which a single arterial trunk arises from the heart, overrides the interventricular septum, and supplies the systemic, pulmonary, and coronary circulations. With truncus arteriosus there are no remnants of a separate pulmonary valve or ventricular-to-pulmonary artery continuity and thus this lesion can be distinguished from the severe forms of tetralogy of Fallot with pulmonary atresia. Truncus arteriosus is relatively uncommon, representing 0.21–0.34% of patients with congenital heart disease [1–4].

Embryologic and Anatomic Features

During embryonic life, the truncus arteriosus normally begins to separate and spiral into a distinguishable anterior pulmonary artery and posterior aorta. Persistent truncus arteriosus, therefore, represents an arrest in embryonic development at this stage [5,6]. Other implicated embryologic events include absence of truncal spiraling and division, twisting of the dividing truncus due to ventricular looping, subinfundibular atresia, and abnormal location of the semilunar valve anlages [1,7–9]. Experimental studies in chick embryos have shown that ablation of the neural crest results in persistent truncus arteriosus [10,11]. The neural crest also develops into the pharyngeal pouches and thence the thymus and parathyroids. This association explains the prevalence of truncus arteriosus with DiGeorge syndrome [12]. Recent studies [13–15] have demonstrated the association of DiGeorge syndrome (chromosome 22q11.2 microdeletion) with conotruncal malformations, including truncus arteriosus. They found a higher incidence of complex cardiovascular anatomy in association with depressed immunologic status, pulmonary vascular reactivity, neonatal hypocalcemia, bronchomalacia and bronchospasm, laryngeal web, and a tendency to airway bleeding.

The most striking characteristic of truncus arteriosus is the single arterial trunk arising from the heart, more or less overriding the ventricular septum, being dominantly positioned over the right ventricle in 42%, the left ventricle in 16%, and equally shared in 42% [16]. Anatomic classifications, however, have been based on the pulmonary artery origin from the truncus. Collett and Edwards [17] subdivided truncus arteriosus into type I – a short main pulmonary artery arising from and to the left of the truncus; type II – separate but closely positioned pulmonary arteries arising from the posterior truncus; type III – widely separated pulmonary arteries arising laterally from the truncus; and type IV – pulmonary arteries arising from the descending aorta (Figure 19.1) [18]. This classification, although helpful, has not explained entirely the more frequently found anatomic variations and is rarely used today.

Van Praagh [9] has offered a modified classification (Figure 19.1) [18]. Type Al is similar to type I; type A2 more accurately combines types II and III since type III is exceedingly rare. In clinical practice one is more apt to see a continuum between types Al and A2 (types I, II, III) depending on the site of origin of the right pulmonary artery. Van Praagh's A3 describes a single pulmonary artery origin from the truncus (usually the right pulmonary artery) with either a ductus or collateral vessels supplying the contralateral side. The A4 classification is truncus arteriosus with an interrupted aortic arch. Type IV truncus (Collett and Edwards) or pseudotruncus classifications ought to be abandoned as they are not true forms of truncus arteriosus and are, more accurately, ventricular septal defect with pulmonary atresia and major aortopulmonary collateral arteries. In addition to these aforementioned truncus arteriosus types are a number of variants including absence of a pulmonary artery [1], crossed pulmonary arteries [19], and various abnormalities of the brachiocephalic arteries [20,21]. Recently Russell, Jacobs, Mavroudis, Anderson,

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

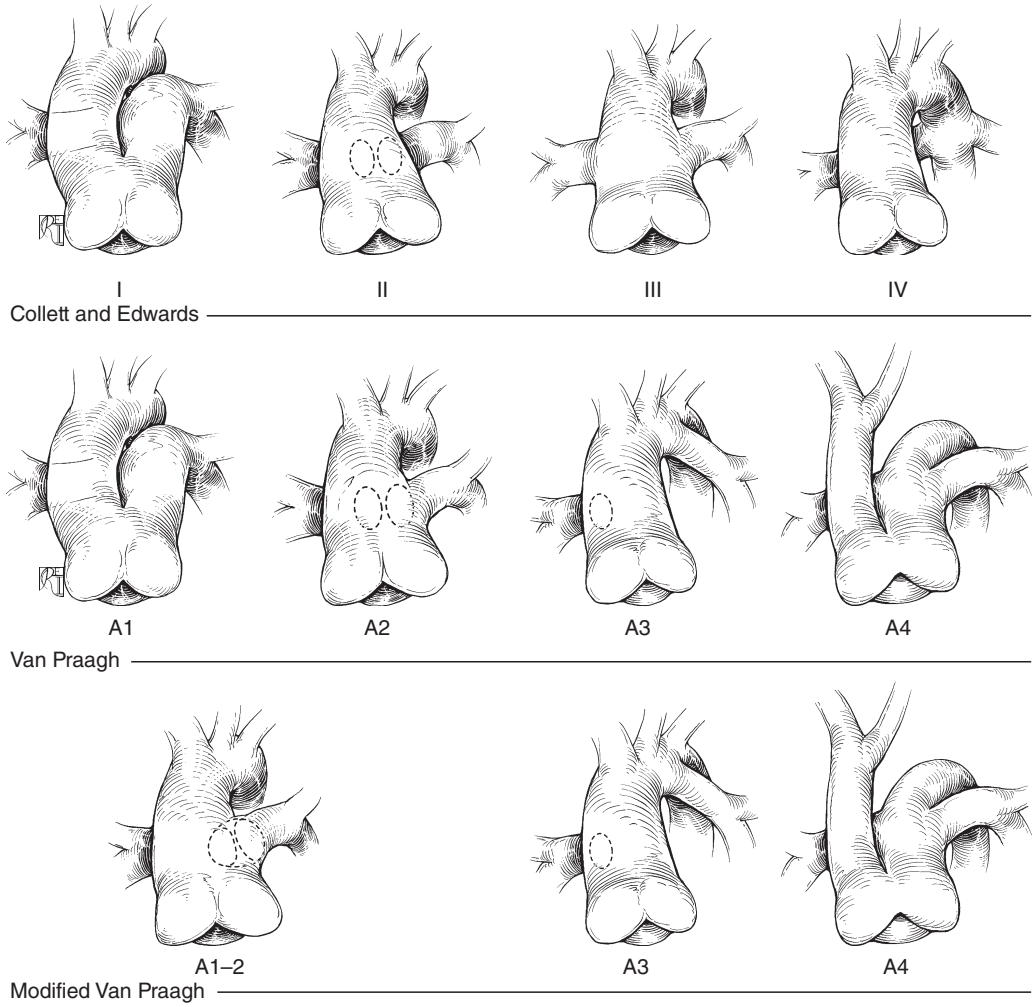

Figure 19.1 There are similarities between the Collett and Edwards and the Van Praagh classifications of truncus arteriosus. Type I is the same as A1. Types II and III are grouped as a single type A2 because they are not significantly distinct embryologically or therapeutically. Type A3 denotes unilateral pulmonary artery with collateral supply to the contralateral lung. Type A4 is truncus associated with interrupted aortic arch (13% of all cases of truncus arteriosus).

and associates have redefined truncus arteriosus as common arterial trunk with either predominantly aortic or pulmonary artery characteristics [22]. This definition allows for description of all the anatomic possibilities associated with this entity (Figure 19.2) [22]. Jacobs [23] developed an extensive and inclusive nomenclature database system by expanding Van Praagh's classification into a stepwise, computerized hierarchical system that allows for all variants and associated anomalies of truncus arteriosus. Such a system can be used world-wide in order to monitor incidence, document surgical results, and develop risk stratification models.

The truncal valve is often insufficient owing to abnormally thickened and deformed leaflets [16]. Very rarely the valve is stenotic. The truncal valve is usually tricuspid (60%), quadricuspid (25%), or bicuspid (5%). The aortic arch is right-sided in 18–36% of patients with truncus arteriosus and is usually associated with mirror-image branching of the brachiocephalic arteries [1,9,16,24]. A patent ductus arteriosus is sometimes encountered and may be associated with interrupted aortic arch, which is present in 11–14% of patients with truncus arteriosus [1,9,16,25]. The ventricular septal defect is usually located in an anterosuperior position, lying between the two superior limbs of the trabecula septomarginalis [21] remote from the conduction tissue (Figure 19.3) [18]. Occasionally the ventricular septal defect extends to the membranous septum closer to the conduction tissue, and will require more careful consideration during patch closure to avoid surgical heart block [26].

Anomalous coronary artery origin and distribution are not uncommon in truncus arteriosus and may impact unfa-

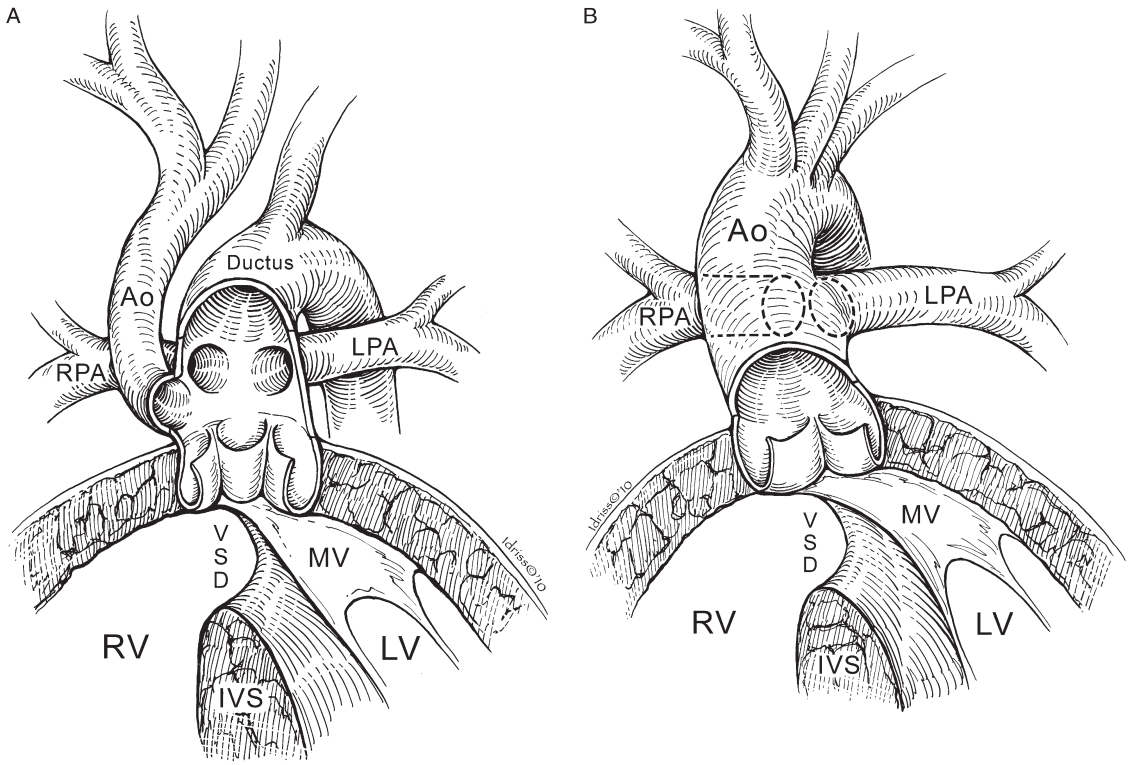

Figure 19.2 The essential features of pulmonary versus aortic dominance as observed in our autopsied specimens with common arterial trunk. **A**, Interruption of the aortic arch. Only in this setting, and in hearts with severe aortic coarctation, did we find origin of the pulmonary arteries from either side of the intrapericardial pulmonary trunk. **B**, The salient features of aortic dominance with the pulmonary arteries arising separately but next to each other from the leftward and dorsal aspect of the common trunk. We also find pulmonary arteries arising more anteriorly and then crossing as they extended toward the pulmonary hilums. vorably on surgical corrections. Single origins of the left and right coronary arteries have been reported [27,28] as well as abnormally high osteal takeoff above the sinuses of Valsalva [1,24] among others [29]. Clearly, the anomalous coronary arteries must be identified and preserved during neoaortic construction after removal of the pulmonary artery trunk [30,31].

Physiology and Clinical Findings

The overwhelming abnormal pathophysiologic feature of truncus arteriosus is a large left-to-right shunt that increases after the neonatal period as the pulmonary vascular resistance falls. Truncal valve regurgitation is present in about 50% of patients and may cause pressure overload to the already volume-overloaded ventricles. Pulmonary vascular obstructive disease may develop as early as 6 months of age, leading to poor results after late surgical correction.

The clinical manifestations of truncus arteriosus usually become apparent within the first weeks of life because of a murmur, tachypnea, and costosternal retractions. The patients are sometimes cyanotic, but the progressive signs of congestive heart failure are most prominent, including tachypnea, hepatomegaly, sweating with feeding, failure to thrive, bounding pulses, a pansystolic murmur at the left sternal border, and sometimes a diastolic murmur if significant truncal regurgitation is present. The second heart sound is predictably single.

The electrocardiogram shows sinus rhythm and biventricular hypertrophy. Left ventricular forces may predominate in the case of large pulmonary flow, while right ventricular forces may predominate if pulmonary vascular obstructive disease develops. The chest roentgenogram shows cardiomegaly, increased pulmonary vascular markings, and an absent pulmonary artery segment. A right aortic arch can be appreciated in about one-third of cases. Unequal vascularity may denote unilateral pulmonary artery atresia, while bilaterally decreased pulmonary markings often reflect long-standing pulmonary vascular obstructive disease.

The various views of two-dimensional echocardiography combined with pulsed-Doppler or Doppler color-flow

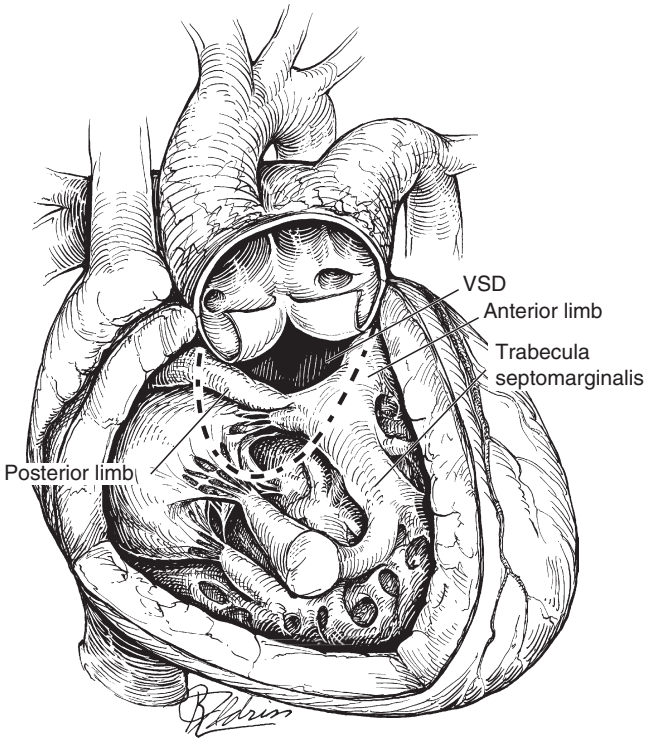

Figure 19.3 In truncus arteriosus the location of the ventricular septal defect (VSD) can be variable. Shown here is the high and anterior type, which is surrounded by the two limbs of the trabecula septomarginalis. Other VSD types resemble those seen in patients with tetralogy of Fallot. These VSDs extend toward the paramembranous area (dotted line).

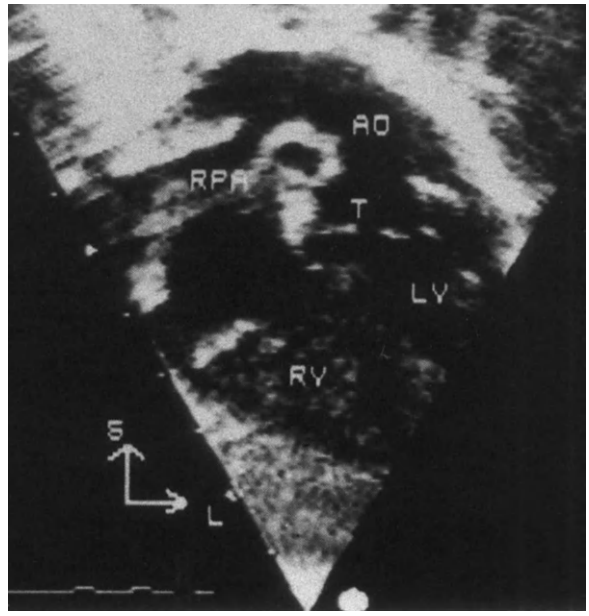

Figure 19.4 Subcostal two-dimensional echocardiographic view of left ventricular outflow in a different patient with truncus arteriosus. This patient has a right aortic arch and right pulmonary artery arising from the truncal vessel. The left pulmonary artery was hypoplastic and originated from isolated ductus arteriosus. (AO, aorta; LV, left ventricle; RPA, right pulmonary artery; RV, right ventricle; T, truncal vessel; arrows: S, superior; L, left.)

mapping can usually provide sufficient information to determine the type of truncus arteriosus, the origin of the coronary arteries and their proximity to the pulmonary trunk, the character of the truncal valve, and to some extent, the degree of truncal insufficiency, if present (Figure 19.4) [18]. The newer and less invasive diagnostic methods of magnetic resonance imaging and computed tomography (Plate 19.1, see plate section opposite p. 594) have helped to provide more accurate anatomic details such as coronary artery location and pulmonary artery origins, which can help in planning the operation and avoiding complications. Despite these advances in imaging techniques, cardiac catheterization is sometimes indicated to further evaluate truncal insufficiency, confirm anatomic details (Figures 19.5 and 19.6) [18], and measure pulmonary vascular resistance, especially in the case of late presentation.

Natural History

Untreated patients with truncus arteriosus have a dismal prognosis with a 65% 6-month and 75% 1-year mortality rate [17]. Occasionally some children will develop a mild degree of increased pulmonary vascular resistance to balance their systemic and pulmonary circulations and live to 10 years and more [32,33]. The greater number, however, fall victim to congestive heart failure due to the large left-to-right shunt or develop accelerated pulmonary vascular obstructive disease with progressive cyanosis. Surgeons now perform complete repair in the first 1–2 weeks of life, which has resulted in improved early and late survival.

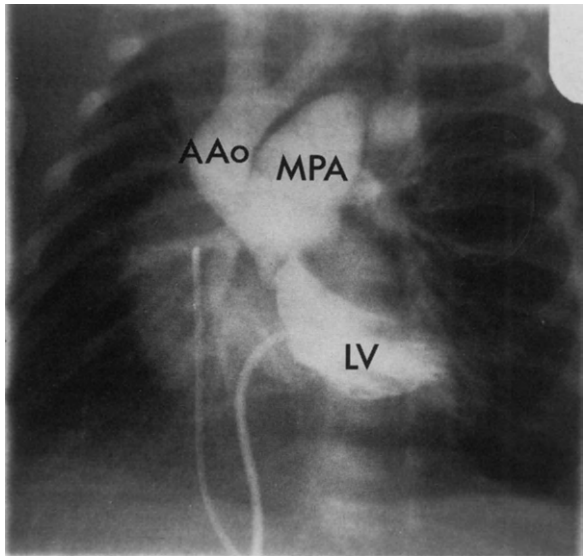

Figure 19.6 Cinecardioangiogram of a patient with truncus arteriosus, interrupted aortic arch (type A4) and truncal valve stenosis. (AAo, ascending aorta; LV, left ventricle; MPA, main pulmonary artery.)

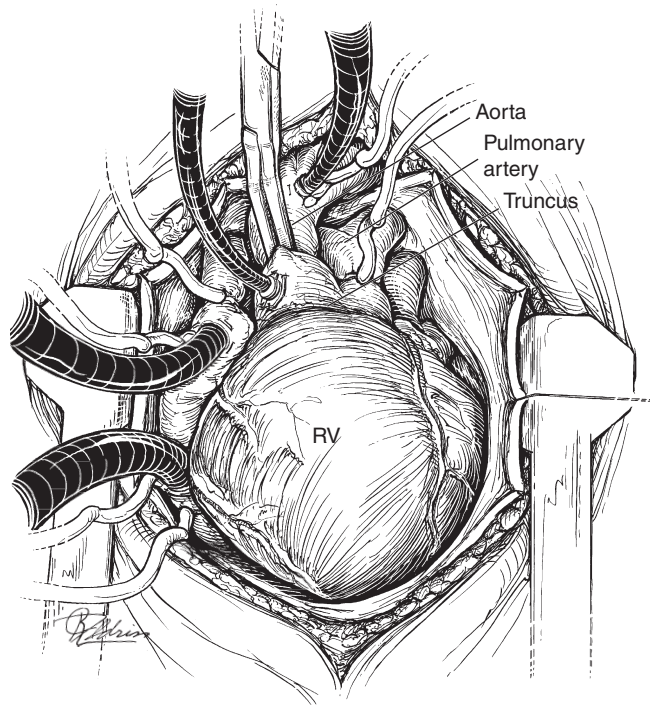

Figure 19.7 Diagrammatic representation of a patient with truncus arteriosus after aorto-bicaval cardiopulmonary bypass, pulmonary artery constriction, and aortic cross-clamping with cardioplegic arrest.

Management

Most infants with truncus arteriosus develop early congestive heart failure and failure to thrive despite medical treatment with digoxin, diuretics, and vasodilator therapy. Early experience with pulmonary artery banding resulted in ineffective palliation and high mortality [34–37]. Complete repair was first accomplished by McGoon and his associates [38] based on the experimental work of Rastelli [39], who introduced the idea that ventricular-to-pulmonary artery continuity could be established by a valved conduit. Early successes occurred in older children, leading surgeons to delay repair. However, many patients decompensated and died while waiting to achieve greater size and weight. Ebert and colleagues [40] demonstrated that operative intervention for complete repair could be undertaken in infants less than 6 months of age with excellent short- and long-term results. Other authors [41–44] have achieved similar results even with concomitant truncal valve repair or replacement in young infants and newborns [45–51]. This has led to early surgical intervention, well before the patient exhibits decompensated congestive cardiac failure, increased pulmonary vascular resistance, or cardiac cachexia.

Operative Technique

The operative techniques for truncus arteriosus repair have undergone evolutionary advances relating to: cannulation and perfusion techniques, myocardial preservation, and types of extracardiac conduits. Early strategies stressed the importance of simplified perfusion techniques and management of postoperative hemorrhage. Ebert [40] achieved his outstanding results with aorto-uniatrial cannulation, no ventricular vent, no cardioplegia, and a 12-mm stiff porcine Dacron conduit despite a high perioperative reoperation rate for bleeding. Wider availability of cryopreserved homografts, improvements with blood cardioplegia, and newer cannulas have allowed the surgeon to perform this operation under more favorable conditions [41–53]. In particular, improved results with transmediastinal interrupted aortic arch reconstruction [54–62] and truncal valve repair [63–68] have positively influenced perioperative survival and long-term outcome. These techniques are discussed in this section.

We prefer high aortic cannulation to allow enough room for the aortic clamp, pulmonary trunk detachment, and aortic reconstruction. Bicaval cannulation and left ventricular venting are employed to minimize venous line air, maximize intraventricular exposure, and enhance the myocardial preservation effects of cold blood cardioplegia (Figures 19.7–19.9) [18]. Cardiopulmonary bypass is commenced as the pulmonary trunk is constricted by a tourniquet. This technique can also be used for patients with interrupted aortic arch since the descending aorta is in continuity with the arterial cannula through the patent ductus arteriosus and pulmonary trunk. A notable difference in techniques is that at the onset of cardiopulmonary bypass, patients

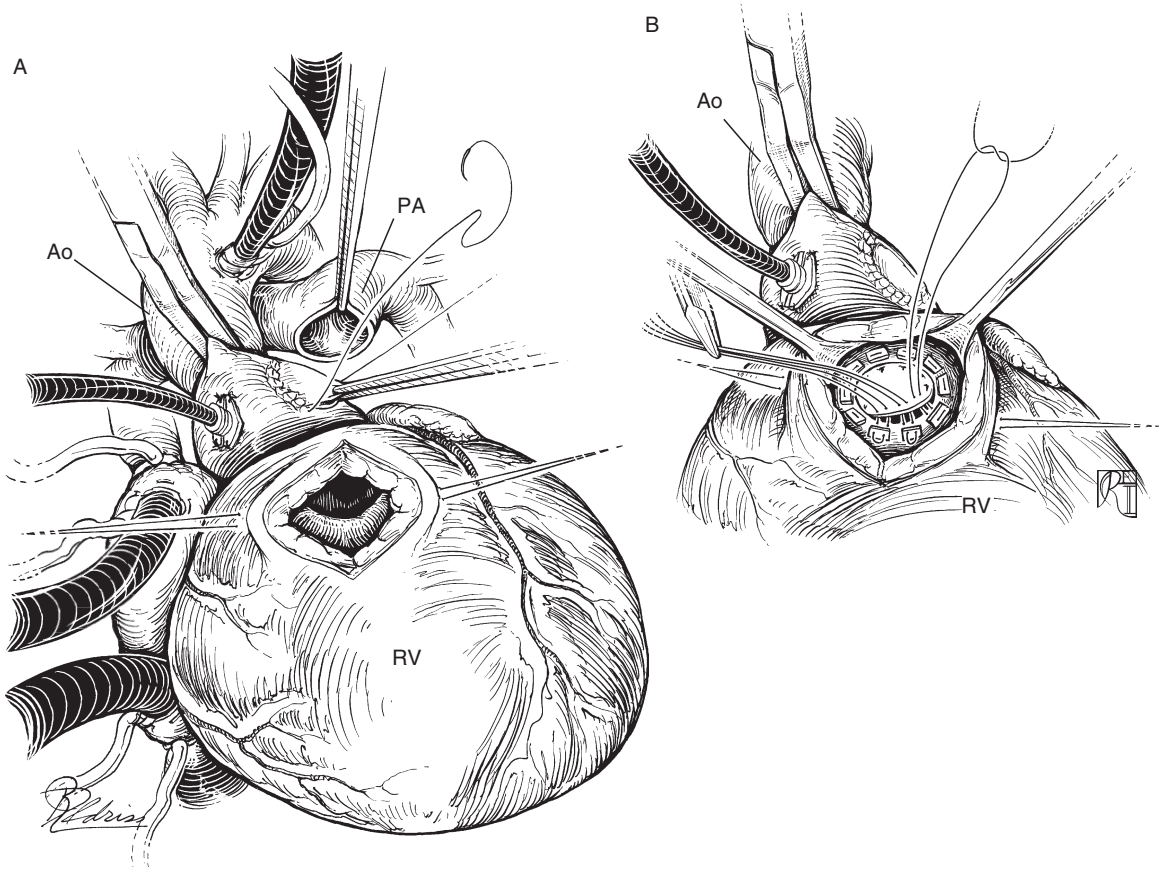

Figure 19.8 A, Pulmonary artery has been disconnected from the arterial trunk, and the aorta has been reconstructed with a PTFE patch to avoid coronary flow complications. **B,** Transventricular closure of the ventricular septal defect is shown with interrupted pledgeted sutures and a Dacron patch. (Ao, aorta; PA, pulmonary artery; RV, right ventricle.)

with intact aortic arch can undergo pulmonary trunk constriction while patients with interrupted aortic arch will require separate pulmonary artery constriction to maintain flow through the patent ductus arteriosus. The conduct of the operation for patients with interrupted aortic arch diverges at this point from patients with intact aortic arch due to the requirement for arch reconstruction which is performed first during a period of deep hypothermia and circulatory arrest or regional perfusion techniques [69]. This part of the procedure will be discussed separately.

For patients without interrupted aortic arch the progression of the operation is straightforward. After left ventricular vent placement, the cross-clamp is applied and followed by antegrade administration of cold blood cardioplegia. In those patients with severe truncal insufficiency, antegrade cardioplegia may not be applicable thereby necessitating direct coronary perfusion or retrograde coronary sinus perfusion (in these circumstances, we prefer retrograde cold blood cardioplegia). The pulmonary artery trunk is then removed with special attention to the coronary artery anatomy and the truncal valve, which are inspected. If the truncal valve is incompetent, valve repair techniques or truncal valve replacement can be undertaken at this point [52,63–68,70]. These techniques will be discussed separately. Aortic closure can be performed directly or with polytetrafluoroethylene (PTFE) patch (we prefer a patch to minimize coronary flow complications). A separate pericardial patch can be placed over the PTFE patch to minimize bleeding if indicated. The distal valved conduit-to-pulmonary artery anastomosis is then performed. Depending on the relative sizes of the conduit and pulmonary artery, incisions can be made in the pulmonary arteries to accommodate the graft. In the event that a Dacron valved conduit is used, care is taken to perform the anastomosis to the Dacron graft close to the valve commissures. This will position the valve distally, thereby minimizing coronary artery and heart compression by the bioprosthetic valve stent [71]. Similar techniques should be used with homografts and heterografts. This is followed by right ventriculotomy, ventricular septal defect closure, and cross-clamp removal. The patent foramen is generally left alone unless the interatrial communication is large. Leaving the patent foramen ovale will help with the postoperative hemodynamics as the right ventriculotomy often

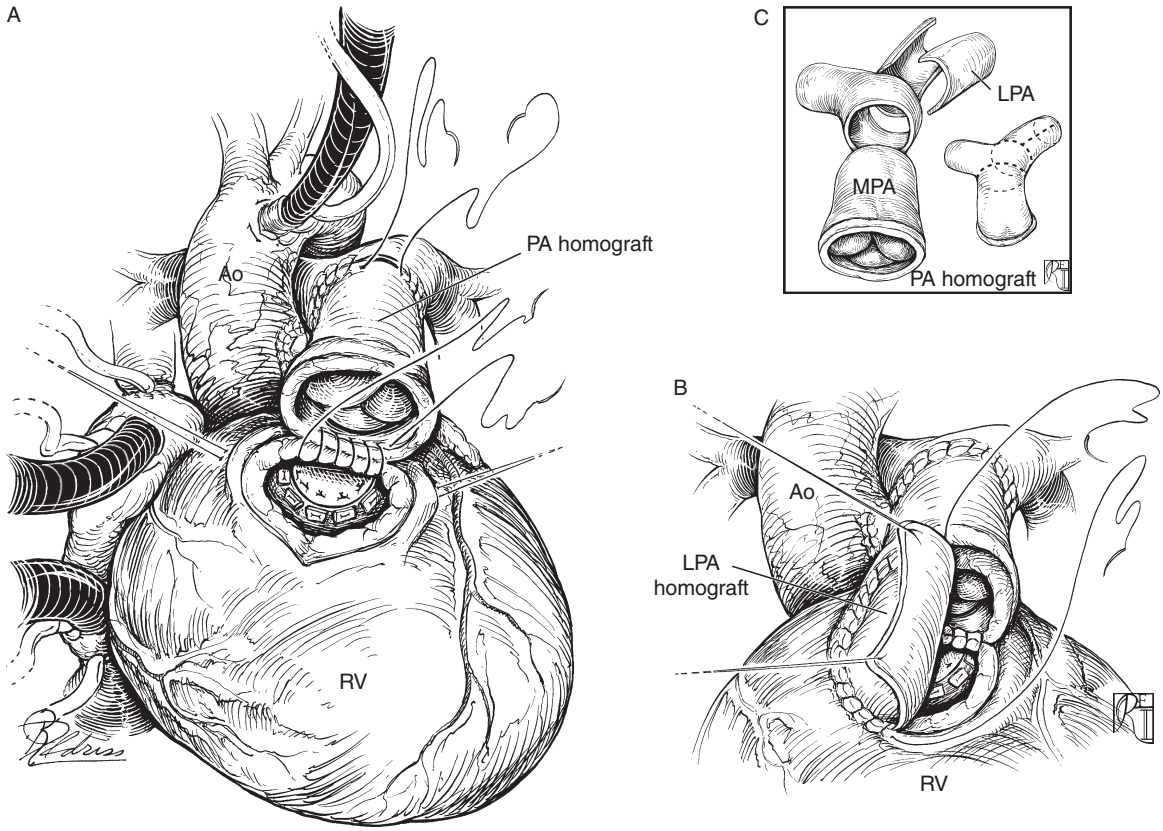

Figure 19.9 A, Distal pulmonary homograft is sutured to the pulmonary artery, and the posterior one-third portion of the homograft annulus is sutured directly to the superior rim of the right ventriculotomy. **B,** Homograft hood technique. The previously harvested left pulmonary artery homograft segment (C) is sutured to the annulus of the proximal homograft and to the remaining portion of the right ventriculotomy. **C,** Pulmonary homograft. The pulmonary bifurcation is separated from the main pulmonary artery and fashioned for the hood technique. (Ao, aorta; LPA, MPA, left, main pulmonary artery; PA, pulmonary artery; RV, right ventricle.)

leads to temporary right ventricular dysfunction. The patent foramen ovale can serve as a "pop-off" to maintain cardiac output when decreased right ventricular compliance limits diastolic filling. The resultant right-to-left atrial shunt during these episodes maintains cardiac output but causes an obligatory mild cyanosis that is usually well tolerated [72]. The patient is then rewarmed while the proximal conduit-to-right ventricular anastomosis is completed. Air and vent removal are followed by separation from cardiopulmonary bypass.

Right ventricular-to-pulmonary artery reconstruction has undergone many changes in the evolution of this repair. Excellent results have been achieved with the relatively stiff 12-mm commercially available porcine-valved Dacron grafts. Accelerated neointimal hyperplasia (Figure 19.10) [18], calcification, and porcine valve degeneration have led surgeons to use cryopreserved homografts and more recently glutaraldehyde-preserved bovine valved internal jugular veins. Because the biological grafts are more pliable, the distal pulmonary anastomosis is less likely to bleed, and can be downsized in the event that the repair need be per-

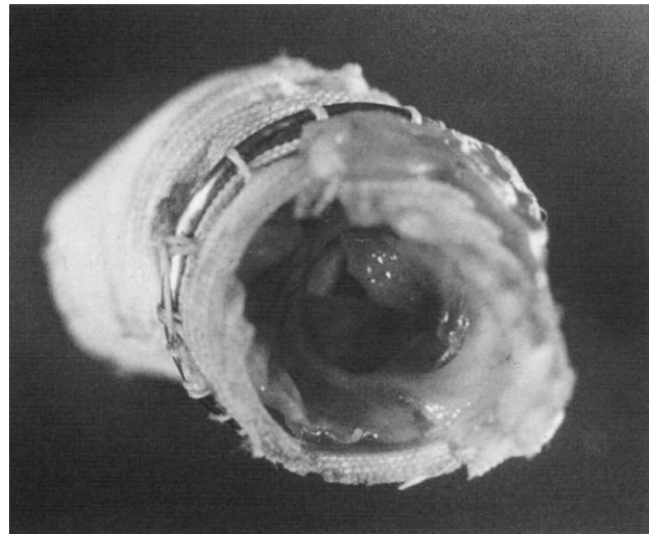

Figure 19.10 Photograph of explanted porcine valved Dacron right ventricular-to-pulmonary artery conduit shows the neointimal peel of fibrous tissue.

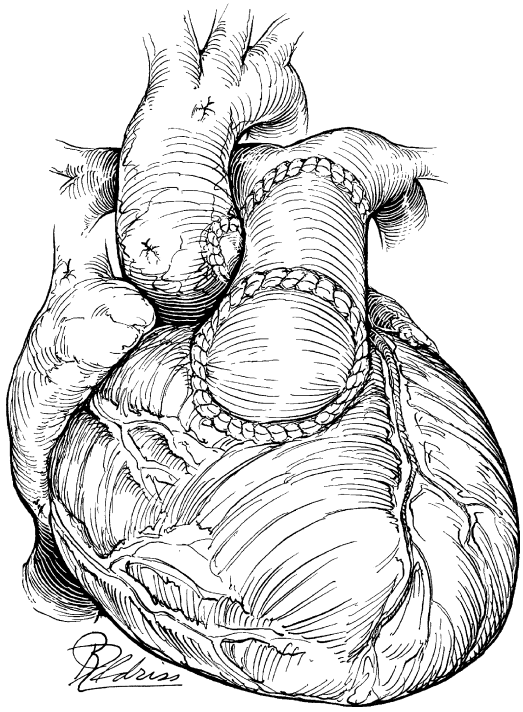

Figure 19.11 Completed homograft hood technique. The homograft hood is used to ensure a generous opening from the right ventricle to the pulmonary artery.

formed in a newborn infant less than 1 month old. Second, homograft or prosthetic material extensions can be employed to minimize the size of the ventriculotomy when desirable. The homograft extension technique has the added benefit of choice between aortic and pulmonary homografts. We and others [52,73,74] have used the Microvel Hemashield (Meadox Medicals, Inc., Oakland, NJ) graft as an extension because of favorable hemostatic properties. However, owing to accelerated neointimal hyperplasia, we have abandoned this technique in favor of homograft hood augmentation techniques using pericardium, homograft material, or PTFE (Figures 19.7–19.9, 19.11) [18]. At the present time, we prefer to use pulmonary homografts and the hood extension technique for right ventricular-to-pulmonary artery continuity. Pulmonary homografts are preferred because they have been shown to resist calcification more than aortic homografts [75,76]. The hood extension technique using PTFE or homograft material allows for a portion of the proximal anastomosis to be performed directly between the right ventricle and the pulmonary homograft, which should limit proximal tubular stenosis. The PTFE hood that completes the reconstruction with rigid material will also limit unwanted cavitary entry in the case of resternotomy for conduit replacement.

Recent technological advances have made available the use of the glutaraldehyde-preserved valved bovine internal jugular graft (Contegra; Medtronic Inc, Minneapolis, MN). While some authors have experienced distal anastomotic stenoses [77–81] with this graft, others have found great utility owing to its accessibility and midterm preservation of valve function [82]. Clearly the comparative long-term benefits and disadvantages of both conduit options will have to be assessed before any informed recommendation can be made.

Repair of Truncus with Interrupted Aortic Arch

After aorto-bicaval cardiopulmonary bypass with separate pulmonary artery constriction is established, the patient is cooled to 18 °C using pH-stat strategy [83,84]. A left ventricular vent is placed; the brachiocephalic vessels are dissected, mobilized, and controlled with snuggers; so too is the descending aorta dissected and mobilized taking care to preserve the recurrent laryngeal nerve. After cardioplegic arrest, a short period (15–30 minutes) of circulatory arrest is used to resect the ductal tissue and perform a direct anastomosis between the proximal and distal aorta thereby performing the arch reconstruction (Figure 19.12) [18]. Cardiopulmonary bypass can then be reinstituted during which time the rest of the operation can proceed. Many variations on this theme have been reported [54–62], both with cardiopulmonary bypass strategies and resultant anatomic configurations. Regional perfusion techniques have been gaining favor since circulatory arrest can be eliminated [85], although there have been no controlled studies to substantiate the utility of this method. Specifically, a Gore-Tex graft is connected, end-to-side, into the innominate or carotid artery (in the case of anomalous descending aorta take-off of the subclavian artery). Cardiopulmonary bypass is commenced with separate pulmonary artery constriction. At 18–20 °C, the proximal brachiocephalic arteries are controlled with snuggers, the descending aorta is clamped, and antegrade cardioplegia is administered. The systemic arterial flow is lowered, allowing direct perfusion to the brain and indirect perfusion to the lower extremity through collateral arteries. The ascending, transverse, and proximal descending aorta is now isolated and can be repaired, segmented, or transposed as necessary. Once the aortic arch reconstruction is completed, whole-body perfusion can be reinstituted through the Gore-Tex graft. After separation from cardiopulmonary bypass, the graft can be clipped, leaving the stump in place. Most anatomic variations use the Lecompte maneuver to transpose the pulmonary artery from the retroaortic area and thus prevent right pulmonary artery compression (Figure 19.12) [18]. Others have used aortic extension techniques to create a larger retroaortic space for the pulmonary artery [62]. Pulmonary artery autologous flaps have also been used for interrupted aortic arch repair [59]. More recent series have documented the high mortality associated with truncus arteriosus and interrupted aortic arch.

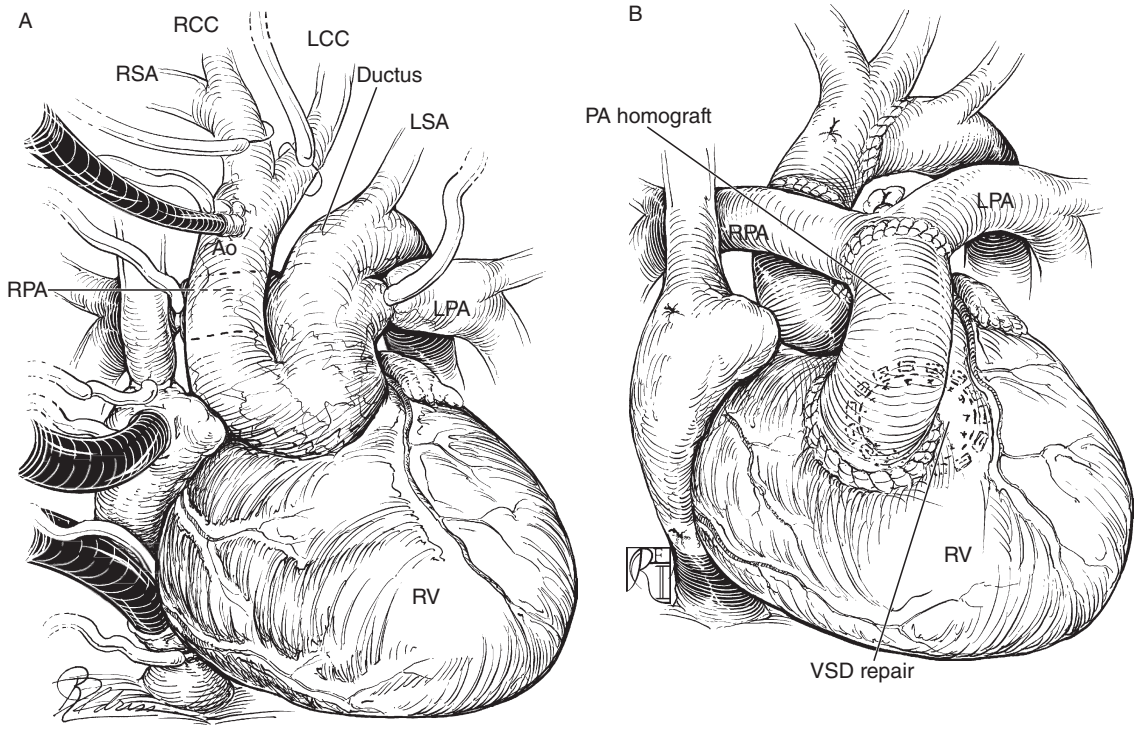

Figure 19.12 Diagrammatic representation shows a patient with truncus arteriosus and interrupted aortic arch. **A,** Aortobicaval cardiopulmonary bypass is established with bilateral pulmonary artery constriction (enforced snuggers). Lower extremity flow is accomplished through the patent ductus arteriosus. **B,** Completed repair of truncus arteriosus with interrupted aortic arch. Direct aortic reconstruction is performed without foreign material. The maneuver of Lecompte facilitates right ventricular-to-pulmonary artery continuity. (Ao, aorta; LCC, RCC, left, right common carotid artery; LPA, RPA, left, right pulmonary artery; LSA, RSA, left, right subclavian artery; PA, pulmonary artery; RV, right ventricle; VSD, ventricular septal defect.)

Konstantinov and the members of the Congenital Heart Surgeons Society reported on 472 neonates between 1987 and 1997 and found the overall mortality to be 44%, 39%, and 31% at 6 months, 1 year, and 10 years respectively [86,87]. Miyamoto and associates [88] reported an operative mortality of 50% owing to the high incidence of truncal valve regurgitation, coronary artery anomalies, and DiGeorge syndrome. They concluded that to improve outcome in these high-risk patients, preoperative management should be optimized, repair should not be delayed, and regurgitant truncal valves should be repaired or replaced. It is clear that surgical repair of truncus arteriosus with interrupted aortic arch is controversial and will require further clinical study if outcomes are to be optimized [55,56]. The surgeon should be cognizant of all repairs and use the best reconstruction for the appropriate circumstance.

Truncal Valve Repair/Replacement

The early surgical solutions to severe truncal insufficiency were prosthetic valve replacement or homograft valve replacement as an aortic root replacement with coronary reimplantation [52,68,70,89,90]. The acute and chronic results were less than satisfactory owing to the increased complexity of the initial and subsequent operations that are necessary because of somatic growth. Truncal valve repair, using a number of techniques, has gained favor over the last few years with excellent results [63–66,68]. Early successful techniques included suturing of partially developed commissures, suspension of cusps, resection of redundant portions of the cusps, annuloplasty of the commissures, and resection of excrescences on the surface of valve leaflets (Figures 19.13 and 19.14) [64,67]. Reports by Jonas [66], Mavroudis and Backer [67], and Mee [65] have emphasized these techniques with excellent short- and mid-term results. Recently, Henaine and associates [91] have analyzed their long-term results with truncus arteriosus repair with special reference to the fate of the truncal valve. They performed truncal valve repair (n = 6) or replacement (n = 3) and achieved a freedom from truncal valve reoperation rate of 96%, 82.3%, and 62.7% at 1, 10, and 18 years postoperatively, respectively, with a low risk for mortality.

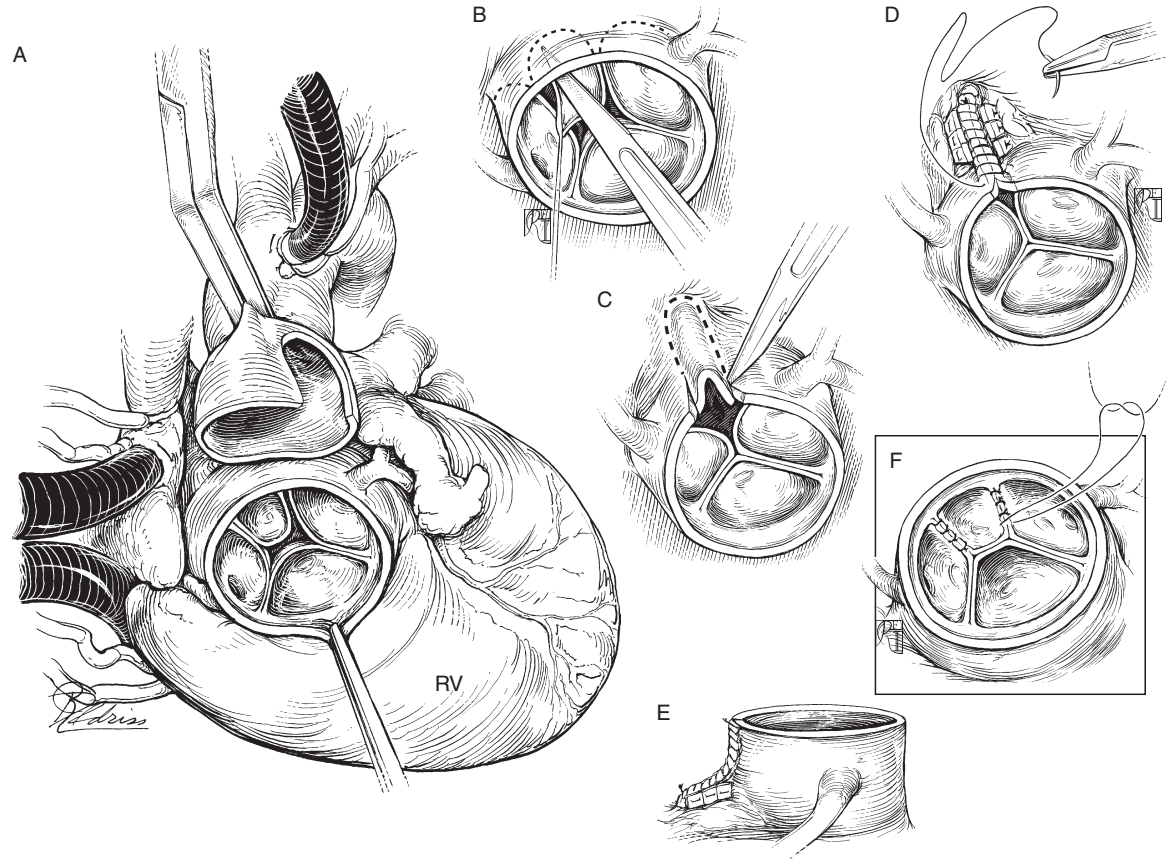

Figure 19.13 Series of diagrams shows two examples of truncal valve repair by (1) leaflet excision and annular remodeling (A to E) and (2) valve suture technique (F). **A,** Translocation of the common arterial trunk shows incompetent quadricuspid truncal valve. Usually one leaflet is grossly prolapsed. In this case, the small prolapsed leaflet does not involve the coronary sinus of Valsalva. **B,** Prolapsed leaflet is removed, care being taken to leave the neighboring leaflets attached. **C,** Sinus of Valsalva truncal wall is resected in preparation for the remodeling procedure. **D,** Pledget-supported sutures are used to tighten the annulus and bring the remaining leaflets together. The rest of the truncal wall is approximated, and the truncal valve is remodeled into a smaller, competent, and nonstenotic neoaortic valve. **E,** Lateral view of the remodeled neoaortic valve. **F,** The suture valvuloplasty technique performed by attaching the edges of the prolapsed leaflet to either one or both adjacent leaflets using fine sutures, thereby creating a functional tricuspid or bicuspid semilunar valve. (Reproduced with permission from Mavroudis *et al.* [67].)

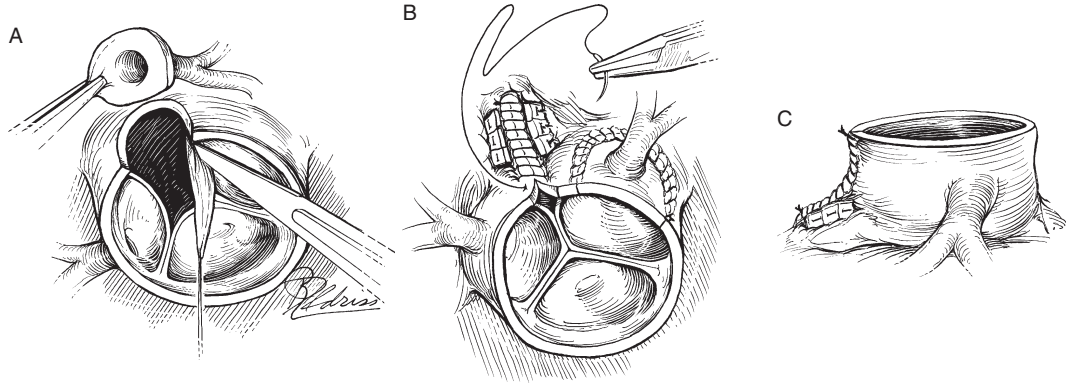

Figure 19.14 The prolapsed leaflet occasionally involves the coronary sinus of Valsalva. Under these circumstances the coronary artery can be reimplanted into the neighboring sinus of Valsalva, and prolapsed leaflet resection and annular remodeling become possible. **A,** Coronary button has been removed from the affected sinus of Valsalva. The prolapsing leaflet is excised. **B,** Annulus is tightened (see Figure 19.13D) and the coronary artery button is reimplanted, using much the same technique as is used for the arterial switch operation. **C,** Lateral projection of the annular remodeling technique. (Reproduced with permission from Mavroudis *et al.* [67].)

Results of Total Correction

The idea that a valved conduit could establish right ventricular-to-pulmonary artery continuity [39] was followed by refinements in infant cardiopulmonary bypass, myocardial protection, and cryopreserved homograft/heterograft availability, which have been instrumental in the evolution of the excellent results that have been achieved. Early perioperative survival, therefore, depends mostly on the amount of increased pulmonary vascular resistance, degree of truncal valve insufficiency, and associated cardiac anomalies rather than perioperative bleeding, coronary compression, or other technical mishaps. The most significant factor responsible for these gains is the steady trend toward earlier correction, which provides a patient with reversible pulmonary vascular obstructive disease and preserved myocardial function.

The early results of complete repair were reported by Marcelletti and colleagues [92], who reviewed the course of 92 patients between 1967 and 1972. They achieved a 75% survival rate, which improved significantly in subsequent reports. Less favorable results were reported by other authors during this time period [93–95]. Ebert's [96] report of 91% survival in 77 infants less than 6 months old showed that improved results were possible. Later reports by Bove [45,52], Pearl [43,44], Hanley [42,49], McKay [53], and others [47,48,51,97–99] confirmed these findings and showed that excellent results are possible even at younger ages and when truncal insufficiency or interrupted aortic arch are also present.

The mid- and long-term survival after complete repair is determined by the degree of truncal insufficiency and the incidence of pulmonary artery conduit replacement. The incidence of truncal valve repair or replacement at the initial repair is low [52]. Subsequent truncal valve repair or replacement may become necessary for progressive truncal valve insufficiency. The intermediate-term surgical results of truncal insufficiency favor repair [66]. This therapy, while not always fully reparative, allows for improved valvar function, avoidance of anticoagulation in the case of prosthetic valve replacement, and somatic growth. The amount of subsequent truncal insufficiency can be re-evaluated either before or at the time of conduit replacement. The truncal valve can be re-repaired or replaced at that time, as noted earlier [91].

Right ventricular-to-pulmonary artery conduit longevity has been the focus of numerous reports that center around the problems of conduit size, valve degeneration, and neointimal hyperplasia [100-120]. Xenograft woven Dacron conduits developed stenosis because of valve calcification and often severe pseudointimal proliferation [100,103,121]. Intimal peel fenestration caused localized dissection, neointimal detachment, and thrombus formation between the intimal peel and the Dacron conduit, which accelerated pseudointimal thickening [100,101]. This process was thought to be the result of low porosity of the woven Dacron graft, which does not allow tight anchoring of the peel to the graft by fibroblastic tissue growth [101,107]. When Dacron low-porosity grafts were used as an extension for homografts, a similar obstructive process was observed [106,114,115]. Kay and Ross [114] reported that the major cause of late homograft obstruction was attributed to peel formation in the composite woven Dacron graft. Bull and associates [106] also showed that conduit obstruction was more often related to the Dacron component than to the homograft portion of the composite graft. Because of these findings, knitted Dacron grafts were employed with the idea that the initial intimal peel would be firmly attached to the graft, thus avoiding constant neointimal detachments, hyperplasia, and obstruction. In animal models, various biologic sealants were used for knitted Dacron grafts to avoid excessive bleeding at the time of implant [104,110,113]. The biologic sealant, in theory, would prevent bleeding in the immediate perioperative period and then be replaced by transitional interstitial ingrowth of fibroblastic tissue into the graft. This would result in a firm neointimal attachment not subject to the forces of disruption that are prevalent in woven grafts. Animal studies confirmed this hypothesis and showed a less than 1-mm neointimal peel when knitted Dacron grafts were used [110]. However, in human studies with Dacron knitted grafts and biologic sealant, the neointimal peel became much thicker, even though the peel was densely and firmly attached to the Dacron graft [73,74]. For these reasons, biologic extension techniques with homografts, PTFE, and pericardial hoods appear to offer the best chance for increased conduit longevity, which should be limited by actual size and not neointimal hyperplasia.

Over the last 10 years, a considerable amount of experience has been gained with use of homograft conduits. The homograft conduits have been shown to have a positive impact on neonatal repair, postoperative bleeding, and perioperative survival when compared with Dacron-housed porcine valves [122]. The durability and replacement statistics of the homograft valves have also been studied. Weipert and associates [123] have noted that reoperation for conduit replacement is dependent on the initial conduit size and somatic growth. They found that all homografts with valve sizes less than 15.0 mm required replacement within 7 years. When the homograft was larger than 15.0 mm, replacement was necessary in 20% at 10 years. Chan and colleagues [124] have closely followed their postoperative truncus arteriosus patients with serial echocardiograms and found that 50% of conduits implanted before 18 months of age could be predicted to stenose by 21.8 months postoperatively compared with only 5% of those implanted after 18 months of age. These data indicate that somatic growth is the discriminating factor that determines the need for conduit replacement.

More recent reports have emphasized that longer intervals between conduit operations can be achieved by valveless right ventricular to pulmonary artery conduits [125–127]. In general, these authors found no difference in operative mortality between the valved conduits and the nonvalved conduits and speculated that early repair will result in less pulmonary hypertension, thereby allowing improved right ventricular tolerance of the valveless strategy. Mayer and coworkers [128,129] have used tissue engineering techniques in experimental animals to "grow" a valved conduit from the animal's own endothelial cells. These conduits have been shown to grow appropriately with the animal and resist degeneration and calcification since the cells are genetically identical to the host. The possibility exists therefore that this strategy could result in only one reparative operation for patients with truncus arteriosus. Further studies and yet undiscovered innovative techniques will surely impact favorably on the long-term therapeutic outcome of these patients.

It appears that patients with successful repair of truncus arteriosus will have to be followed closely for aortic (truncal) insufficiency and right ventricular-to-pulmonary artery conduit failure and can be expected to undergo at least two subsequent open-heart procedures. Fortunately, the results of conduit replacement have been excellent thus far. New areas of clinical research should ameliorate and resolve the problems of neointimal hyperplasia and valve degeneration. These patients can then look forward to longer intervals between operations and fewer complications.

CHAPTER 20

Aortopulmonary Window and Aortic Origin of a Pulmonary Artery

Stephanie Fuller[1,2] and J. William Gaynor[1]

[1]The Children's Hospital of Philadelphia, Philadelphia, PA, USA
[2]University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Introduction

Aortopulmonary (AP) window is a rare congenital heart defect resulting from abnormal separation of the truncus arteriosus into the aorta and pulmonary artery [1–3]. An AP window is found in 0.2% of patients with congenital heart disease [2]. A variety of terms have been applied to this defect, including AP fistula, aortic septal defect, AP septal defect, and AP fenestration. A closely related defect is origin of a pulmonary artery (either the right or the left) from the ascending aorta. The term *hemitruncus* has been used for aortic origin of a pulmonary artery, but this term is inaccurate and should be avoided.

Historical Aspects

Aortopulmonary window was first described by Elliotson in 1830 [4]. Cotton reported the first case in the United States in 1899 [5]. Abbott's classic review of 1000 cases of congenital heart disease included only 10 cases of AP window [6]. In 1948, Gross successfully ligated an AP window in a patient undergoing thoracotomy for closure of a patent ductus arteriosus but noted that this method would be dangerous in many patients [7]. Scott and Sabiston described a closed method for division of AP window [8]. In 1957, Cooley and associates reported the first successful division of AP window during cardiopulmonary bypass [9]. A variety of techniques [2,7,10,13–15,17,18,20,21] have since been described for repair of AP window (Table 20.1).

Aortic origin of a pulmonary artery was first reported by Fraentzel in 1868 [22]. Armer and associates in 1961 reported the first successful repair of aortic origin of the right pulmonary artery by means of an interposition graft [23]. Kirkpatrick and colleagues in 1967 reported the first successful repair [24].

Embryology and Anatomy

In the truncus arteriosus, two opposing truncal cushions form on the right superior and left inferior walls and fuse to form the proximal portion of the septum between the aortic and pulmonary channels [25]. Distally, the fourth aortic arches align with the aortic channel. The distal AP septum, which fuses with the proximal truncal cushion, is formed by the wall between the origins of the fourth and sixth aortic arches. Failure of fusion or malalignment of the truncal cushions can result in a proximal defect in the AP septum. Abnormal migration of the sixth aortic arches can result in distal AP window or aortic origin of a pulmonary artery [26,27].

Most commonly, AP window is a single defect beginning a few millimeters above the semilunar valves on the left wall of the aorta [3,25,28]. Both AP window and aortic origin of a pulmonary artery usually are associated with two normal semilunar valves, differentiating these defects from truncus arteriosus. The defect can be very small or as large as several centimeters in diameter. Aneurysmal dilatation may be seen in large defects. There is usually minimal length to the defect, as the term *window* implies. However, a ductus-like structure occasionally is present.

Either the right or left pulmonary artery may arise from the ascending aorta. Aortic origin of a pulmonary artery should be differentiated from absence of the proximal portion of a pulmonary artery with the distal artery supplied by either a patent ductus arteriosus or AP collateral vessels [27]. The anomalously arising pulmonary artery

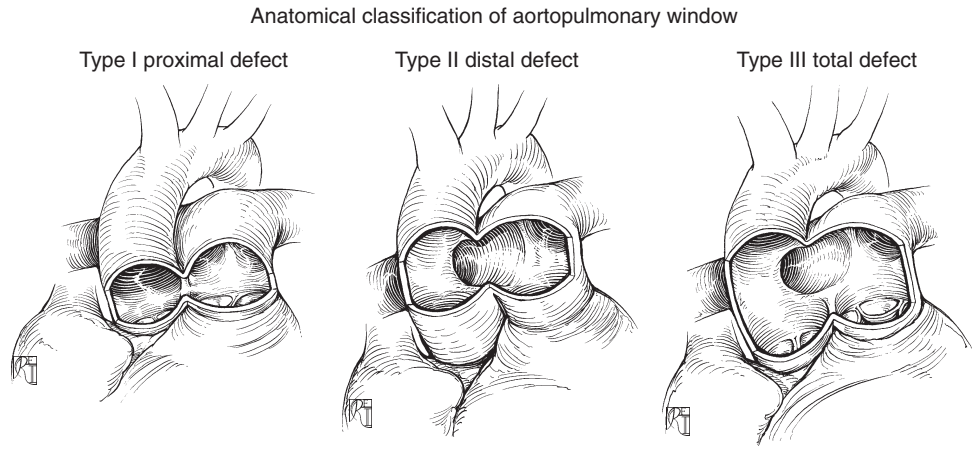

Figure 20.1 Classification of aortopulmonary window.

(commonly the right) usually originates from the posterior aspect of the ascending aorta a short distance above the sinotubular junction. The anomalous pulmonary artery usually is opposite the laterality of the aortic arch, and there is no defect between the ascending aorta and the main pulmonary artery.

In the classification of AP window proposed by Richardson and associates, type I AP window is a proximal defect on the medial wall of the ascending aorta immediately above the sinus of Valsalva [3]. Type II AP window is a more distal defect on the posterior wall of the ascending aorta, usually near the origin of the pulmonary artery. Type III AP window is actually anomalous origin of either pulmonary artery from the ascending aorta. Mori *et al*. proposed an alternative classification (Figure 20.1) [21,29]. Types I and II defects are the same as in Richardson's classification; however, type III AP window is defined as complete absence of the AP septum. Aortic origin of a pulmonary artery is not considered a type of AP window. The Congenital Heart Surgery Nomenclature and Database Project [30] uses a classification system for AP window similar to that proposed by Mori *et al*. [29]. Aortic origin of either pulmonary artery is classified as a separate defect.

Aortopulmonary window is frequently found as an isolated defect. Associated cardiac lesions, including patent ductus arteriosus [31], interruption of the aortic arch [32–34], ventricular septal defect [35], and tetralogy of Fallot [36], are present in one-third to one-half of patients with AP window.

Unlike the common form of interrupted aortic arch, the ventricular septum usually is intact in patients with AP window and aortic arch interruption. Subaortic obstruction is rare in these patients. Diversion of aortic blood into the pulmonary circulation *in utero* with decreased flow to the arch has been proposed as the cause of this combination of defects. When AP window is found in association with interruption of the aortic arch, the arch anatomy usually is that of type A interrupted aortic arch. In a review of the cases of 46 patients with AP window and interruption of the aortic arch, 30 patients were found to have type A interrupted aortic arch, seven patients had type B, and the arch anatomy was not described in nine cases [32]. Associated ventricular

septal defect is more common with AP window and type B interrupted aortic arch. Other associated anomalies include atrial septal defect and systemic venous anomalies.

The association of the tetralogy of Fallot and AP window is unusual, and the diagnosis can be difficult [36]. The left-to-right shunt through the AP window may provide adequate palliation for tetralogy of Fallot until significant pulmonary vascular disease develops. The presence of a right aortic arch with AP window may indicate the presence of tetralogy of Fallot. Ventriculoarterial concordance usually is present, although in rare instances transposition of the great arteries has been reported in association with AP window [37]. In some patients with AP window (5.1% in one series) [35], anomalous origin of either coronary artery from the pulmonary artery is found [38–41]. The orifice usually is found within a few millimeters of the AP window. Unlike the situation for isolated origin of a coronary artery from the pulmonary artery, the coronary artery is exposed to aortic pressure and oxygenated blood. Thus myocardial ischemia is not present, and shunting through the coronary artery does not occur. Chen *et al*. described in 2005 the first reported case of left pulmonary artery sling and AP window [42]. Although narrowed by external compression, the airway was left untreated as no segmental stricture was found [42].

In rare instances, AP window is found in association with extracardiac anomalies, including the VATER complex (vertebral defects, imperforate anus, tracheoesophageal fistula with esophageal atresia, and radial and renal dysplasia). Despite the frequency of associated AP window and interrupted aortic arch, no consistent association of AP window and DiGeorge syndrome has been found. Aortic origin of a pulmonary artery can occur as an isolated defect; however, as with AP window, associated anomalies, including patent ductus arteriosus, interrupted aortic arch, ventricular septal defect, atrial septal defect, and tetralogy of Fallot, may be present.

Clinical Features and Natural History

The physiology of AP window is similar to that of patent ductus arteriosus, ventricular septal defect, and truncus arteriosus. The magnitude of the shunt is related mainly to the size of the defect and to pulmonary vascular resistance. Small defects are associated with small left-to-right shunts and minimal or no symptoms. The defect often is large, and a marked left-to-right shunt is present, resulting in congestive heart failure, pulmonary hypertension, and early development of pulmonary vascular obstructive disease. Cyanosis usually is absent unless severe pulmonary vascular disease has developed, but poor feeding, delayed growth, and repeated respiratory infections are frequently present. At cardiac examination, the heart is enlarged, and a systolic murmur frequently is heard in the third or fourth left intercostal space. Unlike patients with patent ductus arteriosus, a continuous murmur is unusual. The peripheral pulses are bounding. The clinical course is thought to be similar to that of untreated patients with large ventricular septal defect; however, the shunt during diastole (at the expense of systemic and coronary perfusion) may produce earlier symptoms in patients with AP window. Patients with a large AP window usually do not survive infancy. Children and young adults with AP window are occasionally encountered and frequently have congestive heart failure, gradual development of irreversible pulmonary hypertension, and death by Eisenmenger's syndrome. Le Bret *et al*. report a case of a patient diagnosed late at 17 years old with an AP window considered irreparable because of severe pulmonary hypertension, who then presented at 31 years of age with acute dissection and rupture of the pulmonary artery [43].

Aortic origin of a pulmonary artery also results in a large left-to-right shunt and exposes the lung to systemic pressure. The contralateral lung receives the entire right ventricular output. Pulmonary vascular disease may develop at an early age, particularly in the lung exposed to systemic flow. Of interest is that pulmonary hypertension usually is present in the contralateral lung.

Diagnosis

The differential diagnosis of AP window and aortic origin of a pulmonary artery includes patent ductus arteriosus, ventricular septal defect, persistent truncus arteriosus, and ruptured aneurysm of the sinus of Valsalva. The chest radiograph usually reveals cardiomegaly and increased pulmonary vascularity. Echocardiography can show the location and size of the defect (Figure 20.2) and is useful for evaluation of associated anomalies [44,45]. Echocardiography is excellent at depicting the AP window, but the diagnosis can be difficult if the patient has associated anomalies. It may be difficult to differentiate AP window from persistent truncus arteriosus. To confirm the diagnosis, the presence of two separate semilunar valves must be demonstrated. In rare cases, aortic or pulmonary atresia has been reported in association with AP window. Patients with this combination of defects have only one semilunar valve. Although the diagnosis can be difficult, the two conditions are differentiated from those with persistent truncus arteriosus by the presence of two arterial trunks (one with an atretic valve) arising from the base of the heart. The electrocardiogram commonly reveals left ventricular or biventricular hypertrophy. Cardiac catheterization is rarely necessary but may be useful for assessment of pulmonary vascular resistance in older patients and in the evaluation of associated cardiac anomalies.

Surgical Treatment

Surgical repair is indicated in the treatment of all patients with AP window or aortic origin of a pulmonary artery. In

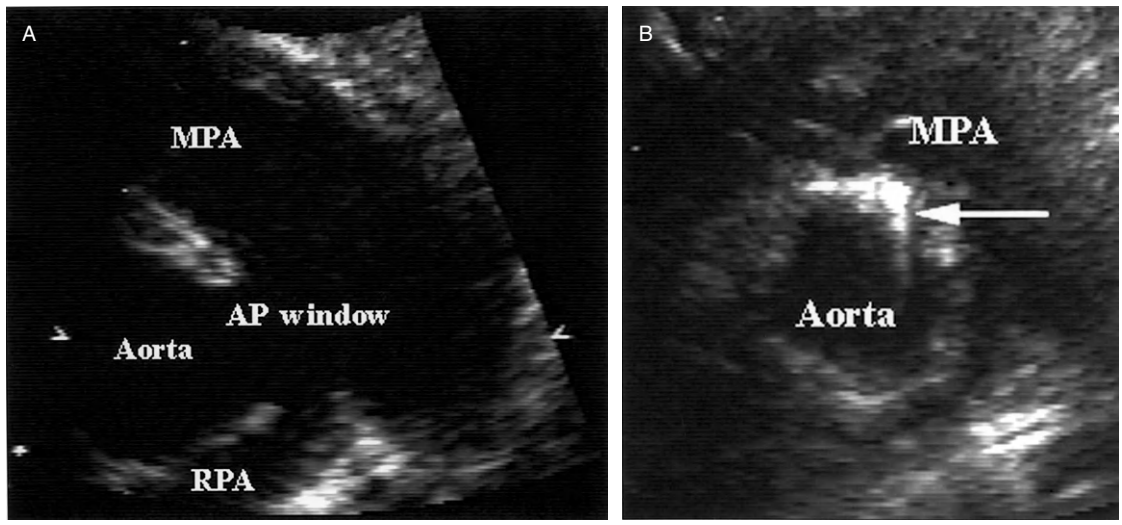

Figure 20.2 A, Preoperative parasternal short-axis echocardiogram shows relations between the aorta, main pulmonary artery (MPA), right pulmonary artery (RPA), and aortopulmonary window. **B,** Postoperative parasternal short-axis echocardiogram shows patch (arrow) between aorta and MPA after anterior sandwich patch repair. (Echocardiograms courtesy of William Mahle, MD.)

rare instances, if the patient has a small asymptomatic defect, an elective operation may be performed after infancy. For most patients, however, repair should be undertaken at the time of diagnosis because of the risk of pulmonary vascular occlusive disease. In patients with associated anomalies, single-stage repair of all defects should be performed.

A variety of techniques have been suggested for repair of AP window. Simple ligation has been used, but there is risk of fatal intraoperative bleeding, incomplete closure, and recanalization. Thus, this method cannot be recommended. Backer and Mavroudis described their single institution experience over a 40-year period in which the mortality for the first 16 patients who underwent simple AP window division was 37% [46]. Attempts at division or suture without the use of cardiopulmonary bypass can result in fatal hemorrhage because the fistula walls are friable and thin.

Other techniques have been described for obliteration of the defect without the use of cardiopulmonary bypass. These procedures, however, are less than satisfactory and cannot be recommended. In general, patch closure of the defect should be performed. Some small defects can be closed primarily. With large defects, direct suture closure may narrow either the pulmonary artery or the aorta and should be avoided. Division of an AP window with simple closure of the aorta and pulmonary artery also can result in stenosis of the vessels. If division is used, patch repair of the resulting defects in the aorta and pulmonary artery should be performed. Backer and Mavroudis describe no deaths in their more recent experience with patients undergoing transaortic patch closure of AP window. At a maximum of 8 years of follow-up, all of these patients demonstrate normal pulmonary artery and aortic growth.

There have been reports of transcatheter closure of AP window [19,47]. Tulloh and Rigby reported successful closure in an 8-kg infant [19]. The surgeons used a double umbrella device. Other reports have documented successful closure in older children and adults. Transcatheter closure may be appropriate in patients with small defects located distal to the semilunar valves and in whom the coronary arteries can be adequately visualized. However, the long-term outcome of transcatheter closure, especially the degree of residual shunting and risk of pulmonary artery stenosis, is not known.

Closure should be performed through a median sternotomy and with cardiopulmonary bypass (Figure 20.3) [21]. The aortic cannula should be inserted as distally as possible on the ascending aorta, well away from the defect, so that placement of the cross-clamp does not interfere with the repair. Single venous or bicaval cannulation may be used, depending on the need for repair of associated anomalies. The pulmonary arteries should be controlled with tourniquets and occluded when cardiopulmonary bypass is instituted. The repair may be performed with either continuous cardiopulmonary bypass or, in small infants, deep hypothermic circulatory arrest. The presence or absence of associated anomalies can alter the operative plan. The anterior wall of the AP window is opened vertically. The coronary ostia must be carefully visualized and included on the aortic side of the patch. If a coronary artery originates from the pulmonary artery, the patch should be positioned to ensure that the coronary ostia remain on the aortic side.

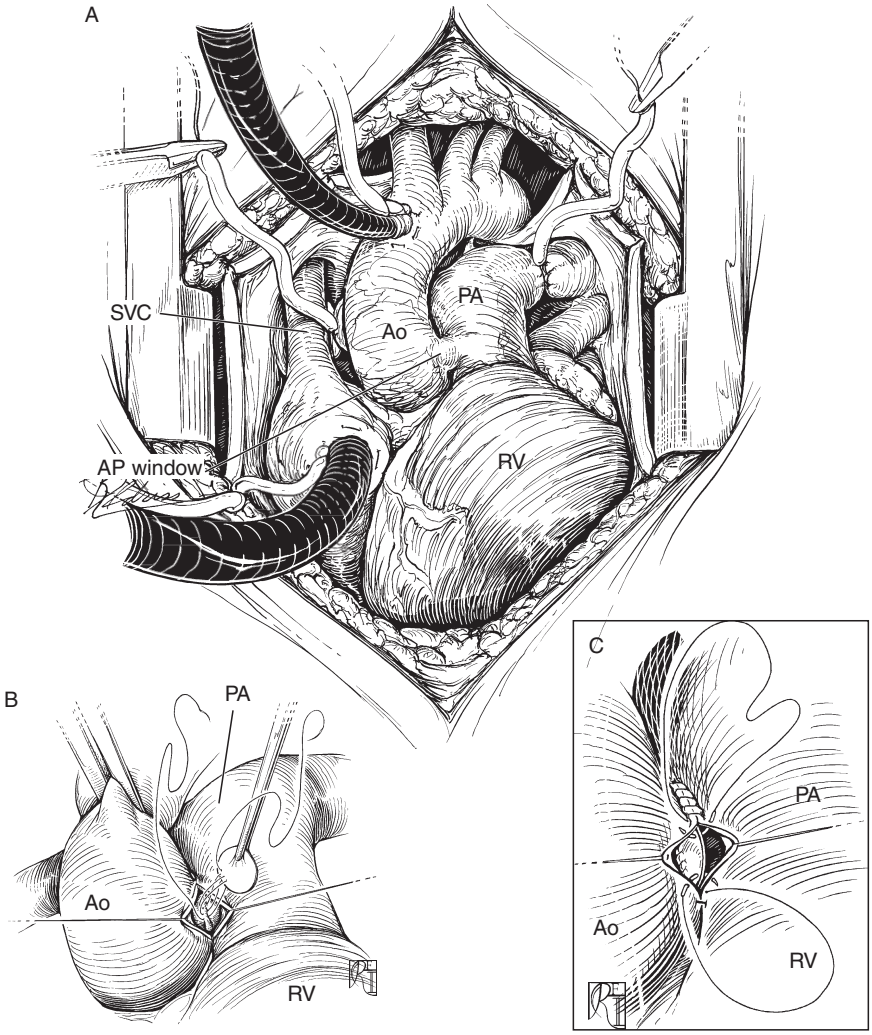

Figure 20.3 Anterior sandwich patch closure of aortopulmonary window. **A,** The aorta is cross-clamped after institution of cardiopulmonary bypass. **B,** The defect is opened anteriorly, and a prosthetic patch is sutured to the superior, posterior, and inferior rims. **C,** The patch is incorporated in the closure of the anterior incision. (Ao, aorta; AP, aortopulmonary; PA, pulmonary artery; RV, right ventricle; SVC, superior vena cava.)

Coronary transfer as in the arterial switch operation may occasionally be required. Repair usually is performed with the anterior sandwich patch technique. A prosthetic patch is sewn to the superior, posterior, and inferior rims of the defect (Figure 20.3) [21]. The incision is closed, incorporating the patch in the anterior suture line. Transpulmonary closure is not recommended because of difficulty in visualizing the fistula and coronary ostia. Transaortic patch closure is an acceptable alternative.

Cannulation for repair of AP window with interrupted aortic arch is the same as that for repair of isolated AP window (Figure 20.4) [21]. A single aortic cannula is positioned in the ascending aorta, and the pulmonary arteries are occluded with snares after institution of cardiopulmonary bypass. Perfusion of the lower body is maintained through the AP window and the ductus arteriosus. The cerebral vessels are controlled with tourniquets and occluded after adequate cooling and institution of deep hypothermic circulatory arrest. There often is little distance between the AP window and the origin of the cerebral vessels. The AP window is divided and the incision carried superiorly onto the left subclavian artery (type A interrupted aortic arch) or the left carotid artery (type B). The ductus is ligated and all ductal tissue is excised. The superior portion of the descending aorta is anastomosed to the superior aspect of the incision in the aorta and subclavian artery. A homograft patch is used to augment the underside of the aorta and extended proximally for closure of the defect caused by the AP window in the ascending aorta. The pulmonary artery is reconstructed with a separate patch to avoid stenosis.

Patients with aortic origin of a pulmonary artery should undergo repair by direct anastomosis of the anomalous pulmonary artery to the main pulmonary artery (Figure 20.5) [21] The use of prosthetic grafts should be avoided. Cannulation and the conduct of cardiopulmonary bypass are similar to those for repair of AP window. The anomalous pulmonary artery is divided at its origin from the

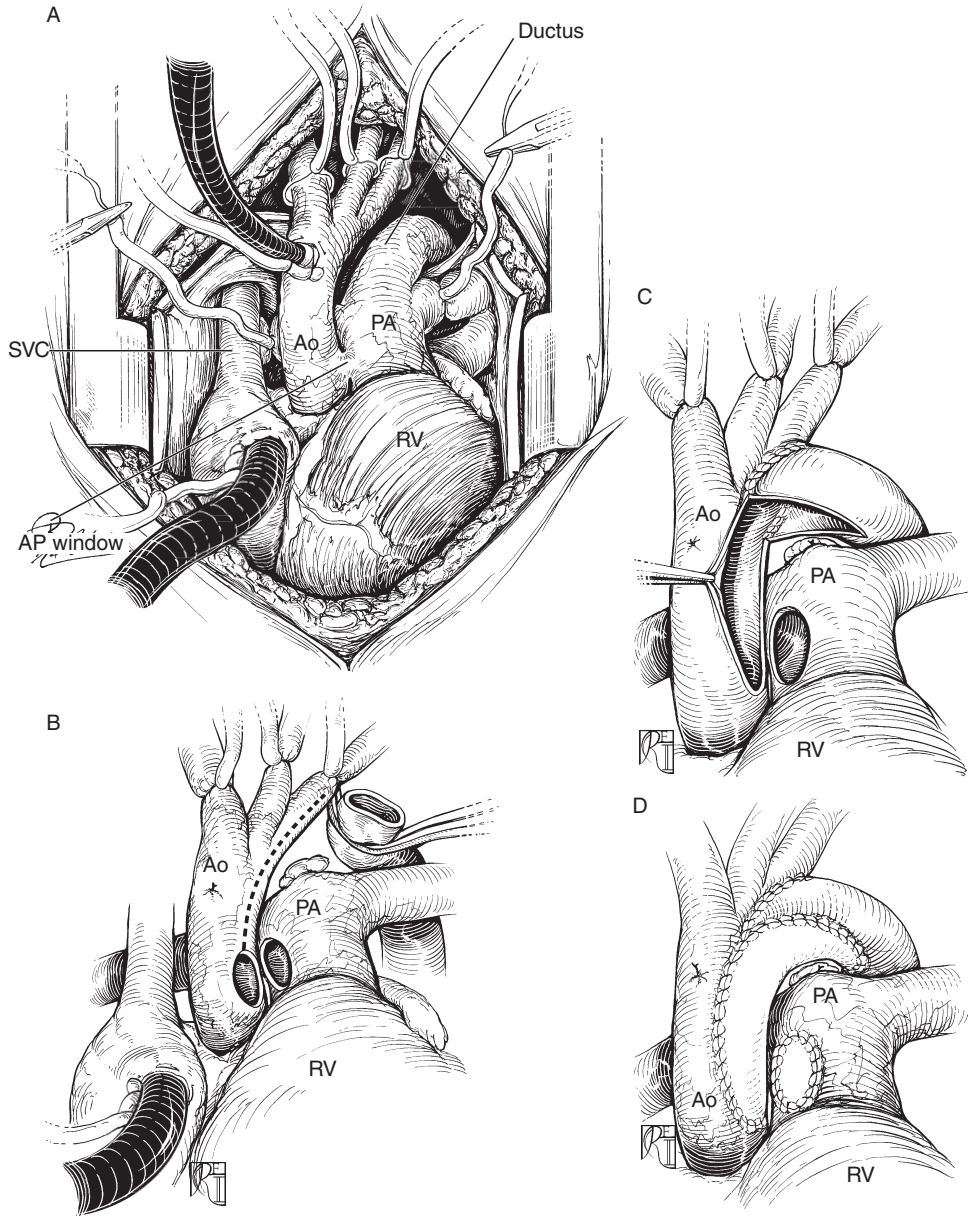

Figure 20.4 A–C, Repair of aortopulmonary window and interrupted aortic arch. (Ao, aorta; AP, aortopulmonary; PA, pulmonary artery; RV, right ventricle; SVC, superior vena cava.)

aorta, and the defect is closed with a patch. An incision is made in the main pulmonary artery. The right pulmonary artery is positioned posterior to the ascending aorta, and the anastomosis is completed. It may be helpful to use a flap of main pulmonary artery to reduce tension on the anastomosis.

Postoperative Course

The postoperative course usually is routine after closure of AP window. Intraoperative transesophageal echocardiography is useful for confirming complete closure of the defect and ensuring that the pulmonary arteries have not been narrowed. In some cases, however, severe pulmonary hypertension occurs. These episodes can occur suddenly in the postoperative period and are characterized by increased pulmonary artery pressure, hypoxia, hypotension, and worsening peripheral perfusion. Therapy consists of sedation, paralysis, and hyperventilation with 100% oxygen. In refractory cases, treatment with inhaled nitric oxide or support with extracorporeal membrane oxygenation may be useful.

Outcome After Surgery

Tkebuchava and colleagues reported on the outcome of repair of AP window in 11 children who, between 1971 and 1993 underwent repair by a variety of techniques at a mean age of 31 months [48]. There was one operative death of a neonate with AP window and interrupted aortic arch, and there were no late deaths. One patient needed reoperation for recurrent AP window and one for pulmonary artery stenosis. Di Bella and Gladstone reported on repair of AP window in six infants between 1993 and 1995 [49]. Four patients with isolated AP window underwent repair with an anterior pulmonary artery flap technique. In two infants with AP window and interrupted aortic arch, the distal aorta was anastomosed directly to the aortic defect after division of the AP window. There were no hospital or late deaths, and no child had needed reintervention after a mean follow-up period of 30 months.

McElhinney and associates reported on outcome after reports of AP window in 24 patients younger than 6 months [28]. Isolated AP window was present in 12 patients, associated interrupted aortic arch in nine, and other anomalies in three. There were no early or late deaths of patients with isolated AP window. There were five early deaths of patients with associated lesions. All patients who survived repair of AP window and interrupted aortic arch had recurrent arch obstruction, but only two needed reintervention.

The operative mortality for repair of isolated AP window or aortic origin of a pulmonary artery approaches zero, even among infants. For patients without associated anomalies, the late results of surgical correction of AP window

are excellent. The risk of recurrent fistula formation is unknown but should be low with patch closure or division of the AP window. Limited data are available on long-term outcome after repair of aortic origin of a pulmonary artery. The patients must be observed closely for development of pulmonary artery stenosis. For patients with complex associated anomalies, the prognosis is determined largely by the presence of associated anomalies. For older patients, outcome depends largely on pulmonary vascular resistance at the time of repair.

CHAPTER 21

Isolated Right Ventricular Outflow Tract Obstruction

John M. Karamichalis,[1] Jeffrey R. Darst,[2] Max B. Mitchell,[3] and David R. Clarke[4]

[4]University of Colorado Denver, Aurora, CO, USA

Isolated right ventricular outflow tract obstruction involves a broad spectrum of lesions ranging from mild valvar pulmonary stenosis to pulmonary atresia with associated secondary right-sided cardiac defects. As indicated by the title, this chapter considers only lesions in which right ventricular outflow tract obstruction occurs in the presence of an intact ventricular septum with normal ventriculoarterial connections. The variety of congenital lesions accompanied by right ventricular outflow tract obstruction is addressed in other chapters. Specifically, this chapter focuses on the surgical management of pulmonary atresia with intact ventricular septum (PA-IVS), neonatal critical pulmonary stenosis, and valvar pulmonary stenosis beyond the neonatal period. Isolated supravalvar pulmonary artery stenosis and subvalvar right ventricular outflow tract obstruction are also discussed. Reference is also made to catheter intervention treatment modalities.

Pulmonary Atresia with Intact Ventricular Septum

Incidence, Definition, and Etiology

Pulmonary atresia with intact ventricular septum is an uncommon lesion with an incidence of approximately 4.5 cases per 100 000 live births [1,2]. As such this lesion represents fewer than 1% of all congenital heart defects [3,4]. The name of this lesion is derived from the fact that there is no physiologic communication between the right ventricle and the pulmonary arteries. Although conceptually simple, PA-IVS is frequently complicated by substantial associated morphologic abnormalities of the right side of the heart and coronary arteries [5]. The degree of right heart development varies widely from minor hypoplasia of the right ventricle to severe underdevelopment with right ventricular-dependent coronary circulation. This spectrum of morphologic variation mandates individualized management that can involve biventricular or univentricular strategies.

The cause of PA-IVS is unknown. Kutsche and Van Mierop [6] postulated that this lesion occurs relatively late in embryologic development after cardiac septation. Variations in the timing of the insult that causes the pulmonary valve to become atretic may account for the spectrum of associated morphologic lesions of the pulmonary valve annulus, right ventricular myocardium, tricuspid valve, and coronary arteries. Conceptually, pulmonary atresia occurring very soon after cardiac septation would result in a completely undeveloped pulmonary valve, a diminutive right ventricle, and extensive right ventricular-to-coronary artery communications. Conversely, pulmonary atresia occurring later in gestation would result in a larger right ventricle, absence of coronary artery anomalies, a pulmonary valve with three developed sinuses of Valsalva, and three distinct, completely fused leaflets. Kutsche and Van Mierop [6] also hypothesized that the etiologic insult is a prenatal inflammatory process. However, histopathologic studies of fetuses and neonates with pulmonary atresia have not demonstrated evidence of inflammation [7].

In most cases the main pulmonary artery is well developed, and the ductus arteriosus is present, a finding suggesting that at some time in utero antegrade right ventricular blood flow was present [4]. Studies with fetal echocardiography have shown antegrade flow across the pulmonary

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

valve in fetuses that have subsequently developed pulmonary atresia [8]. This finding suggests that altered hemodynamics may be a primary cause of pulmonary atresia. Increased left-heart loading owing to changes in the tricuspid valve, foramen ovale, and patent ductus arteriosus during early development could lead to left-to-right ductal flow with lack of right heart ejection. The result is fusion of the pulmonary valve leaflets as development proceeds [9].

Other authors have proposed a genetic cause of PA-IVS [10–14]. A recent report of PA-IVS occurring in monozygotic twins [11], points to a genetic etiology of this disorder. The significance of the array comparative genomic hybridization (aCGH) results, which show a 55-kb deletion in 20q13.12 involving the WFDC8 and WFDC9 genes in both of these patients is unclear, however they suggest that a combination of genetic and environmental factors may be responsible for some cases of PA-IVS.

A different study [10], showed for the first time an association of 22q11.2 deletion with PA-IVS and absent pulmonary arteries, discussing a possible role of the deletion in pulmonary artery arborization, and also increasing the spectrum of deletion 22q11.2 associated cardiac malformations. Autosomal dominant inheritance with incomplete penetrance of PA-IVS was suggested by a report of two first cousins with PA-IVS [13]. The authors suggest a genetic cause that is mitochondrial, autosomal dominant with incomplete penetrance or multifactorial. Laterality defects (heterotaxy) have been associated with connexin43 mutations, and mice lacking connexin43 developed PA-IVS [12].

Morphology

Pulmonary atresia with intact ventricular septum almost always occurs in hearts with a situs solitus position that have concordant atrioventricular and ventriculoarterial connections [15]. The branch pulmonary arteries are confluent and arborize normally in the lungs. In most cases a single ductus arteriosus connects the pulmonary arteries to the systemic circulation. The confluence of the main pulmonary artery with the branches usually is normal, and a well developed main pulmonary artery tapers proximally to an atretic valve. The pulmonary valve may vary from a minuscule fibrous dimple with long segment muscular atresia to a fused trileaflet valve with well developed commissures and sinuses (Figure 21.1) [16].

Although the right-sided structures distal to the atretic valve are relatively normal, structures proximal to the valve often are markedly abnormal. The heart usually is enlarged owing to right atrial dilatation. In the presence of severe tricuspid regurgitation, the heart may be massively enlarged and resemble a severe form of Ebstein anomaly. Secundum atrial septal defect or patent foramen ovale must be present to allow *in utero* development and subsequent live birth. The tricuspid valve is nearly always abnormal [17]. Tricuspid regurgitation is present in essentially all cases; severe regurgitation is present in approximately 25% of cases [18]. The tricuspid annulus is typically hypoplastic. The tricuspid valve leaflets are dysplastic, having shortened chordae and restricted leaflet motion. In other cases concomitant Ebstein anomaly occurs and is characterized by a dilated tricuspid annulus, redundant sail-like anterior leaflet, and downward displacement of the septal and posterior leaflets. In rare instances, severe deficiency of tricuspid leaflet tissue leaves the tricuspid orifice essentially unguarded [19].

The right ventricle is abnormal. In 90% of cases it is hypertrophied and hypoplastic (Figure 21.2) [16,18].

Figure 21.1 Pathologic specimen from a neonate with pulmonary atresia with intact ventricular septum viewed from main pulmonary artery. Developed sinuses and valve commissures are evident.

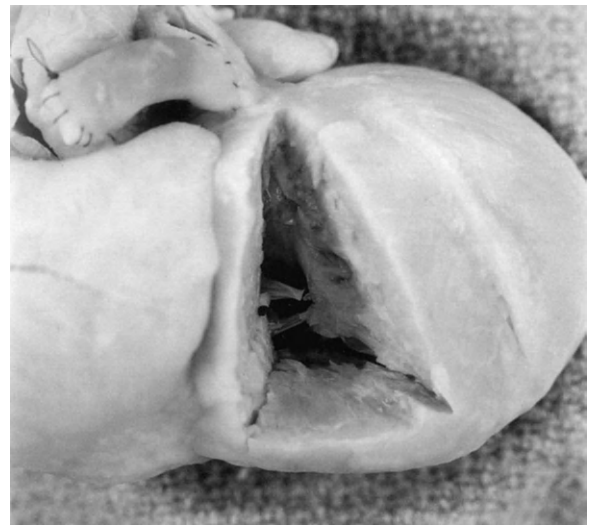

Figure 21.2 Pathologic specimen of neonate with pulmonary atresia with intact ventricular septum. Hypertrophy of right ventricular wall and marked reduction of ventricular cavity are evident.

Ventricular cavity size is severely reduced in more than 50% of cases [16,18]. Less commonly the right ventricle is thinned and markedly dilated. This situation occurs only with more severe degrees of tricuspid regurgitation, particularly when Ebstein anomaly or unguarded tricuspid valve orifice is present [19]. In the usual case of a small right ventricle, the degree of hypoplasia varies. The size of the right ventricle correlates very closely with the size of the tricuspid valve annulus [16,18]. In an effort to direct appropriate treatment choices, Bull and colleagues [20] categorized right ventricular morphology in PA-IVS as unipartite (inlet part only), bipartite (inlet and outlet parts), and tripartite (inlet, outlet, and trabecular parts). This classification has been questioned on a developmental basis because even very small right ventricles are thought to have all three components with massive hypertrophy obliterating the trabecular and/or outlet portions. The importance of this distinction is that even very hypoplastic ventricles composed of all three parts can grow and eventually function normally after decompression [21,22].

A spectrum of intramural and extramural coronary artery abnormalities can occur with PA-IVS. These abnormalities can be congenital or acquired, and many of them are specific to hearts with PA-IVS [7]. More than one half of all cases are accompanied by some form of coronary artery abnormality [18]. Fistulas between the right ventricle and the coronary arteries are the most common abnormality. When a fistula is present, the coronary artery tree usually communicates with the right ventricular cavity through endothelium-lined channels, known as sinusoids, within the right ventricular muscle mass. When a coronary fistula enters a sinusoid, this is also known as coronary-cameral fistula. Sinusoids most likely represent remnants of sinusoidal channels that provide myocardial blood before formation of the coronary arteries during development. In many cases localized areas of myointimal hyperplasia result in development of coronary artery stenosis and, more rarely, complete interruption. These lesions have been identified in fetuses as well as newborns with PA-IVS. Interestingly, the coronary stenosis does not occur in the absence of ventriculocoronary connections. When present the stenotic lesions are near the fistulas. Furthermore, these lesions occur in association with PA-IVS only when the right ventricle is a thick-walled high-pressure chamber [7]. These findings suggest that the cause of the stenotic coronary lesions in PA-IVS may be acquired intimal injury secondary to turbulent competitive blood flow from the high-pressure right ventricle through the fistulas into the coronary arteries [5,7,23].

In rare cases there is no proximal aortocoronary connection, and all coronary perfusion is supplied from the right ventricular cavity. This type of coronary lesion usually is remote from the ventriculocoronary connection, and the cause of such a lesion is thought to be congenital. The importance of concomitant coronary stenosis or obstruction and ventriculocoronary connections is that perfusion of the myocardium distal to stenotic lesions may depend on desaturated venous blood from the high-pressure right ventricular cavity. Importantly the presence and physiologic implications of ventriculocoronary connections correlate closely with small tricuspid valve diameter, small right ventricular cavity, and increased right ventricular pressure [18,24].

Myocardial abnormalities are the rule with PA-IVS [5]. In most cases there is severe right ventricular hypertrophy with reduced cavity volume. Myocardial fiber disarray is a distinctive histopathologic finding associated with the hypertrophy present in this lesion [25]. Ischemic changes with infarction and diffuse fibrosis may occur in the myocardium [26]. In severe cases endocardial fibroelastosis may occur. Sinusoids with or without concomitant coronary artery fistulas occur in as many as 50% of cases [18] but only when there is a thick-walled high pressure right ventricle. In the approximately 5–10% of cases with severe tricuspid valve incompetence, dilatation and marked thinning of the right ventricle are common. In such cases sinusoids and coronary fistulas do not occur [7].

Natural History

In the absence of medical therapy and surgical intervention during the newborn period, survival of patients with PA-IVS is rare [27]. Within 2 weeks of life mortality is approximately 50% and by 6 months mortality is approximately 85% [27]. Survival beyond the neonatal period requires an alternative source of pulmonary blood flow. In rare cases patients have survived to the third decade because of the presence of a patent ductus arteriosus or aortopulmonary collateral vessels [28,29].

Pathophysiology

Infants born with PA-IVS depend on the ductus arteriosus for pulmonary blood flow, and systemic venous return enters the left atrium through a nonrestrictive atrial level communication. Consequently, all of these children are cyanotic to some degree. Closure of the ductus arteriosus produces profound hypoxemia, acidosis, and hemodynamic collapse. Prostaglandin E (PGE_1) infusion is required to maintain ductal patency. In unusual cases restriction at the atrial septal defect causes elevated central venous pressure, diminished left heart loading, and hypotension. In most cases, however, shunting at the atrial level is unrestricted, and cardiac output is preserved as long as the ductus arteriosus remains patent.

Cardiac output is markedly elevated because the left ventricle must also provide pulmonary blood flow. The ratio of pulmonary to systemic blood flow ranges between 2:1 and 4:1 depending on the relative resistance of the two circulations. Systemic oxygen saturation depends on pulmonary blood flow and usually ranges from 70–90%.

Saturation greater than 90% suggests pulmonary overcirculation. The low-resistance runoff into the pulmonary circulation results in a widened pulse pressure. In the absence of severe tricuspid regurgitation, the hypoplastic right ventricular cavity has systemic or suprasystemic systolic pressure and elevated diastolic pressure. Less commonly a dilated right ventricle, present when there is gross tricuspid incompetence, has lower intracavitary pressure.

Myocardial perfusion is perturbed relative to that in a normal heart, in which most perfusion occurs during diastole and myocardial oxygen consumption is near maximal. Oxygen transport is limited by cyanosis. Tachycardia, common in these infants, shortens the diastolic time interval and increases myocardial oxygen demand. Elevated wall tension in the right ventricle also increases myocardial oxygen demand and limits perfusion because of the decreased gradient between aortic diastolic pressure and the right ventricular coronary bed. This situation is further compounded by decreased aortic diastolic pressure, which occurs in the presence of a patent ductus arteriosus. Consequently, such patients have markedly decreased coronary reserve.

Coronary reserve is even more limited in the presence of ventriculocoronary connections with right ventricle-dependent coronary circulation. In some cases coronary blood flow may even be retrograde into the ascending aorta (Figure 21.3) [16]. Regions of myocardium supplied by coronary arteries distal to interruptions or areas of marked stenosis depend on desaturated blood supplied by the high-pressure right ventricle, which always is present in this circumstance. Despite elevated right ventricular systolic and diastolic pressure, intracavitary diastolic pressure usually is lower than normal aortic diastolic pressure. Therefore in contrast to the normal situation, perfusion of right ventricle-dependent myocardium may not occur primarily during diastole. Any reduction in right ventricular pressure, owing to hypovolemia, right ventricular outflow tract decompression, or balloon disruption of the tricuspid valve, can compromise the extremely marginal coronary reserve in these patients and have disastrous consequences. Varying configurations of coronary fistulas and proximal coronary stenosis may result in lesser degrees of myocardial dependence on right ventricular coronary blood flow with important but less severe consequences from right ventricular decompression.

Moderate to severe tricuspid valve regurgitation occurs in most cases because of elevated right ventricular pressure and anatomic abnormalities of the leaflets, chordae, and papillary muscles [17]. In cases of deficiency of leaflet tissue or concomitant Ebstein anomaly, regurgitation is massive.

Figure 21.3 Right ventricular angiogram of a neonate with pulmonary atresia with intact ventricular septum shows severe right ventricular hypoplasia and multiple ventriculocoronary connections. Retrograde flow of contrast material from the coronary bed into the ascending aorta is evident. (Courtesy Dr K Chan Chen, University of Colorado, Denver, CO, USA.)

Clinical Presentation and Diagnosis

Most infants with PA-IVS are born at term. Soon after birth, progressive cyanosis develops. With closure of the ductus arteriosus, profound hypoxemia unresponsive to supplemental oxygen occurs. Even with appropriate resuscitation and PGE_1 infusion, such infants usually have tachycardia and tachypnea. Auscultation reveals a systolic murmur of ductal flow and single first and second heart sounds. Depending on the degree of severity, a pansystolic murmur of tricuspid regurgitation may be heard at the left sternal border. The electrocardiogram demonstrates dominant left ventricular forces in contrast to the usual dominant right ventricular forces found in the neonate. On a chest radiograph the cardiac silhouette appears normal unless severe tricuspid regurgitation and associated right atrial and ventricular enlargement are present. Pulmonary vascular markings are diminished but may become more normal with resuscitation. Echocardiography demonstrates absence of the right ventricular outflow tract and is the primary diagnostic modality. Right ventricular cavity size and function (Figure 21.4) [16], tricuspid valve dimensions

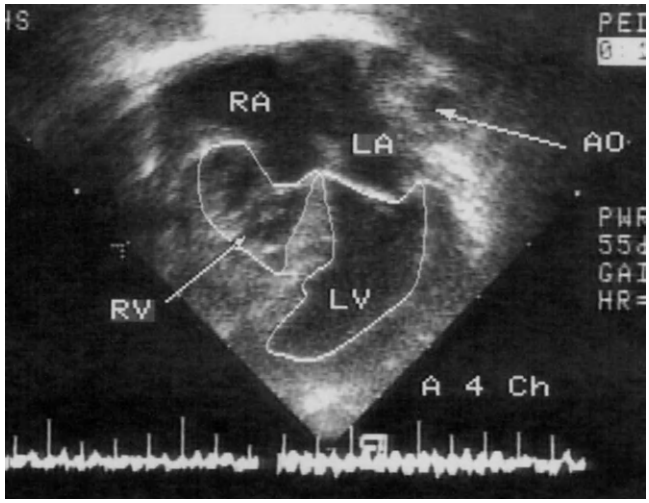

Figure 21.4 Two-dimensional echocardiogram in apical four-chamber view shows pulmonary atresia with intact ventricular septum at end diastole. Hypoplasia of right ventricular cavity is evident. (AO, aorta; LA, RA, left, right atrium; LV, RV, left, right ventricle.)

and function, and right-to-left atrial level shunting as well as patency of the ductus arteriosus all can be reliably assessed. In some cases echocardiography documents coronary artery fistulas (Plate 21.1, see plate section opposite p. 594) [16]. Echocardiography and cardiac catheterization are complementary, and both studies should be performed in all cases. Cardiac catheterization is the only means of conclusively defining coronary anatomy and demonstrating the presence or absence of ventriculocoronary fistulas. In some cases interventional catheterization may play a stabilizing or even therapeutic role. For example, balloon atrial septostomy may be necessary in a patient with a restrictive atrial level shunt.

The differential diagnosis of PA-IVS includes neonatal conditions marked by cyanosis, soft systolic murmur, and decreased pulmonary vascular markings. The diagnostic possibilities include critical pulmonary stenosis, tetralogy of Fallot, pulmonary atresia with ventricular septal defect, neonatal Ebstein anomaly, tricuspid atresia with pulmonary atresia, and complex univentricular heart with pulmonary atresia.

Management

Preintervention Medical Management

The initial medical treatment of a patient with PA-IVS usually must begin before a specific diagnosis can be established. Therefore treatment is similar to that of any neonate with suspected cyanotic congenital heart disease. Vascular access should be established, and PGE_1 infusion should be initiated to maintain ductal patency. Metabolic acidosis should be corrected, and inotropic support should be initiated if perfusion is inadequate. Mechanical ventilation and pharmacologic paralysis may be necessary for very ill neonates.

Choice of Initial Therapy

The diagnosis of PA-IVS is in itself an indication for surgical or in some cases catheter-based intervention. Because this lesion manifests with such a wide degree of morphologic variability, the choice of therapy is complex. The primary options for initial therapy include decompression of the right ventricle alone by surgical or transcatheter valvotomy or transannular patch, construction of a systemic-pulmonary artery shunt alone, or a combination of a pulmonary outflow tract procedure and shunt. Possible outcomes encompass a gamut that includes biventricular repair, the perceived middle ground of the so-called one-and-a-half ventricular repair, and univentricular management. Cardiac transplantation has been advocated in severe cases.

A study of 210 consecutive patients with PA-IVS concluded that outcomes have improved over time [30]. This study also indicated that careful initial management, and better selection, are still needed for those patients destined to undergo biventricular repair.

Appropriate management must balance the operative risk of the initial therapeutic choice with long-term functional outcome. The primary goals of initial therapy should be to minimize mortality and simultaneously optimize the likelihood of eventual biventricular repair. One difficulty is that the strategy that achieves the lowest initial mortality (systemic-pulmonary artery shunt alone [18]) may prevent achieving biventricular repair. Several reports have indicated that patients with severely hypoplastic right ventricle can be treated with medium-term mortality equivalent to that of patients with less severe morphology; however, precise management algorithms are difficult to derive from these reports [31,32]. The long-term goal of achieving biventricular repair in the maximum number of patients may be offset by the reasonable clinical outcome of management schema in which a larger number of patients undergo univentricular management [31,32].

Most single-center reports of surgical outcome of PA-IVS either describe too few patients or are too vague to provide useful morphologic criteria for the initial treatment of these patients. Several centers have proposed various morphologic criteria for guiding the choice of initial management [24,33–37]. Most of these reports describe some measure of right ventricular size or morphology. More recently, fetal tricuspid valve Z score and rate of growth have been

suggested to predict postnatal outcome [38]. One simple approach has been to attempt right ventricular decompression with pulmonary valvotomy and construct a systemic-pulmonary artery shunt in all patients found to have a right ventricular infundibulum. Patients without an infundibulum or those having right ventricle-dependent coronary circulation undergo shunt alone. Results with this strategy have been mixed. The need for eventual biventricular, intermediate, or univentricular repair is determined on the basis of subsequent right ventricular development [22,24,37,39]. Unfortunately, there is considerable morphologic variability in patients who have a right ventricular infundibulum, and this strategy may subject some patients to an unnecessary shunting procedure with the obligatory need to occlude the shunt at a later date.

There is no consensus on the therapeutic intervention most appropriate in all cases [24,31–33,37,40–51]. This lesion is rare, and individual institutional experiences are relatively limited. Ideal therapeutic management depends on the morphologic and physiologic substrate of the individual patient. The recognition that right heart growth may occur in markedly hypoplastic right ventricles after establishment of right ventricular-to-pulmonary artery continuity has added further complexity to initial decision making, largely because accurate guidelines for predicting eventual right heart functional capacity are limited [21,22,52–56]. There are cases at the worst end of the morphologic spectrum in which univentricular physiology is the only possible course. There are also cases at the most favorable end in which biventricular repair is likely. The most difficult decisions must be made for patients with intermediate cases, that is, most patients. For the intermediate group it is simpler to understand that without decompression of the right ventricle and establishment of antegrade flow into the pulmonary arteries early in the neonatal period, right heart growth is unlikely to occur, and biventricular circulation is not attainable [21,22,46]. Therefore it is logical to approach intermediate cases in a manner that does not preclude the possibility of eventual biventricular physiology as long as the mortality risk of the initial procedure does not exceed the mortality of a procedure that would likely preclude biventricular repair in the future.

The only study of sufficient size to provide a reliable morphologic basis on which to base appropriate initial management is the prospective multicenter study conducted by the Congenital Heart Surgeons Society (CHSS) consisting of 171 neonates treated between 1987 and 1991 [18]. Although there was considerable management variability among participating institutions, initial management was categorized into three basic procedures: relief of right ventricular outflow tract obstruction alone, relief of right ventricular outflow tract obstruction plus systemic-pulmonary artery shunt, and systemic-pulmonary artery shunt alone. The overall survival rate in this study was 81%

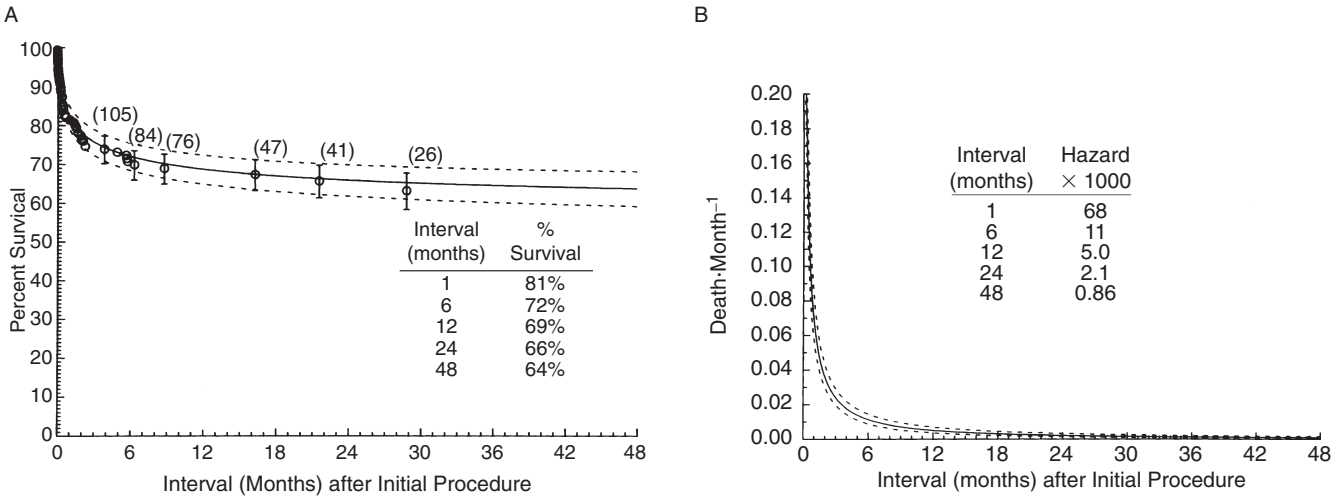

Figure 21.5 Survival (determined by life table methods and parametrically) after the initial procedure (performed, on average, at 3 days of age) of neonates with pulmonary atresia and intact ventricular septum (n = 171). Patients with abnormally large right ventricles with or without Ebstein anomaly and those who did not undergo a procedure are not included. The depiction is of 153 patients. Numbers in parentheses represent the number of patients available for follow-up study after the actuarial estimate. Patients were not censored at any subsequent procedure. Circles represent each death and are positioned along the horizontal axis at the time of death and actuarially along the vertical axis. Vertical bars represent 70% confidence interval. Solid line represents the parametrically determined continuous point estimate. Dashed lines enclose 70% confidence interval. **A,** Survivorship. **B,** Hazard function. at 1 month and 64% at 4 years (Figure 21.5) [18]. An important finding in this study was that the size of the tricuspid valve (expressed as Z value) correlated very closely to right ventricular cavity volume. Second, smaller tricuspid Z value, marked right ventricular coronary artery dependency, and choice of initial procedure were important risk factors for death (Table 21.1) [18]. However, a smaller tricuspid Z value was a risk factor for death only when the initial procedure included right ventricular decompression either by valvotomy or transannular patch. If a systemic-pulmonary artery shunt alone was performed, the size of the tricuspid valve (right ventricle) did not influence survival. The outcome of the three initial procedures as a function of the severity of right ventricular hypoplasia expressed as the tricuspid valve Z value was determined in this study (Figure 21.6) [18]. The need for secondary nondefinitive procedures was considerable. Of the patients who underwent valvotomy as the initial right ventricular outflow tract procedure, 55% required a subsequent transannular patch within 3 years. Similarly, 51% of patients not receiving a systemic-pulmonary artery shunt at the initial procedure needed a shunt within 1 month.

The initial report of the CHSS study suggested that eventual biventricular repair may be achieved in some patients with tricuspid annulus Z values as small as –4. In addition, the early risk of a combined pulmonary outflow procedure and systemic-pulmonary shunt in this group

Summary excludes 13 patients with Ebstein anomaly or large right ventricle. Variables with footnotes are interaction terms, not true risk factors.

*Interaction term that applies only when the initial procedure involved valvotomy or transannular patch but not when it was shunt alone.

†*p* value was .001 if valvotomy or transannular patch was performed without a shunt.

‡Interaction term that applies only to isolated systemic-pulmonary artery shunt without atrial septectomy but not to any other initial procedure.

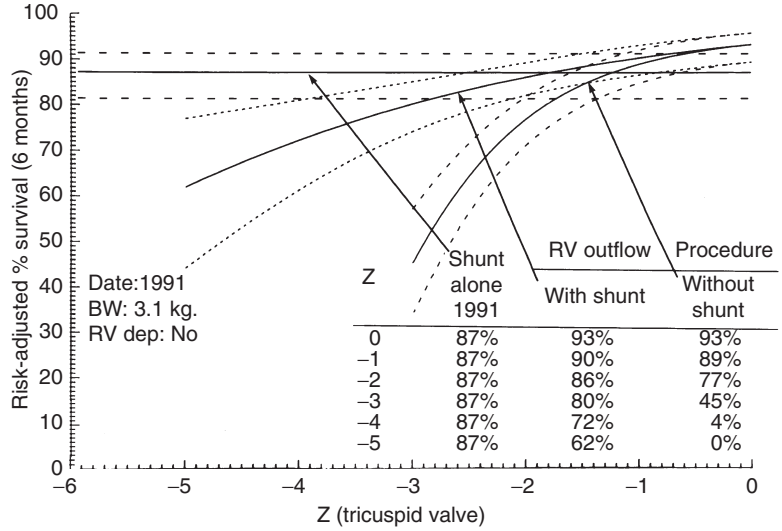

Figure 21.6 Nomogram shows a specific solution of a multivariable equation illustrating the effect on survival of the diameter (Z value) of the tricuspid valve and the type of initial procedure on neonates with pulmonary atresia and intact ventricular septum. Right ventricular outflow procedure includes both valvotomy and transannular patching. A Z value of zero represents the normal mean value of the diameter of the tricuspid valve. A Z value of –1 represents a diameter one standard deviation below the normal mean value; + 1 represents one standard deviation above normal, and so on. (Reproduced with permission from Hanley *et al.* [18].)

versus shunt alone was similar at or above a tricuspid Z value of –4 [18]. Consequently, the recommendation for patients with moderate right ventricular hypoplasia (tricuspid Z value –1 to –4) was a combined pulmonary outflow tract procedure with shunt. More recent analysis of the CHSS data, including a total of 247 patients with more follow-up time, suggested that patients with tricuspid Z values less than –3 have a higher initial mortality for combined pulmonary outflow procedure and shunt than for shunt alone [9]. No patient in this group underwent biventricular repair. These findings suggest that the recommendations for initial therapeutic intervention made in the original report should be modified. The following recommendations have been made by Reddy and colleagues [9] and are based on the more recent analysis of the patients accrued by the CHSS.

Mild right ventricular hypoplasia. Patients with mild hypoplasia of the right ventricle have a tricuspid Z value ranging from 0 to –2. The goal of treatment of these patients is to promote right ventricular growth and to minimize intervention. Initial treatment of this group should consist of decompressing the right ventricle by means of establishing right ventricular to pulmonary artery continuity. In rare cases with very mild right ventricular hypoplasia, radio frequency valve perforation and balloon valvuloplasty may obviate initial surgical intervention for some patients [44,45,48,50]. Reports of long-term outcome for such patients are scant, and there is insufficient information to allow comparison with the outcome among surgically treated patients with similar anatomy. Most patients with mild right ventricular hypoplasia should undergo either valvotomy or transannular patch. Valvotomy alone does not require cardiopulmonary bypass, but a number of patients need infundibular muscle resection and transannular patch to relieve residual outflow tract obstruction. Initial transannular patching achieves more long-standing right ventricular outflow tract decompression, but this advantage is offset by more serious pulmonary insufficiency, which may have deleterious early and long-term effects on right ventricular function. There are no data indicating that one approach is superior to the other. Regardless of the initial outflow tract procedure, the atrial septal defect should be left open to allow early right-to-left decompression, because almost all cases require time before right ventricular function becomes capable of carrying the entire cardiac output. In addition, severe postoperative hypoxemia may necessitate the addition of a systemic-pulmonary artery shunt in as many as 50% of cases [18].

Moderate right ventricular hypoplasia. Moderate right ventricular hypoplasia is a tricuspid Z value ranging from –2 to –3. These patients have the potential to achieve future biventricular repair, and the probability of this outcome is directly related to the size of the right ventricle. Because a pulmonary outflow tract procedure and a systemic-pulmonary artery shunt carry a mortality risk similar to that of a shunt alone, a combined procedure is favored [9,18]. This approach preserves the chance that the right ventricle will grow and allows subsequent biventricular repair. This approach also minimizes the need for subsequent procedures. Options for the right ventricular outflow tract procedure are the same as for management of mild right ventricular hypoplasia and carry the same risks and benefits.

Severe right ventricular hypoplasia. Severe right ventricular hypoplasia is a tricuspid annulus Z value less than or equal to –3. No patient in the CHSS study in this group successfully underwent biventricular repair [9]. Second, the early mortality risk of a combined pulmonary outflow tract procedure and shunt was significantly higher than that for a shunt alone in this category (see Figure 21.6) [18]. Third, many of these patients have extensive coronary fistulas or marked right ventricle-dependent coronary circulation. Patients in this category should undergo systemic-pulmonary artery shunt alone.

In a more recent report from Japan [57], patients were treated according to a management protocol based on a quantitative assessment of right ventricular morphology with good results. For initial palliation the right ventricular development index (RVDI) was determined. Right ventricular end-diastolic volume (RVEDV) expressed a percentage of expected normal volumes (%N), and tricuspid valve diameter (TVD) measured in end diastole expressed as a percentage of the predicted diameter (%N) were derived. The diameter of the right ventricular outflow (RVOD) tract was measured at the narrowest portion in the lateral projection at end-diastole. RVDI was then calculated according to the equation:

$$\text{RVDI}=\text{RVEDV}(\%\text{N})*\text{TVD}(\%\text{N})*\text{RVOD}(\text{mm})*10^{-5}/\text{BSA}(\text{m}^2)$$

For patients with RVDI>0.7, open transpulmonary valvotomy was recommended as an initial palliation. When RVDI is between 0.35 and 0.7, beta blocker therapy was added to valvotomy. When RVDI is lower than 0.35, concomitant valvotomy and systemic to pulmonary shunt was done. For patients with muscular atresia of the right ventricular outflow tract or right ventricle dependent coronary circulation only a shunt was performed [57].

For later definitive operation the right ventricle-tricuspid valve (RV-TV) index based on measurements in end diastole is calculated:

$$\text{RV-TV index} = \text{RVEDV}(\%\text{N}) * \text{TVD}(\%\text{N}) * 10^{-4}$$

Complete biventricular repair is accomplished in patients with the RV-TV index >0.4. For patients with RV-TV index ranging between 0.2 and 0.4, a biventricular repair with partial closure of atrial septal defect was recommended.

When RV-TV index is between 0.1 and 0.2, one and half ventricular repair was chosen. For patients with RV-TV index of lower than 0.1, univentricular definitive palliation was used [57].

Right Ventricle-Dependent Coronary Circulation

There is uniform agreement that patients with complete right ventricle-dependent coronary circulation (RVDCC) should not undergo decompression of the right ventricle [18,58,59]. These patients should undergo systemic-pulmonary artery shunt alone. Some centers recommend consideration for cardiac transplantation. However, for lesser degrees of right ventricular dependency, opinions vary widely. One difficulty is that the description of what constitutes "significant" right ventricular dependency is subjective. Consequently, careful analysis of various management protocols is difficult because of uncertainty regarding the comparability of patient populations. An important distinction is the existence of fistulas with or without concomitant stenosis or obstruction. Most patients who have coronary artery fistulas alone may undergo decompression safely [58]. The risk of death upon right ventricular decompression increases significantly if one of three major coronary arteries (left anterior descending, left circumflex, right coronary artery) contains fistulous connections and is obstructed. The likelihood of mortality is very high if two major arteries are affected [58].

One method of decision making allows for decompression of the right ventricle unless two major vessels are obstructed, complete atresia of the coronary ostia is demonstrated, or a significant portion of the left ventricular myocardium is supplied by coronary fistulas from the right ventricle, regardless of proximal stenosis [60]. This approach assumes reasonable right ventricular size and no additional anatomic confounders. As most patients with significant right ventricular coronary dependency have severe right ventricular hypoplasia, the recommendation for initial treatment (systemic-pulmonary artery shunt alone) can be based on tricuspid Z value only.

Precise definition of coronary arterial anatomy remains imperative to the management of neonates with PA-IVS. Early mortality among such patients appears to be related to coronary ischemia at or around the time of initial palliation. In an early study, 12 patients with PA-IVS-RVDCC who underwent single ventricle palliation between 1986 and 1997 were found to have an 83% 5-year actuarial survival. The two deaths (17%) in that series occurred within 4 months after the systemic to pulmonary shunt from presumed coronary ischemia [59]. The results of single ventricle palliation from a more recent retrospective review [61], were practically identical, with 18.8% overall mortality and 81.3% 5, 10, and 15 year actuarial survival. All deaths in this series occurred within 3 months of the shunt from presumed coronary ischemia. In both series there were no perioperative or late deaths after bidirectional Glenn or Fontan. It is clear that in patients surviving the initial shunt, single ventricle palliation yields excellent mid- to long-term survivals with well preserved LV systolic function and should be the preferred management strategy for the majority of these patients. Longer follow-up will be necessary to assess whether these patients will be at risk either from sudden death owing to ventricular dysrhythmias or for ventricular dysfunction as a result of coronary perfusion with subnormal saturated blood.

Neonates with aortocoronary atresia, the most extreme form of RVDCC, or those with significant left ventricular dysfunction should undergo cardiac transplantation [61]. Patients listed for transplant may wait weeks to months and face significant risk during this time. Prolonged PGE_1 administration, ductal stenting, or systemic to pulmonary shunt can be used to manage patients on the waiting list.

Severe Tricuspid Regurgitation

Patients with Ebstein anomaly or unguarded tricuspid orifice usually have an enlarged tricuspid annulus and a dilated, poorly contractile right ventricle. From a clinical standpoint these patients are similar to neonates with severe cyanosis and Ebstein anomaly (see Chapter 29, *Ebstein Anomaly*). The mortality in this group is high, and right ventricular outflow tract procedures combined with tricuspid valve repair have poor results. In fact, patients with pulmonary atresia and Ebstein anomaly have been demonstrated to have a higher risk of in-hospital mortality [62]. Nearly all surviving patients with severe tricuspid regurgitation need univentricular management, which is only avoided by primary cardiac transplantation. Currently, most centers attempt initial therapy with a systemic-pulmonary artery shunt alone. Another alternative is conversion of the anatomy to tricuspid atresia with construction of a systemic-pulmonary artery shunt [63].

Other Procedures

Other procedures, including tricuspid valve disruption, tricuspid valve closure, right ventricular thromboexclusion, ligation of coronary fistula, and attempts at tricuspid valve repair for regurgitation, have been advocated in the initial treatment of neonates with PA-IVS. The use of these procedures is not supported by evidence of a favorable effect on outcome.

Subsequent Surgical Management

All patients with PA-IVS need close follow-up care after initial treatment. Nearly all surviving patients need at least one secondary intervention, and the timing and selection of subsequent interventions are complicated. Patients initially undergoing systemic-pulmonary artery shunt

alone who are anticipated to need subsequent univentricular management should undergo cardiac catheterization between 3 and 6 months of age in preparation for a bidirectional superior cavopulmonary shunt and systemic-pulmonary artery shunt takedown. Ideally, this procedure should be completed before the age of 12 months. Between the ages of 2 and 4 years, depending on patient growth, a total cavopulmonary connection (Fontan procedure) should be completed. In patients with significant right ventricle-dependent coronary circulation, the Fontan procedure should involve a modification that allows maintenance of right ventricular pressure, directs oxygenated blood into the right ventricle, and allows drainage of coronary sinus blood into the low-pressure atrial chamber. Options include the lateral tunnel and extra cardiac modifications of the Fontan procedure. Although not widely practiced, another solution is concomitant Fontan procedure and construction of an aortic-to-right ventricular conduit to maintain coronary perfusion [64,65]. There is no evidence to support the superiority of this approach over conventional total cavopulmonary connection. In patients with known right ventricle-dependent coronary circulation, even temporary decompression of the right ventricle that occurs with standard cardiopulmonary bypass techniques can cause lethal myocardial ischemia; therefore altered perfusion strategies may be needed during a Fontan procedure on these patients [66].

Patients with mild right ventricular hypoplasia who have successfully undergone right ventricular outflow tract decompression (balloon valvuloplasty, surgical valvotomy, or transannular patch) without a systemic-pulmonary artery shunt should undergo echocardiography and cardiac catheterization between 3 and 6 months of age. Right ventricular function and the degree of residual right ventricular outflow tract obstruction should be assessed during temporary occlusion of the atrial septal defect. Right atrial pressure, systemic arterial pressure, and mixed venous oxygen saturation should be measured to determine whether the right ventricle is capable of carrying the entire systemic output. In addition, simultaneous recording of right atrial and right ventricular pressure, when technically feasible, can evaluate tricuspid valve stenosis. In cases of only valvar pulmonary outflow tract obstruction and good right ventricular function, balloon valvuloplasty may be used, and closure of the atrial septum can be accomplished with a catheter-delivered device. In the most favorable situation, catheter-based closure of the atrial septal defect may be all that is needed to achieve biventricular physiology.

Though not always the case, criteria for determination of a suitable right heart that can sustain full cardiac output over the long-term is frequently unclear. More commonly, residual right ventricular outflow tract obstruction is not amenable to balloon valvuloplasty, and surgical treatment is needed. Appropriate surgical intervention consists of infundibular muscle resection with repeated valvotomy or a transannular patch. In either case the atrial septal defect should be closed concomitantly. If right ventricular function is borderline and there is residual outflow tract obstruction, the atrial septal defect may be left open at the time of right ventricular outflow tract enlargement and reassessed for delayed closure either surgically or with a catheter-based device. Some authorities advocate the use of an adjustable atrial septal defect closure method to allow simple closure of the atrial septal communication either in the early postoperative period or at a later date [65].

In patients with borderline right heart development, a newer approach has been to construct a bidirectional superior cavopulmonary connection with or without right ventricular outflow tract enlargement. This option is known as the one-and-a-half ventricular approach. Total separation of the two circulations can be achieved if the patient tolerates concomitant closure of the atrial septal defect. If the atrial septal defect cannot be closed because of inadequate left-sided filling, the defect can be restricted in anticipation of delayed closure. The one-and-a-half ventricular approach has been used more commonly because it seems intuitively superior to total cavopulmonary connection [67,68]. However, there is no long-term evidence that demonstrates superiority of the one-and-a-half ventricular repair over univentricular circulation [69].

Patients with moderate right ventricular hypoplasia necessitating an initial combined systemic-pulmonary artery shunt and outflow tract procedure should undergo echocardiography at approximately 3 months of age for assessment of growth of the right ventricle and the tricuspid valve. Patients with growth of the right heart structures should undergo cardiac catheterization at 6 months of age. At catheterization the systemic-pulmonary artery shunt should be temporarily occluded. If adequate arterial oxygen saturation is maintained, permanent coil occlusion can be accomplished at this time. In addition, temporary closure of the atrial septal defect can be performed to determine whether the right ventricle is capable of carrying the entire cardiac output. Management options then become identical to those in the treatment of patients with mild right ventricular hypoplasia necessitating only an initial outflow tract procedure, as discussed in the preceding paragraph.

There are several options for patients with moderate hypoplasia who do not have adequate right ventricular growth to allow biventricular repair. The patient can be committed to univentricular circulation consisting of a bidirectional superior cavopulmonary shunt and takedown of the systemic-pulmonary artery shunt. Thereafter, suitability for completion Fontan versus one-and-a-half ventricular repair consisting of atrial septal defect closure with or without right ventricular outflow tract enlargement can be determined. A second option is to proceed with planned one-and-a-half ventricular repair at this stage. This approach consists of bidirectional superior caval anas-

tomosis (with or without right ventricular outflow tract enlargement) and atrial septal defect closure. If atrial septal defect closure is not tolerated, the defect may be left restrictive with the intent of achieving closure at a subsequent procedure. A third option is the right ventricular overhaul approach advocated by Mee and colleagues [24]. This strategy consists of a second-stage procedure with cardiopulmonary bypass to perform tricuspid valvotomy with or without repair, infundibular muscle resection with repeated pulmonary valvotomy or transannular patch, and enlargement of the trabecular portion of the right ventricle by division of hypertrophied muscle bundles. The systemic-pulmonary artery shunt is left open at this time, and the atrial septal defect is restricted to enhance flow across the tricuspid valve to promote right ventricular growth. If right ventricular development is later judged adequate, the systemic-pulmonary artery shunt is occluded, and the atrial septal defect is closed to achieve biventricular repair. If inadequate right heart development occurs, then a one-and-a-half repair or univentricular approach is pursued. Although this approach has not been widely reported, impressive results with this strategy have been obtained in a few centers [24,37].

Surgical Technique

Relief of Right Ventricular Outflow Tract Obstruction

The main pulmonary artery and ductus arteriosus are dissected through a standard median sternotomy. If valvotomy is the intended procedure, it can be accomplished with or without cardiopulmonary bypass. If cardiopulmonary bypass or a concomitant systemic-pulmonary artery shunt is not planned, the distal pulmonary artery is clamped just proximal to the pulmonary artery bifurcation to allow pulmonary blood flow through the ductus arteriosus. Longitudinal pulmonary arteriotomy is performed, and the atretic pulmonary valve is examined. Stay sutures of 7-0 monofilament are placed at both ends of the arteriotomy to assist in clamp placement after valvotomy. A no. 11 blade scalpel is used to perforate the valve plate, and a hemostat is inserted to dilate the annulus. A side-biting vascular clamp is applied to control the arteriotomy, and the distal pulmonary artery clamp is released. The arteriotomy is then closed with the previously placed stay sutures.

When transannular patch is the intended procedure, venous drainage through a single right atrial cannula is sufficient if the atrial septal defect is adequate. Cardiopulmonary bypass is initiated, and the ductus arteriosus is temporarily occluded. Normothermic normocalcemic perfusion is maintained because aortic clamping is not necessary. The distal main pulmonary artery is clamped to enhance exposure, and the pulmonary artery is opened longitudinally. The pulmonary valve plate is incised in an anteroposterior direction, and the pulmonary artery incision is extended proximally across the annulus and carried into the right ventricular free wall until the communication into the right ventricular cavity is slightly smaller than normal. An opening of 7–8 mm is typical for the usual neonate. A dilator of the desired luminal diameter of the outflow tract is placed in the transannular incision, and an oval patch of 0.4-mm polytetrafluoroethylene is cut to the appropriate length and width to close the defect. The patch is sutured to the edges of the incision to complete the procedure. The patient is weaned from cardiopulmonary bypass. If systemic saturations are adequate, the ductus arteriosus is ligated.

Systemic-Pulmonary Artery Shunt

If a systemic-pulmonary artery shunt is to be performed alone, the modified Blalock-Taussig shunt can be approached through a right thoracotomy or median sternotomy. The thoracotomy allows spontaneous closure of the ductus arteriosus while the sternotomy enables ductal ligation if indicated. The distal innominate artery is dissected, and the proximal right subclavian artery is exposed. The pericardium is opened parallel to the phrenic nerve and anterior to the right pulmonary artery. The upper lobe branch and continuation of the right pulmonary artery are encircled with silk ligatures. An appropriately sized polytetrafluoroethylene conduit (usually 4 or 5 mm) is selected and beveled on one end. The patient is then given systemic heparin (100 units/kg). The beveled end of the conduit is sutured end to side to an arteriotomy in the proximal right subclavian artery. Thereafter the conduit is cut to the appropriate length without a bevel. The proximal right pulmonary artery is clamped, and tension is placed on the silk ligatures to control the distal branches of the pulmonary artery. The distal end of the shunt is sutured end to side into an arteriotomy placed proximal to the upper lobe branch of the right pulmonary artery. Shunt flow is established, and prostaglandin infusion is discontinued.

When a systemic-pulmonary artery shunt is performed concomitantly with a right ventricular outflow tract procedure, the technique is similar (modified Blalock-Taussig shunt) except that a median sternotomy approach is used. If cardiopulmonary bypass is intended, it is technically easier to perform the shunt during bypass, either before or after the right ventricular outflow tract procedure. After completion of the procedure, shunt flow is established, and the patient is weaned from cardiopulmonary bypass. The ductus arteriosus is ligated after adequate systemic oxygen saturation is confirmed. When cardiopulmonary bypass is not used, it is prudent to construct the shunt as the initial procedure. The rationale for this is that exposure during pulmonary valvotomy is improved by temporary occlusion of the ductus arteriosus and individual control of the branch pulmonary arteries; a clamp on the distal

pulmonary artery is unnecessary. Single right lung perfusion is maintained through the shunt during the brief time required to perform the valvotomy, which is performed as described previously. When antegrade flow is established and adequate systemic saturation is confirmed, the ductus arteriosus is ligated.

Transcatheter Valvotomy

If the right ventricle is of adequate size, and the atretic valve has the usual membrane-like configuration, perforation of the pulmonary valve can be performed in the catheterization lab. Hand injections from both the infundibulum and the main pulmonary artery (retrograde via the ductus arteriosus) are usually adequate to characterize the anatomy of the right ventricular outflow tract. A catheter can be manipulated into position just below the valve. In some cases, a pinhole of antegrade flow can be demonstrated and a wire can be passed across the "atretic" valve. If no flow is appreciated, radiofrequency perforation can be performed [70]. Alternatively, the stiff end of a wire can be used if radiofrequency is not available or not successful. Obviously, the risk of unintended perforation outside the heart or pulmonary artery is not trivial and must be recognized immediately. Pericardiocentesis or surgical intervention may be required.

Recently, other innovative methods of decompressing the right heart have been described. Hybrid approaches, with valvuloplasty performed via a subxiphoid incision to access the right heart, have been used with success [71]. This approach was first employed during emergent treatment of perforation of the outflow tract during transcatheter radiofrequency perforation. Patients selected for this hybrid approach are first evaluated in standard fashion with a cardiac catheterization. The angle of catheter course to the right ventricular outflow tract via the tricuspid valve is evaluated. If deemed unsuitable for safe radiofrequency valve perforation, the hybrid method is employed from the subxiphoid approach. A sheath and dilator are introduced, rather than a ventriculotomy incision, and perforation and balloon dilation can be performed over a more direct course. The angle of approach from the base of the heart allows excellent alignment of the radiofrequency catheter with the infundibulum and valve plate. Similar to traditional transcatheter perforation, this does not necessarily obviate the need for additional intervention such as additional valvuloplasty or shunt placement, depending on the clinical course of the patient. Of the three patients in which this has been described, one required PV dilation and another returned for a shunt.

A report in 2006 concluded that balloon valvotomy alone for PA-IVS rarely obviates the need for an additional source of pulmonary blood flow provided by either a shunt or ductal stenting [72,73]. If shunt placement is needed after valvuloplasty, mid-term results from at least one center suggest eventual two, or one-and-one-half ventricle repair are often achievable in this population [74]. Anatomy that mandates a shunt at the outset, however, may be associated with early mortality. Similarly a study published in 2007 found that catheter interventions rarely avoid surgical repair and that right ventricle-dependent coronary circulation and Ebstein anomaly were associated with high mortality. These authors concluded that the single-ventricular pathway is likely a better strategy for these patient populations [62].

Intervention in the yet unborn child has been employed to potentially alter the course of congenital disease [75]. Attempted relief of right-sided obstruction by pulmonary valve dilation in utero is a newer technique that is under investigation at a limited number of centers. Evaluation of procedural success and longer-term outcomes is ongoing, and time will tell if fetal intervention has a role in management of right ventricular outflow obstruction.

Valvar Pulmonary Stenosis

Unlike PA-IVS, isolated pulmonary valvar stenosis is not commonly accompanied by major associated architectural anomalies of the other right heart components. Although pulmonary stenosis can be viewed as occupying the more favorable end of the spectrum of right heart obstructive lesions, the lack of major associated tricuspid valve and right ventricular structural abnormalities greatly simplifies diagnostic and therapeutic decision making relative to pulmonary atresia and intact septum. In reality, pulmonary stenosis represents an entity clinically distinct from PA-IVS. Pulmonary stenosis does, however, manifest with widely varying degrees of severity, and secondary infundibular hypertrophy can contribute to right ventricular obstruction. Unlike PA-IVS, which almost always manifests during the neonatal period, valvar pulmonary stenosis can manifest at any age. In subsequent discussion, the diagnosis and treatment of patients with pulmonary stenosis are considered separately for patients with disease manifesting in the neonatal period and for those who come to medical attention after the neonatal period.

Incidence and Etiology

Isolated pulmonary valvar stenosis is one of the most common cardiac defects, accounting for between 8% and 10% of all cases of congenital heart disease [76]. Patients with isolated severe pulmonary stenosis who need emergency intervention as neonates or young infants are only a small fraction of these patients [77]. The cause of pulmonary valvar stenosis is not known. Most theories are similar to those previously discussed for the cause of PA-IVS

[78,79]. Genetic factors play an important role in the pathogenesis of some cases. There is an increased prevalence of congenital heart disease among siblings of patients with isolated pulmonary valvar stenosis [80]. Familial cases of pulmonary stenosis have been described [81]. A number of clearly defined chromosomal abnormalities and genetic syndromes are accompanied by pulmonary valvar stenosis, including Noonan's syndrome, trisomy 18, multiple lentigines (leopard syndrome), Watson syndrome, neurofibromatosis, and others [82–85].

Morphology

The morphology of the pulmonary valve in isolated valvar pulmonary stenosis has been categorized into six distinct anatomic subgroups [86]. These subgroups include domed, tricuspid, bicuspid, unicommissural, dysplastic, and hypoplastic annulus. Regardless of subgroup the leaflets are almost always thickened, and in most types there is commissural fusion. An important exception is the dysplastic type, which comprises approximately 10–20% of all cases of isolated valvar pulmonary stenosis. Most syndrome-associated cases of valvar pulmonary stenosis are of the dysplastic type. The dysplastic valve usually has three redundant and thickened leaflets, but the commissures are not fused. The annulus is hypoplastic, and both the infundibulum below the valve and the pulmonary artery above the valve are narrowed. Microscopic examination shows dysplastic valves are myxomatous with a paucity of elastic fibers [86]. Obstruction is because of the narrowing of the lumen at all levels of the pulmonary outflow tract and the excess bulk of the leaflet tissue. This finding has important therapeutic implications, which are addressed later.

Other associated right heart findings with pulmonary stenosis most likely represent secondary changes owing to valvar obstruction [78]. Poststenotic dilatation of the main pulmonary artery is common with most types, the notable exception being dysplastic valve. The degree of poststenotic pulmonary artery dilatation does not correspond to the severity of valvar obstruction. Poststenotic dilatation is frequently more marked in older patients with relatively moderate degrees of obstruction. Right ventricular hypertrophy is caused by the increased pressure load imposed on the right ventricle. This pressure overload is the fundamental factor underlying the pathophysiologic mechanism of this lesion. Significant infundibular muscular obstruction having both fixed and dynamic components frequently develops. Increased stress on the tricuspid valve may lead to chordal lengthening, annular dilatation, and tricuspid regurgitation. In neonates with critical pulmonary valvar stenosis, the tricuspid valve and right ventricle often are hypoplastic, and severe tricuspid regurgitation is common [87]. The right atrium often is dilated, the degree of dilatation corresponding to the degree of tricuspid regurgitation, and often is thickened [78]. A patent foramen ovale or atrial septal defect almost always is present in younger babies. In older infants and children, a patent foramen ovale or atrial septal defect is present more than two thirds of the time [88]. With very severe pulmonary valvar obstruction, subendocardial ischemia in the right ventricle can produce areas of myocardial infarction and fibrosis [89].

Critical Pulmonary Stenosis of the Neonate

Severe pulmonary valvar stenosis manifesting as cyanosis in the neonatal period is commonly called critical pulmonary stenosis. This term denotes both the severity of valvar obstruction and the critically ill nature of babies born with this condition. In a strict sense this clinical entity is defined by fetal pulmonary stenosis severe enough to limit right heart output and lead to a larger than normal right-to-left atrial level shunt in utero [76,77]. In most cases the pulmonary valve is tricuspid, and commissural fusion results in a small orifice. The dysplastic type valve rarely presents with critical pulmonary stenosis. There usually is only mild hypoplasia of the pulmonary annulus [87]. During fetal development, right heart growth may be limited by low flow through the right ventricle. Consequently, hypoplasia of the tricuspid valve and right ventricle is present in approximately 50% of neonates with critical pulmonary stenosis, and there usually is severe right ventricular hypertrophy [87]. Severe hypoplasia of the right ventricle is uncommon. Coronary fistulas are uncommon with critical pulmonary stenosis, and right ventricular coronary dependency is encountered in only a small fraction of cases.

Pathophysiology and Natural History

Severe obstruction of right ventricular output and right ventricular hypertrophy are accompanied by decreased diastolic compliance and elevated right ventricular diastolic pressure. Tricuspid regurgitation usually is present. These factors combine to produce elevated right atrial pressure and a right-to-left shunt at the atrial level through the patent foramen ovale or atrial septal defect. Severely reduced right ventricular output renders the left side of the heart dependent on loading through the atrial level shunt. Marked restriction at the atrial level results in left heart preload inadequate to sustain adequate cardiac output. As with PA-IVS, pulmonary blood flow depends on the ductus arteriosus. Left heart output must be several times normal to supply adequate systemic and pulmonary perfusion. Consequently, left ventricular myocardial oxygen demand is increased. Similarly, right ventricular oxygen demand is increased owing to elevated wall tension resulting from

severe pressure overload. Simultaneously, myocardial oxygen supply is compromised by the cyanosis resulting from the obligatory right-to-left atrial level shunt. Lower diastolic coronary perfusion pressure resulting from low-resistance runoff into the pulmonary circulation through the patent ductus arteriosus further compromises myocardial oxygen supply. Consequently, neonates with critical pulmonary stenosis are born in a precarious hemodynamic state. If the lesion is not detected soon after birth, closure of ductus arteriosus leads to decreased pulmonary blood flow, progressive hypoxemia, acidosis, cardiovascular collapse, and death. Not surprisingly, patients with this entity die within the first days to weeks of life. Longer survival is possible only when the ductus arteriosus remains patent and there is minimal restriction of atrial level shunting.

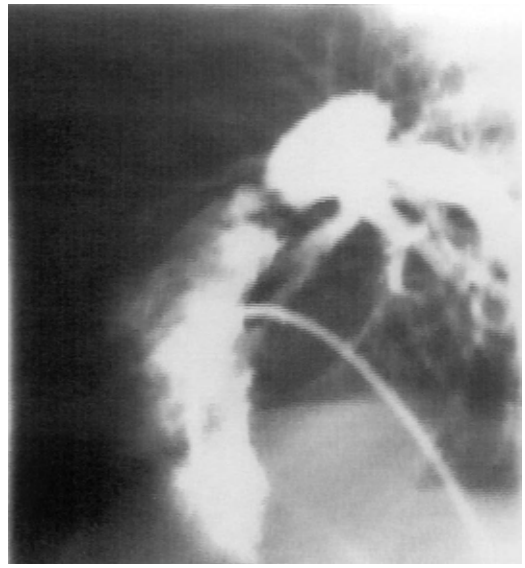

Figure 21.7 Angiographic representation of critical pulmonary stenosis. Well developed pulmonary arteries are evident.

Presentation and Diagnosis

In the absence of associated syndromes, the body habitus is normal. Infants with critical pulmonary stenosis are cyanotic at birth and have systemic or suprasystemic right ventricular pressure. Most infants with this defect have an adequate atrial level shunt that allows maintenance of cardiac output. Patients come to medical attention in much the same way as infants with PA-IVS. If ductal closure ensues, the degree of cyanosis increases with progressive hemodynamic deterioration. Depending on the degree of pulmonary valve narrowing, antegrade flow of blood into the pulmonary arteries may be sufficient to allow relative stability in some patients. Tachypnea and tachycardia are typically present, and respiratory distress develops as cyanosis and metabolic deterioration progress before resuscitation. Auscultation may reveal a loud systolic ejection murmur at the upper left sternal border; however, in critically ill infants the murmur is often much softer because of diminished cardiac output and shunting of blood at the atrial level. Tricuspid insufficiency is commonly present and produces a holosystolic murmur at the lower left sternal border. A murmur associated with the ductus arteriosus may be heard in the upper sternal region. Cardiomegaly owing to right atrial enlargement may be evident on precordial palpation. Chest radiography confirms cardiomegaly and may show diminished vascular markings depending on the state of the ductus arteriosus. In most cases the electrocardiogram shows right axis deviation and right ventricular strain indicative of right ventricular hypertrophy.

Two-dimensional echocardiography with color Doppler examination is the diagnostic modality of choice. The anatomy and function of the pulmonary valve, tricuspid valve, and right ventricle, and patency of the foramen ovale and ductus arteriosus can be determined. Cardiac catheterization is complementary (Figure 21.7) [16] and is indicated when echocardiographic findings suggest the diagnosis of critical pulmonary stenosis. Catheterization best shows pulmonary and coronary arterial morphology. Percutaneous balloon valvuloplasty is the management of choice of critical pulmonary stenosis [76,78,90,91]. Angiocardiography defines the severity and location of the obstructing components of pulmonary stenosis. The pulmonary valve annulus may be nearly normal or may be hypoplastic, and the right ventricle may be hypoplastic with filling defects, findings that indicate marked hypertrophy.

In most cases the diagnosis of critical pulmonary stenosis is readily made with the combination of physical examination and echocardiography. The differential diagnosis of critical pulmonary stenosis includes PA-IVS, tetralogy of Fallot, and severe Ebstein anomaly.

Management of Critical Pulmonary Stenosis

Most children born with critical pulmonary stenosis should eventually be able to undergo biventricular repair. As discussed later, this may necessitate interventional catheter techniques, surgery, or a combination of these modalities. Preinterventional management of critical pulmonary stenosis mirrors that of pulmonary atresia and intact septum. Intravenous access should be established and PGE_1 infusion initiated even before establishment of a definite diagnosis. Mechanical ventilation, inotropic support, and management of metabolic acidosis should be provided as needed. In unusual cases a restrictive atrial septal communication may mandate urgent or even emergency balloon atrial septostomy.

A surgical procedure for pulmonary stenosis in older children was first performed in the late 1940s [92–94]. The history of surgical pulmonary valvotomy is fascinating for the ingenuity involved and the number of notable cardiac surgeons who made contributions in this area [95–97]. A variety of techniques were developed, including closed techniques and open techniques with surface cooling, inflow occlusion, and cardiopulmonary bypass [98–101]. As surgical management of pulmonary stenosis evolved, it was used to treat younger and younger children, including neonates with critical pulmonary stenosis [87,98,102,103]. In the timeframe before percutaneous balloon valvuloplasty, the mortality associated with surgery for critical pulmonary stenosis was considerable and would no doubt be much lower today with state-of-the-art perioperative techniques. In 1982 the first successful outcome of percutaneous balloon valvuloplasty of congenital pulmonary stenosis was reported for an older child [90]. This treatment was quickly adapted to younger patients, including neonates [104–108]. Interventional catheter techniques with outcome equivalent to that of surgery have supplanted initial surgical management of this disease, and balloon valvuloplasty is now the treatment of choice [43,87,105,109–114]. There are no surgical series with which to compare outcome of balloon valvuloplasty during the same time period. Given that outcomes were nearly equivalent for the two techniques (6% mortality and similar gradient reduction) in the multicenter CHSS study [87] reported in 1993 and that balloon valvuloplasty has low morbidity, there has been no stimulus for further comparison.

The diagnosis of critical pulmonary stenosis is the indication for prompt treatment. After resuscitation, the urgency of the intervention is dependent on the patient's clinical status. If right ventricular function is preserved with an adequate atrial septal communication and patent ductus arteriosus, and the patient demonstrates hemodynamic stability, catheterization may be performed semi-electively on the first day or two of life. If the above is not true, and the baby is unstable, he or she should be taken immediately to the catheterization suite for diagnostic angiography followed by balloon valvuloplasty. Concurrent balloon atrial septostomy may be performed at this time when indicated. After successful decompression of the right ventricle, many patients continue to be cyanotic and need continued PGE_1 infusion to maintain adequate pulmonary blood flow. Diastolic compliance and right ventricular dysfunction may take considerable time to improve before adequate antegrade blood flow is achieved. Thereafter, the child should be weaned from PGE_1 infusion. Mild to moderate cyanosis may persist for weeks or even months after initial therapy because of continued right-to-left shunting at the atrial level. In most cases, dynamic right ventricular outflow tract obstruction owing to infundibular muscle hypertrophy gradually regresses, diastolic compliance improves, and antegrade blood flow increases [115,116]. In some cases early recatheterization may be indicated on the basis of serial echocardiographic findings, and repeated balloon valvuloplasty may be used. Less commonly, cyanosis persists, and a surgical systemic-pulmonary artery shunt is needed to alleviate the need for PGE_1 infusion [87].

By 1 year of age, catheterization should be repeated for assessment of hemodynamics in children who remain cyanotic. Balloon occlusion of the atrial septum may determine whether complete separation of the two circulations is feasible, as described previously for PA-IVS. Thereafter the atrial septal defect can be closed either surgically or with a percutaneous atrial septal defect occlusion device. Management is similar for patients who need an early surgical systemic-pulmonary artery shunt, except that at repeated catheterization, test occlusion of the shunt should be performed to determine whether the shunt can be safely closed. If oxygenation remains adequate, coil occlusion can be accomplished percutaneously. Simultaneous test occlusion of the atrial septal defect should then be performed. If right atrial pressure does not increase, superior vena caval oxygen content remains stable, and systemic blood pressure is maintained, the atrial septal defect can usually be closed. In the situation in which surgical closure of the atrial septal defect is required, division of the shunt can be performed concomitantly. The atrial septal defect occasionally cannot be closed at this time, and assessment should be repeated within 6 months. If the shunt cannot be closed, a univentricular or one-and-a-half ventricular treatment strategy may be required. Decision making regarding these options is similar to that previously discussed for PA-IVS.

The primary indication for surgical treatment is unsuccessful balloon valvuloplasty. Because expertise with balloon valvuloplasty is widespread, the inability to transfer a child to an experienced center is now an uncommon indication for surgical intervention. In rare cases the pulmonary annulus or right ventricle may be markedly hypoplastic. Although the need for initial surgical management can be argued, the perception that balloon valvuloplasty does not prevent subsequent surgical intervention is prevalent, and almost all neonates undergo percutaneous treatment as the initial therapy. In the unusual circumstance in which initial surgical management is selected, there is no consensus about the appropriate surgical method or procedure. Options include open valvotomy, either under inflow occlusion or with cardiopulmonary bypass, and closed valvotomy. Reports comparing these options are now relatively outdated [98]. Given the safety and ability to perform a precise valvotomy, most surgeons favor the use of cardiopulmonary bypass. It is clear, however, that in the absence of severe right heart hypoplasia, initial treatment should

include only direct relief of pulmonary stenosis [87]. The ductus arteriosus should be not be ligated so that PGE_1 infusion may be reinitiated in the event that antegrade blood flow is inadequate. A surgical shunt should be necessary in fewer than 10% of cases [87]. However, patients now referred for surgical treatment are likely to have marked pulmonary annulus and right ventricular hypoplasia. As with PA-IVS, establishment of antegrade right ventricular blood flow is required for right heart growth [55,87,117]. A transannular patch with surgical shunt may be required as initial treatment for patients with marked hypoplasia of the pulmonary annulus (Z value less than –3). This approach requires cardiopulmonary bypass. In any case the atrial septal defect should be left open initially. Subsequent evaluation and intervention are similar to those described for initial balloon valvuloplasty. Should right ventricular growth prove inadequate for biventricular repair, univentricular or one-and-a-half ventricular repair options must be assessed.

In the rare circumstance in which critical pulmonary stenosis is accompanied by coronary fistulas, management is not altered unless coronary artery stenosis or evidence of substantial right ventricle-dependent coronary circulation is present. In the latter case right ventricular decompression is contraindicated, and a surgical systemic-pulmonary artery shunt should be performed in anticipation of univentricular management. A similar approach should be considered for patients with concomitant Ebstein anomaly.

Outcome in Critical Pulmonary Stenosis

The only prospective, multicenter trial assessing outcome among infants with critical pulmonary stenosis was conducted by the CHSS, and the results were reported in 1993 [87]. The investigators evaluated 101 neonates from 27 institutions. The patients were initially treated by balloon valvuloplasty or one of a variety of surgical techniques. The overall survival rate was 89% at 1 month and 81% at 4 years (Figure 21.8) [87]. After initial treatment the right ventricular-to-pulmonary artery gradient was less than 30 mmHg in 81% of patients, and there were no differences between surgical and balloon valvuloplasty. There were no identifiable morphologic or other patient-specific risk factors for death. The lack of identified risk factors was probably because of the morphologic homogeneity of patients with critical pulmonary stenosis evaluated in this trial. Open pulmonary valvotomy without cardiopulmonary bypass or inflow occlusion was the only procedure that proved to be a risk factor for early death (Table 21.2) [87]. The survival rate after balloon valvuloplasty, open valvotomy (with cardiopulmonary bypass or inflow occlusion), and closed valvotomy was 94%. Reintervention of any type was necessary in 26% of cases and was similar for surgical and balloon valvuloplasty. Risk factors for requiring a systemic-pulmonary artery shunt were small right ventricular cavity and use of closed surgical valvotomy. Only two patients underwent subsequent Fontan proce-

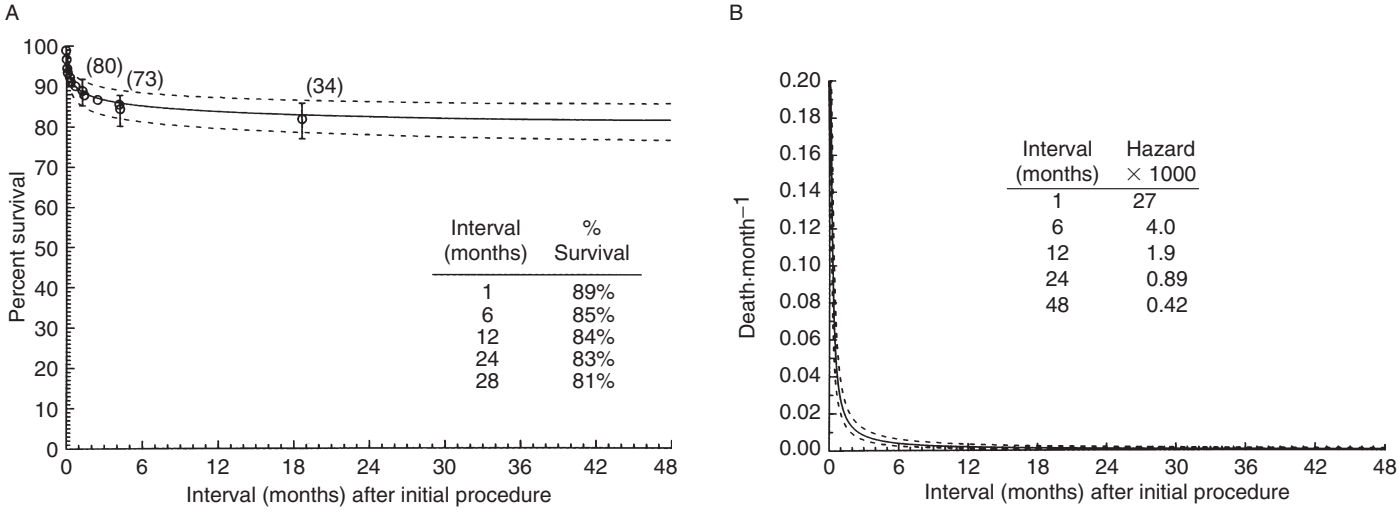

Figure 21.8 Survival and hazard function for death after the first procedure. Each circle represents an individual death, positioned along the horizontal axis at the time of death and actuarially (Kaplan-Meier) along the vertical axis. Vertical bars indicate 70% confidence interval of the actuarial estimates. Numbers in parentheses are the number of patients available for follow-up evaluation after the actuarial estimate. (By 24, 36, and 48 months after the initial procedure, 29, 14, and 1 patient were still being observed.) Solid line indicates the continuous point estimate of survival (or hazard function in B obtained by a separate hazard function regression analysis). Dashed line encloses 70% confidence interval. **A,** Survival. **B,** Hazard function. (Reproduced with permission from Hanley *et al.* [87].)

dures, and 85% of patients had undergone correction to two-ventricle circulation within 48 months of study entry. All other patients in this study were predicted to be able to undergo biventricular repair within 6 years of study entry.

Because of the excellent results of balloon valvuloplasty, this intervention has become the dominant initial treatment strategy for patients with pulmonary stenosis, including critical pulmonary stenosis. Smaller and technically improved balloon catheters and increased experience with this technique have contributed to this trend. Unfortunately, few reports have detailed the long-term outcome among patients treated as neonates. The initial success, procedural survival, and likelihood of sustained relief of right ventricular outflow tract obstruction are higher for older children treated by balloon valvuloplasty than for neonates [112,118–120]. Successful balloon valvuloplasty can be achieved by experienced interventionalists in 90–95% of neonatal patients [111,120,121]. Approximately 5–10% of patients need a subsequent systemic-pulmonary artery shunt. The procedural mortality of balloon valvuloplasty in neonates is approximately 3–5%, and major complications occur in approximately 10% of cases [118,120,122,123]. In patients with pulmonary annulus hypoplasia necessitating a transannular patch, the risk of mortality is increased if a concomitant systemic-pulmonary artery shunt is not performed (Table 21.2) [87]. In this scenario, use of a combined transannular patch and systemic-pulmonary artery shunt is advised.

The rate of long-term freedom from reintervention, excluding patients who need an early systemic-pulmonary artery shunt, has been approximately 85% at 3–8 years [118,120]. Severe pulmonary valve insufficiency is uncommon in older children, but one report indicated that the use of oversized balloons in neonates carries substantial risk of late severe pulmonary valve insufficiency [124].

Surgical Technique for Critical Pulmonary Stenosis

The most common indication for surgical relief of critical pulmonary stenosis is unsuccessful balloon valvuloplasty. Lack of success usually is associated with the presence of extremely tight valvar obstruction, in which crossing the pinhole-like pulmonary valve can be very difficult.

Surgical valvotomy is achieved with a standard median sternotomy. Inflow caval occlusion or preferably cardiopulmonary bypass should be used. The aorta is cannulated in the standard manner. A single right atrial cannula is satisfactory for venous drainage because the atrial septal communication should be left alone. Before bypass is initiated, the ductus arteriosus is encircled with a tourniquet. Aortic occlusion is not necessary and should be avoided; therefore normothermic normocalcemic perfusion is used. After bypass is initiated, the ductus arteriosus is snared. Occlusion of each branch pulmonary artery facilitates exposure. The main pulmonary artery is opened longitudinally and the pulmonary valve is exposed. Careful commissurotomies are performed with a sharply pointed scalpel so that each commissure is incised into the wall of the pulmonary artery (Figure 21.9) [16]. The commissures frequently are tethered to the wall of the pulmonary artery so that valve motion is limited. Valve function is improved by careful release of each commissure from the sinus wall by precise sharp dissection. The main pulmonary artery is then closed. The branch pulmonary arteries are released, and cardiopulmonary bypass is discontinued. The ductus arteriosus should not be ligated permanently because temporary ductal patency may be necessary to allow adequate pulmonary blood flow until right ventricular function recovers. The results of balloon valvuloplasty indicate that aggressive transannular patching, subvalvar resection, and concomitant systemic-pulmonary artery shunts are only rarely necessary.

Valvar Pulmonary Stenosis in Older Infants and Children

Pathophysiology and Natural History

The pathophysiology of valvar pulmonary stenosis is directly related to the severity of obstruction of right ventricular output. The delayed presentation of this lesion in older children results from the progression of obstruction and secondary morphologic changes that occur if sustained elevation of right ventricular pressure is not corrected. Progression from moderate to severe valvar obstruction is

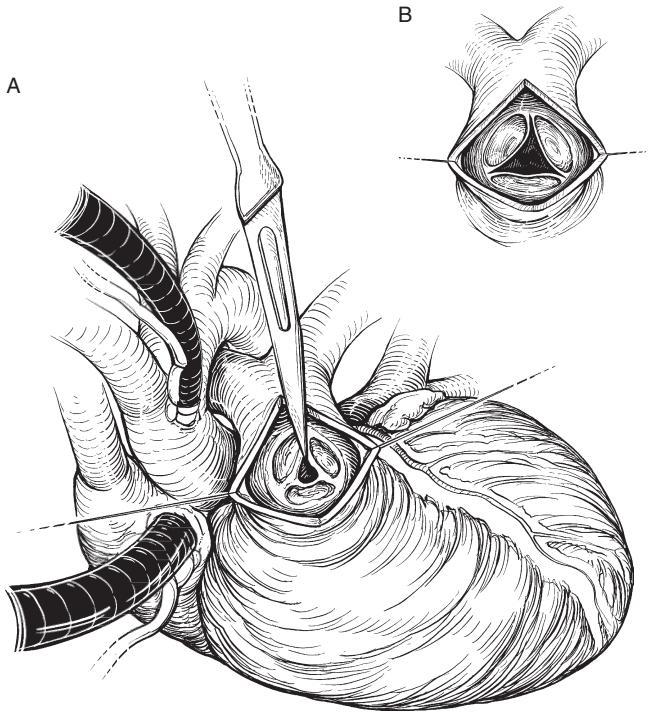

Figure 21.9 Technique of pulmonary valvulotomy. **A,** Fused leaflet commissures are incised to the pulmonary artery wall. **B,** Completed valvulotomy.

not usually because of relative underdevelopment of the pulmonary annulus, because the annular dimensions in older children and adults with this lesion are only mildly decreased in most cases. Progression of stenosis does not occur in all patients, and the underlying mechanism of progression is not known. Possible mechanisms of progression include increased demand for cardiac output owing to somatic growth with maintenance of a constant and reduced pulmonary valve orifice area [125]. The development of infundibular hypertrophy may contribute to the progression of obstruction. Increased pressure overload of the right ventricle causes muscle hypertrophy and increases myocardial oxygen demand while oxygen delivery is limited by decreased cardiac output. This condition can lead to subendocardial ischemia and myocardial infarction. As right heart failure ensues, right ventricular compliance decreases, and right atrial pressure increases. In the presence of atrial level communication, right-to-left flow can occur at the atrial level and produce cyanosis.

Early studies of the natural history of pulmonary stenosis were biased by selection criteria limited to patients undergoing cardiac catheterization [126,127]. These studies indicated that younger children were more likely than older children to have progression of stenosis and that rapid progression was more common among younger patients. Mody [126] found that more than one half of children with moderate pulmonary stenosis diagnosed before 1 year of age had severe stenosis by the age of 5 years. Results of more recent studies with two-dimensional echocardiography with Doppler and color-flow mapping techniques confirmed that younger children are more likely to have lesions that progress to severe obstruction, although the likelihood of progression is lower than reported in older studies [128,129]. Most studies have shown that the degree of stenosis at initial diagnosis correlates with the progression of obstruction [130]. It has not been possible, however, to identify which children at a given age or with a given level of obstruction will have disease progression. One study conducted with serial echocardiographic examinations showed that 58% of children with mild or moderate stenosis actually had a decreasing degree of stenosis [131].

Presentation and Diagnosis

Most patients with isolated valvar pulmonary stenosis have no symptoms and exhibit normal growth. Asymptomatic lesions typically manifest when a pathologic heart murmur is detected at a physical examination performed for other reasons. Syndromic valvar pulmonary stenosis, such as Noonan's syndrome, commonly is identified early because of the recognized association of these syndromes with pulmonary stenosis. This lesion should be specifically sought in such patients. The onset of symptoms usually occurs after infancy and even into adulthood when the severity of stenosis and secondary right ventricular hypertrophy begins to limit cardiac output. Symptoms are absent in patients with mild and even moderate stenosis but become evident with exertion in some patients with moderate stenosis. Early symptoms include fatigue and exertional dyspnea. Only one fourth of patients with severe pulmonary stenosis are free of symptoms [78]. Patients with longstanding severe obstruction may have right-sided congestive heart failure. Patients with advanced right ventricular obstruction and a large atrial septal defect may have cyanosis. Other less common presenting symptoms associated with severe pulmonary stenosis include chest pain, syncope, and ventricular arrhythmias.

The differential diagnosis of isolated mild or moderate pulmonary stenosis in symptom-free children includes mild aortic stenosis, atrial septal defect, idiopathic dilatation of the main pulmonary artery, peripheral pulmonary artery stenosis, mitral valve prolapse, and innocent heart murmur. The differential diagnosis of severe pulmonary stenosis includes ventricular septal defect, ventricular septal defect with pulmonary stenosis, and moderate aortic stenosis [76,78].

Auscultatory findings include a normal first heart sound followed by a characteristic ejection click in patients with mild or moderate stenosis. As the severity of stenosis

increases, the ejection click occurs earlier in systole until it merges with the first heart sound and may become inaudible in patients with severe stenosis. A prominent systolic ejection murmur is heard maximally at the upper left sternal border with radiation to the entire precordium, neck, and back. In general the intensity of the ejection murmur is proportional to the severity of stenosis, except in patients with advanced right-heart failure, in whom the murmur may be relatively soft owing to diminished cardiac output. The second heart sound usually is split, and the degree of splitting corresponds to the severity of stenosis. A wide, fixed, split second heart sound is indicative of associated atrial septal defect. Jugular venous distention occurs with a prominent A-wave pulse in cases of severe obstruction. In such patients hepatic enlargement and pulsation usually are present. At precordial examination a prominent right ventricular heave is present, and a systolic thrill usually is palpable in the left second intercostal space or at the suprasternal notch.

Abnormal electrocardiographic findings are present in most patients with moderate pulmonary stenosis and in almost all patients with severe stenosis. Right axis deviation occurs, and there is evidence of right ventricular hypertrophy. The height of the R wave in lead V_1 correlates with the degree of right ventricular hypertension. Heart size on chest radiographs usually is normal, although impressive cardiomegaly may be present in advanced cases. The most distinctive radiographic finding is prominence of a main pulmonary artery segment caused by the poststenotic dilatation present in most patients after infancy. The pulmonary vasculature usually is normal, but the lungs may appear oligemic in severe cases.

Two-dimensional echocardiography with color Doppler examination is the primary definitive diagnostic technique and should be used for all patients. This modality allows accurate assessment of both the valvar and subvalvar components of obstruction and is a noninvasive means of quantifying the severity of stenosis. Other cardiac lesions can be excluded. The morphology of the valve can be assessed, and in most cases the dysplastic pulmonary valve type can be identified. Right ventricular function and the degree of right ventricular hypertrophy can be evaluated. Tricuspid valve anatomy and function can be defined, and when tricuspid regurgitation is present, right ventricular pressure can be estimated. Acceleration of blood flow across the pulmonary valve allows estimation of the peak instantaneous pressure gradient between the right ventricle and the pulmonary artery. Last, the presence of atrial septal defect can be confirmed, and Doppler evaluation can be used to determine the direction of shunting at the atrial level. Findings at echocardiographic assessment of the severity of obstruction have been shown to correlate well with direct hemodynamic measurements obtained at cardiac catheterization [132].

The ability to accurately diagnose and grade the severity of pulmonary stenosis has made cardiac catheterization a technique primarily reserved for therapeutic intervention rather than a diagnostic tool. However, the grading criteria for severity of valvar pulmonary stenosis were established with hemodynamic measurements, and angiography still contributes useful anatomic details in the evaluation of patients for whom either operative or percutaneous intervention is warranted. Angiography illustrates the anatomy of the right ventricular outflow tract, and doming of the pulmonary valve is a characteristic finding. Angiography is useful in assessing the anatomy of the main and branch pulmonary arteries. The grading scale of pulmonary stenosis is based on the measurements of right and left ventricular pressure and the peak-to-peak gradient measured across the right ventricular outflow tract. These definitions are based on the assumption that the patient is in the resting state and has normal cardiac output. In a healthy patient, resting right ventricular systolic pressure is 30 mmHg or less, and the gradient across the pulmonary valve is less than 10 mmHg. Mild pulmonary stenosis is defined as a right ventricular outflow tract pressure gradient less than 40 mmHg and a right ventricular-to-left ventricular pressure ratio of 0.5 or less. Moderate stenosis is defined as a pressure gradient greater than 40 mmHg but less than 80 mmHg and a right ventricular-to-left ventricular pressure ratio greater than 0.5 but less than 1.0. Severe stenosis is defined as a pressure gradient of 80 mmHg or greater and a right ventricular-to-left ventricular pressure ratio of 1.0 or greater [78].

Management of Pulmonary Stenosis

Percutaneous Balloon Valvuloplasty

Percutaneous balloon valvuloplasty is the treatment of choice for nearly all patients who need intervention for isolated valvar pulmonary stenosis. All patients with symptoms should undergo intervention. Specific treatment is not indicated if the patient has asymptomatic mild pulmonary stenosis. These patients need only careful surveillance with serial physical examinations and echocardiography for detection of progression of obstruction. Cardiac catheterization is indicated if symptoms develop or echocardiography shows progression of obstruction. Older studies with long-term follow-up evaluation of patients with pulmonary valvar gradients ranging from 50–79 mmHg who were treated medically showed that most of these patients eventually needed intervention [130]. Balloon valvuloplasty after the neonatal period carries very low risk of morbidity and mortality and is highly efficacious. Consequently, most authorities recommend that any patient with a pulmonary valve gradient greater than 50 mmHg undergo balloon valvuloplasty. It seems logical to intervene at this stage to avoid the long-term deleterious effects of right ventricular

hypertrophy that may lead to the development of myocardial fibrosis [76]. Patients in whom recurrent pulmonary stenosis develops after previous percutaneous or surgical intervention also need repeated balloon valvuloplasty as the first-line treatment.

Management of dysplastic pulmonary valvar stenosis is controversial. In this type there usually is no commissural fusion. The mechanism of balloon valvuloplasty is the splitting of fused leaflet tissue present in the other types of pulmonary stenosis. In the dysplastic type, subannular narrowing, annular hypoplasia, lack of commissural fusion, unusual leaflet tethering, and the mass of dysplastic valvar tissue all contribute to obstruction and complicate balloon valvuloplasty. Early results of balloon valvuloplasty for this type of valve revealed a high failure rate; however, adequate relief has been reported in 35–65% of cases [112,133,134]. Consequently, balloon pulmonary valvuloplasty usually is still recommended for first-line management of dysplastic pulmonary valvar stenosis [76,78]. Surgical therapy is reserved for patients who do not respond to balloon valvuloplasty.

The intermediate results of balloon valvuloplasty in children and adults with pulmonary valvar stenosis have been excellent [111,112,133,135,136]. Predictors of poor intermediate outcome of balloon valvuloplasty include smaller pulmonary annulus size and a higher immediate residual gradient. Long-term results of balloon pulmonary valvuloplasty remain limited. Compared with patients treated surgically, patients undergoing balloon valvuloplasty have had a lower incidence of late moderate or severe pulmonary insufficiency requiring pulmonary valve replacement [136]. However, there have been no direct comparisons of patients treated percutaneously with surgical patients over a contemporaneous period. The long-term survival rate after surgical intervention for this disease is 97% at 25 years. It is reasonable to assume that survival after balloon valvuloplasty will be equally excellent [130].

Surgical Management

Surgery for pulmonary valvar stenosis has been supplanted by balloon valvuloplasty. There have been no recent reports of early results of surgery for this lesion, because surgery now is used only rarely. The early mortality of surgical valvotomy in the most recently published surgical series has ranged from 0–4% [27,102,137]. Consequently, it is reasonable to state that surgery in the current era carries very low risk. The primary indications for surgical pulmonary valvotomy are failure of balloon valvotomy and anatomy unsuitable for successful valvotomy. The most common type managed surgically is dysplastic pulmonary valve. Because annular hypoplasia is a substantial component of obstruction, pulmonary valvotomy or valvectomy alone is rarely sufficient operative management, and a transannular patch with subvalvar resection is more commonly needed. Nearly all such patients have at least moderate pulmonary insufficiency. In general this condition is well tolerated in the medium term. However, the long-term deleterious effects of unmanaged clinically significant pulmonary insufficiency have been recognized, and replacement of the pulmonary valve may be necessary for many of these patients.

Surgical Technique

Standard median sternotomy with bicaval and aortic cannulation is used for surgical pulmonary valvotomy. This approach allows the surgeon to close any associated atrial septal communication and facilitates transatrial resection of obstructing infundibular muscle bundles and precise valvotomy. Cardioplegia is not necessary for cases in which simple valvotomy or transannular patching is performed. However, if transatrial resection of obstructing muscle bundles is to be performed, cardioplegic arrest is required. In the unusual circumstance of operation for simple valvar pulmonary stenosis with typical poststenotic dilatation, a transverse pulmonary arteriotomy is made, and commissural fusion is sharply divided back into the wall of the pulmonary artery. Valvar tethering is released with sharp dissection, and thickened valve edges are trimmed. Primary closure of the pulmonary artery is then performed with monofilament suture. More commonly, marked annular hypoplasia is present (diameter two standard deviations below normal or smaller), and a transannular incision is needed. In this case longitudinal arteriotomy is preferred. Commissural fusion when present is addressed as described previously. The arteriotomy is extended through the anteriorly located commissure and crosses the annulus into the right ventricular muscle just until a dilator of appropriate size can be passed retrograde through the valve. Obstructive infundibular muscle bundles are divided to further relieve right ventricular outflow tract obstruction. In the case of a dysplastic pulmonary valve with no commissural fusion, the valve is resected, and a transannular incision is made as necessary. After muscle resection, the transannular incision is closed with a patch of autologous pericardium or 0.4 mm polytetrafluoroethylene with an appropriately sized dilator for judging the width of patch necessary to provide adequate relief of obstruction. Before the right ventricular outflow tract is closed, the heart is either arrested with cardioplegia or electrically fibrillated, and the atrial septal defect or patent foramen ovale is closed. Closure of the right ventricular outflow tract can be accomplished during reperfusion. If there is marked right ventricular dysfunction or hypoplasia, the atrial septal defect should not be completely closed. In the case of patent foramen ovale the atrial communication should be left open at this time. The patient is then weaned from cardiopulmonary bypass. Intraoperative transesophageal echocardiography

is recommended to aid in assessing residual gradients, valvar insufficiency, shunt direction at the atrial septum when left open, and ventricular function.

Other Forms of Isolated Right Ventricular Outflow Tract Obstruction

Supravalvar Pulmonary Artery Stenosis

Supravalvar main pulmonary artery stenosis is a very rare lesion. It occurs most commonly in association with Noonan's syndrome and occasionally with Williams' syndrome. In rare instances this form of arterial stenosis occurs in the absence of an associated syndrome. The indications for management of such stenosis mirror those for isolated pulmonary stenosis. However, the primary mode of management is surgical, as supravalvar narrowing is frequently resistant to balloon angioplasty. In most cases simple patch enlargement is all that is needed.

Peripheral pulmonary artery stenosis is much more common and can affect the branch or intraparenchymal pulmonary arteries. In most cases balloon angioplasty with or without intravascular stenting, often on a recurrent basis, is preferred when treatment is needed.

Primary Infundibular Stenosis

Primary infundibular stenosis accounts for approximately 5% of all cases of isolated right ventricular outflow tract obstruction [76]. This entity manifests similarly to isolated pulmonary valvar stenosis after the neonatal period. The diagnosis is made with echocardiography. The indications for treatment are identical to those for valvar pulmonary stenosis. Unlike pulmonary valvar stenosis, management of primary infundibular stenosis is surgical. There are two distinct types of primary infundibular stenosis. In one type there is fibromuscular thickening in the wall of the right ventricular infundibulum. This process exists immediately below the pulmonary valve and can extend into the proximal portion of the infundibulum. Treatment consists of longitudinal infundibulotomy with patch enlargement. In most cases the pulmonary valve is normal, therefore, the incision must be kept below the annulus of the pulmonary valve to avoid damage to the valve. Recently, stent placement in the right ventricular outflow tract has been used as a palliative modality to enable patient growth before definitive surgical repair [138].

The other type of primary infundibular stenosis is characterized by an obstructive fibrous muscle band at the junction of the main right ventricular cavity and the proximal infundibulum. This lesion is often referred to as double-chambered right ventricle. Surgical treatment can usually be accomplished by transatrial resection of the obstructing band, but in some cases a right ventriculotomy is needed [139].

Conclusion

The category *isolated right ventricular outflow tract obstruction* encompasses a wide range of complexity from lesions that are among the easiest to treat to anomalies that are the most difficult to manage successfully. It is clear that catheter intervention alone or combined with surgery is currently and increasingly important among the therapeutic alternatives for these abnormalities. Frequently associated pathologies of the right ventricle, tricuspid valve, and coronary arteries continue to negatively impact outcomes in these patients. In a small group of the most complex cases, cardiac transplantation is the most reasonable option.

Definition, Morphology, and Nomenclature

Arthur Louis Etienne Fallot was born in 1850 in southern France, and after studying medicine in Marseilles, went on to become Professor of Hygiene and Legal Medicine. In 1888, he published a 104-page treatise entitled "Contribution a 'l'anatomie pathologique de la maladie bleue [1]." He used "tetralogie" to refer to the aggregate of four features of the anatomy seen in the majority of specimens coming into his autopsy service from patients with "la maladie bleue": pulmonary artery stenosis, ventricular septal communication, rightward deviation of the aorta's origin, and hypertrophy of the right ventricle (Figure 22.1) [2]. This characteristic morphology had in fact been recognized and illustrated long before Fallot's description. The first published report is from 1671 by the Danish monk, Niels Stenson, famous for his description of the parotid duct, who described the association of lesions after observing the findings in an ectopic heart from a fetus [3]. The first attribution to Fallot came from Ambrose Birmingham, a Professor of Anatomy at the Catholic University in Dublin, Ireland. He called the constellation of lesions "Pentalogy of Fallot" in 1892, adding the common presence of an atrial septal defect (ASD) [4]. However, widespread use of the term tetralogy of Fallot (TOF) did not follow until its use by Maude Abbott in an article on the classification of congenital heart defects published by Dawson and Abbott in 1924 [5].

More recently, attempts have been made to identify one of the four anatomic features as being paramount. This, of course, acknowledges that it is most likely that the four features of pathologic anatomy are collectively secondary consequences of a common pathway of altered cardiac development, as opposed to the possibility that they represent four "coincident" errors of morphogenesis. Van Praagh and his colleagues asserted that it was underdevelopment of the subpulmonary infundibulum that was the primary feature, stating that this part of the heart was "too narrow, too shallow, and too short" [6,7]. Anderson and associates observed that the infundibulum is unequivocally narrow and hypoplastic, but that its length is variable, and that in many hearts with TOF the infundibulum is longer than normal [8,9]. They suggested that anterocephalad deviation of the insertion of the infundibular septum relative to the septomarginal trabeculation was the key feature. Further investigation suggested that this was not a completely satisfactory unifying hypothesis. First, the outlet septum could be deviated in anterocephalad fashion without producing subpulmonary obstruction, as in the Eisenmenger defect [10]. Second, in some hearts, there could be subpulmonary obstruction when the outlet septum was fibrous, rather than muscular. A more satisfactory explanation does involve anterocephalad deviation of the outlet septum, be it muscular or fibrous, but requires an abnormal relation of the outlet septum to the septoparietal trabeculations, producing subpulmonary obstruction [11].

The ventricular septal defect (VSD) occurs as a result of the anterocephalad malalignment and deviation of the insertion of the infundibular septum relative to the limbs of the septomarginal trabeculation. The resulting hole between the ventricles is directly beneath the overriding aortic valvar orifice. Thus, Anderson considers it an outlet defect [11], while others refer to it as a malaligned conoventricular defect. The VSD in TOF is large and, in nearly all instances, physiologically nonrestrictive. In most cases, the ventriculoinfundibular fold stops short of the posteroinferior limb of the septomarginal trabeculation, resulting in fibrous continuity between the aortic and tricuspid

(Ao, aorta; MPT, main pulmonary trunk; VSD, ventricular septal defect; TV, tricuspid valve.)

valves. Such defects are accurately described as perimembranous. Less often, there is muscular continuity throughout the right ventricular margins of the defect. In such cases, the muscular fold located inferoposteriorly, together with the membranous septum, separates the conduction tissues from the crest of the ventricular septum. There is then yet a third variety of defect, characterized by presence of a fibrous rather than a muscular outlet septum. This is the doubly committed and juxta-arterial defect, by far the least common in the western world, but commoner in the Far East and South America.

In addition to the variability described above with respect to the limits of the VSD, the spectrum of TOF with pulmonary stenosis (as opposed to atresia) is characterized by several other important anatomic variants, as well as associated malformations. Anterior and cephalad deviation of the outlet septum results in varying degrees of right ventricular outflow tract (RVOT) obstruction, related to hypoplasia of the right ventricular infundibulum and the presence of prominent septoparietal muscle bands or trabeculations, which tend to undergo progressive hypertrophy postnatally. A localized narrowing, or os infundibulum, frequently occurs at the inferior border of the right ventricular infundibulum. In most cases, the pulmonary valve morphology is abnormal, frequently with thickened immobile leaflets, often with commissural fusion and/or tethering of leaflets to the pulmonary artery wall. The pulmonary valve ring or annulus is hypoplastic in comparison to normal hearts, and the pulmonary valve is bicuspid in more than half of cases [12]. More distal levels of RVOT obstruction include hypoplasia or discrete stenoses within the main pulmonary trunk and/or the branch pulmonary arteries. Not uncommonly there is a discrete narrowing with a fibrous shelf within the left branch pulmonary artery at a level corresponding to the site of insertion of the ductus arteriosus.

Other anatomical variants include the presence of one or more additional VSDs, which occur in approximately 5% of cases [13]. Most commonly, the secondary defects are located anteriorly, within the muscular septum. Variants of coronary artery anatomy are seen in TOF, with the most common being origin of the anterior descending coronary artery from the right coronary artery [14,15]. In such cases the anterior descending artery traverses the anterior surface of the RVOT a short distance below the pulmonary annulus. It is susceptible to injury if a ventriculotomy incision is required to affect repair. Less commonly, there is dual supply to the anterior interventricular septum, with branches originating from both the right coronary artery and the left main coronary artery. Rarer still is origin of all coronary branches from a single ostium within the right sinus of Valsalva. Other TOF-associated congenital heart defects include complete atrioventricular septal defect (AVSD; described in more detail later in this chapter), patent foramen ovale (PFO) or ostium secundum type ASD, patent ductus arteriosus (PDA), persistent left superior vena cava, ductal origin of one branch pulmonary artery (most often the left pulmonary artery), and right-sided aortic arch, which is seen in 15–25% of patients [16].

Pulmonary atresia is present in approximately 7% of patients with TOF [17]. An important distinction is made between those with a PDA and those without. When there is a PDA in the setting of TOF with pulmonary atresia, it is most often the only source of pulmonary blood flow. In such cases, there may be varying degrees of hypoplasia of the pulmonary arteries, but it is most often the case that all or nearly all lung segments are supplied by branches arborizing from the right and left pulmonary arteries. In the absence of a PDA, pulmonary artery arborization is much less predictable, and varying amounts of pulmonary parenchyma are supplied partially or entirely by multiple major aortopulmonary collateral arteries (MAPCAs). The clinical presentation and natural history of this variant is considerably different from that of the more typical TOF, and a variety of distinctive treatment strategies have evolved. Pulmonary atresia with VSD and MAPCAs is described in detail in Chapter 23, *Surgical Treatment of Pulmonary Atresia with Ventricular Septal Defect.*

In view of the contemporary understanding of the pathologic anatomy, the issue of a unifying definition of TOF was debated by the International Working Group for Mapping and Coding of Nomenclatures for Pediatric and Congenital Cardiac Disease in 2008. The following consensus definition was adopted: *Tetralogy of Fallot is defined as a group of malformations with biventricular atrioventricular alignments or connections characterized by anterosuperior deviation of the conal or outlet septum or its fibrous remnant, narrowing or atresia of the pulmonary outflow, a ventricular septal defect of the malalignment type, and biventricular origin of the aorta. Hearts with tetralogy of Fallot will always have a ventricular septal defect, narrowing or atresia of the pulmonary outflow, and aortic override; hearts with tetralogy of Fallot will most often have right ventricular hypertrophy* [18]. The diagnostic choices used for coding in the contemporary version of the Society of Thoracic Surgeons Congenital Heart Surgery Database are listed in Table 22.1 [19]. In the database, however, pulmonary atresia with VSD is not linked in a hierarchical fashion to TOF, acknowledging that not all cases of pulmonary atresia with VSD can be conclusively said to fall within the category of TOF.

Tetralogy of Fallot and associated variants are thought to constitute as much as 10% of all forms of congenital heart disease, and TOF is the most common form of cyanotic congenital heart disease with an incidence of 421 cases per million live births [20]. In a recent report of the Society of Thoracic Surgeons Congenital Heart Surgery Database outcomes of 67 596 operations on 59 163 patients between July 2004 and June 2008, 3518 (5.2%) of all operations were performed on patients with a primary diagnosis of TOF (exclusive of pulmonary atresia with VSD) [21].

Genetic syndromes are identified in at least 20% of TOF patients. The most common associated syndrome is DiGeorge syndrome, which results from one of several known deletions on chromosome 22 (del 22q11). In one study looking specifically at associated genetic syndromes in 306 patients with TOF, 28% had genetic defects or syndromes, of which 32% were del 22q11, 15% were trisomy 21, and 14% were VACTERL [22].

History of Surgical Management

One of the most significant and exciting accomplishments by any of the pioneers of congenital heart surgery is the historical "blue baby operation" by Dr. Alfred Blalock in 1944 [23]. Helen Taussig, the physician in charge of the pediatric cardiology clinic at Johns Hopkins Hospital hypothesized that creation of an arterial duct would confer significant relief of the hypoxemia of patients with TOF. Taussig took her idea to Blalock, who had previously proposed an operation to bypass coarctation of the aorta based on turning down the divided distal end of the left subclavian artery. Coincidently, Vivien Thomas, the research assistant in Blalock's surgical laboratory had created a canine model to study pulmonary arterial hypertension in which the divided distal end of a branch of the subclavian artery was connected to a pulmonary artery. Ironically, while this model failed to reliably create pulmonary arterial hypertension, it was precisely the equivalent of the artificial duct sought by Taussig. On November 29, 1944, Alfred Blalock performed the first operation on a cyanotic 1-year-old child with TOF. The Blalock-Taussig shunt had a high rate of success, and by 1950, 1000 such operations had been performed by Blalock and his team [24].

In the same timeframe, other surgical pioneers of the time devised a variety of related closed-heart procedures, either to address obstruction within the RVOT or to augment pulmonary blood flow by creation of a systemic-to-pulmonary arterial shunt. In London in 1948, Thomas Holmes Sellors and Russell Claude Brock separately described the use of genitourinary sounds to probe and dilate the RVOT [25,26]. Charles Bailey later reported treating eight patients with TOF in Philadelphia with the Brock procedure [27]. In Chicago, Willis Potts created an anastomosis between the descending thoracic aorta and the left pulmonary artery [28]. Alternatively, David Waterston developed posterior anastomosis of the ascending aorta to the right pulmonary artery [29]. These side-to-side connections were touted as being more easily created than the Blalock-Taussig shunt in very small infants. Thousands of patients benefited from the Potts shunts and Waterston shunts, which at the time were intended as definitive palliation. Unfortunately, they also posed a significant challenge to take down.

The first intracardiac repair of TOF was by C. Walton Lillehei and his team at the University of Minnesota during their remarkable series of 45 cross-circulation cases that started on March 26, 1954 [30]. On August 31 of that same year, Lillehei, Varco, and Warden performed the first suc-

cessful repair of TOF on a 10-year-old boy [31]. Unique among the cross-circulation cases, this operation was the first where cross-circulation did not involve the parent or a relative as the circulatory donor, but rather a random volunteer with compatible blood type who was recruited by the Red Cross. The patient was the first of 10 patients with TOF who underwent repair using cross-circulation, and he was one of six survivors, a remarkable feat given the ground-breaking nature of the endeavor [32]. An additional technical milestone developed by Lillehei and his team was the development of a patch to close the VSD. This patch was used in the last three patients after the experience of primary VSD closure in the initial seven. One year after the Lillehei team's success, John Kirklin performed the first successful repair of TOF using extracorporeal support with a mechanical pump oxygenator at the Mayo Clinic in 1955 [33].

Presentation and Diagnosis

Tetralogy of Fallot is a common cyanotic congenital heart defect [20], however, only a small percentage of patients present with deep cyanosis in the neonatal period following closure of the PDA. These are colloquially referred to as "blue TETs" in contradistinction to the acyanotic "pink TETs." Among the group of acyanotic TOF patients, a few may have normal arterial oxygen saturation measurements and even present with signs of pulmonary overcirculation if the pulmonary stenosis is mild. More typically there is initial mild desaturation in the range of 80–90% depending on the presence of a PDA and the degree of pulmonary stenosis. The infants with profound cyanosis typically have severe valvar level stenosis, or near atresia. Occasionally, these patients remain undiagnosed in the presence of a moderate to large PDA and can present days or weeks after birth with profound cyanosis after ductal closure. When this presentation is at a time where ductal patency cannot be re-established with prostaglandin infusion, it represents an emergent surgical situation to establish adequate pulmonary blood flow. The most common natural progression of acyanotic TOF patients is slowly decreasing baseline saturations as they develop progressive right ventricular hypertrophy and subvalvar stenosis. Close follow-up of acyanotic TOF patients is required to provide appropriate timing of intervention before the development of moderate to severe cyanosis. Acyanotic and mildly cyanotic TOF patients can also develop episodic profound hypercyanosis. These "TET spells" result from dynamic changes in the relative pulmonary and systemic resistances leading to severe right to left shunting through the VSD with systemic oxygen saturations often dropping well below 50%. The most commonly touted, though unproven, etiology for hypercyanotic spells is infundibular muscle spasms leading to a large dynamic increase in the subvalvar obstruction with resulting right-to-left shunting through the VSD.

Clinical exam is notable for varying degrees of cyanosis, from slight pallor to marked generalized cyanosis. Clubbing can occasionally be seen in advanced cases. Auscultation reveals a systolic murmur from the right ventricular outflow obstruction. During a "TET spell" this murmur will soften or disappear as a result of the limited flow through the RVOT. Because of the large size of the VSD and systemic level pressure in the right ventricle, little or no VSD murmur is typically appreciated. The second heart sound is usually not split as the small, abnormal pulmonary valve and low poststenotic pulmonary pressures often do not create a sound. Electrocardiography shows marked right ventricular hypertrophy and a right axis deviation, however, these findings are neither specific nor diagnostic. Chest X-rays may show the classic "boot-shaped" heart resulting from right ventricular hypertrophy and small pulmonary arterial knob (Figure 22.2). The right aortic arch present in 15–25% of patients with TOF may be appreciated on chest X-ray. The lung fields are generally dark as a result of relative hypoperfusion. Echocardiography is the primary diagnostic modality in the vast majority of cases (Figure 22.3). The combination of M-mode and Doppler echocardiography provides a complete evaluation of the TOF anatomy [34,35] including estimations of the pressure gradient at the subvalvar, valvar, and supravalvar levels of the RVOT. Echocardiography has been shown to reliably determine the coronary pattern in the majority of cases, including left anterior descending artery from the right coronary artery [36]. Prenatal echocardiography increasingly makes the in utero diagnosis of TOF and has a high degree of accuracy, though it cannot fully determine the degree of pulmonary stenosis [37]. There is no clear evidence that prenatal diagnosis benefits long-term survival [38].

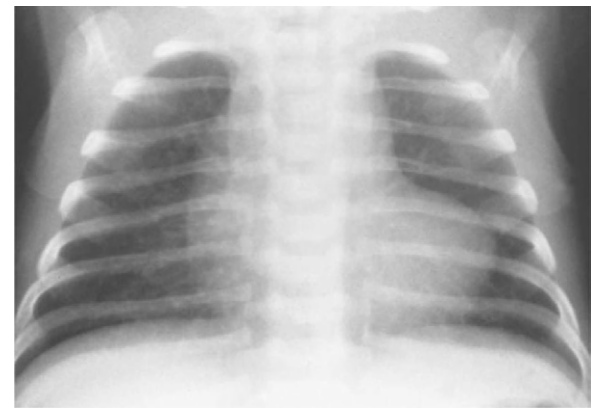

Figure 22.2 Typical chest radiograph of the boot-shaped heart in a patient with tetralogy of Fallot. This appearance results from right ventricular hypertrophy and hypoplasia of the main pulmonary artery.

Three-dimensional echocardiography has yet to prove any substantial benefit over two-dimensional studies for diagnosis and preoperative assessment. However, three-dimensional echocardiography may prove an important modality for long-term follow-up of morphological and functional changes to the right ventricle in repaired TOF [39]. Cardiac catheterization was the gold standard for diagnosis of TOF before the advancements in echocardiography and Doppler technology. Most patients with TOF currently do not require cardiac catheterization before reparative surgery (Figure 22.4). The most common current indications for cardiac catheterization are unclear anatomy of the branch pulmonary arteries and confirmation of the presence of a left anterior descending artery from the right coronary crossing anterior to the RVOT. This is particularly important in any patient who had a palliative operation where the branch pulmonary artery architecture may be distorted and where the postoperative adhesions on the right ventricle may obscure an unsuspected anomalous coronary artery. Axial imaging with three-dimensional reconstruction, including computed tomography (CT) scan and magnetic resonance imaging (MRI), have an important role in the evaluation of TOF. Before complete repair, these modalities can be used as an alternative to cardiac catheterization as they may reveal branch pulmonary artery and aortic arch anatomy and also delineate coronary anomalies. Cardiac magnetic resonance imaging (CMR) is emerging as one of the most useful studies for long-term evaluation of the repaired TOF patient (Figure 22.5) [2].The volumetric measurements of the right ventricle and quantification of pulmonary regurgitant fraction and right ventricular function are superior to those obtained by means of two-dimensional echocardiography [40–42]. Such CMR measurements are becoming the benchmarks for timing of reinterventions, most importantly regarding the timing of pulmonary valve insertion or replacement [43,44]. Finally, postnatal screening with pulse oximetry has been used to detect unsuspected congenital heart defects including TOF, but has failed to demonstrate cost effectiveness [45,46].

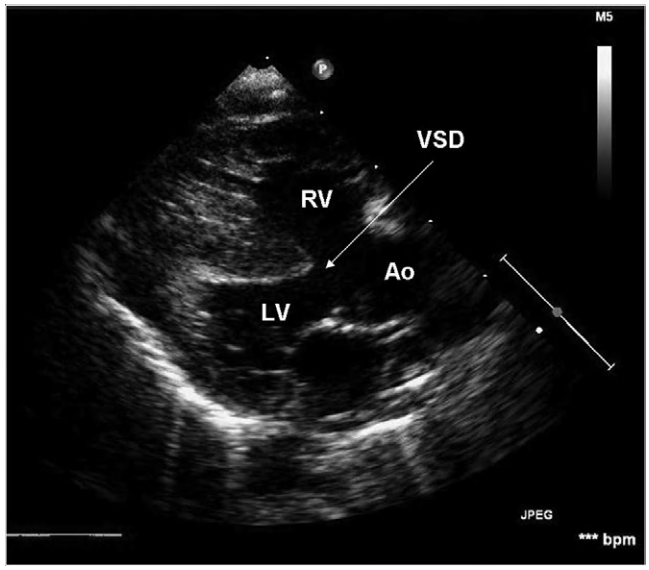

Figure 22.3 Two-dimensional echocardiogram with a parasternal long access view of a patient with tetralogy of Fallot. The large unrestrictive malalignment ventricular septal defect is clearly evident with significant aortic override. (Ao, aorta; LV, left ventricle; RV, right ventricle; VSD, ventricular septal defect.)

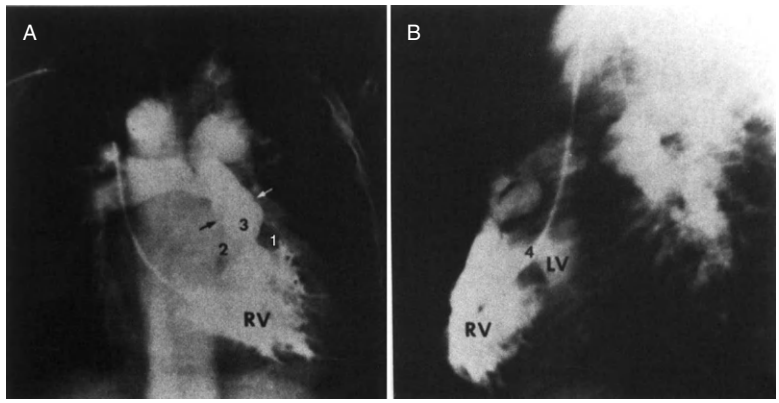

Figure 22.4 Right ventricular angiograms in a patient with tetralogy of Fallot. **A,** Frontal view demonstrating right ventricular obstruction caused by hypertrophied septal (1) and parietal (2) bands. There is mild stenosis of the right pulmonary artery origin and filling of the ascending aorta with contrast. The aortic arch is on the right and the left Blalock-Taussig shunt is visible. **B,** The lateral view demonstrates the right ventricular obstruction with anterior displacement of the infundibular (conal) septum. The stenotic pulmonary valve is seen. Contrast material outlines the VSD (4) and the left ventricle (LV). (RV, right ventricle.)

Figure 22.5 Cardiac magnetic resonance image with a sagittal view of a patient with long-standing repaired tetralogy of Fallot. The right ventricle is significantly dilated, and there is severe pulmonary insufficiency.

Medical Management

There is no long-term medical solution for TOF, and the definitive treatment is surgical repair. However, there are a few significant medical adjuncts; most important of these being the use of prostaglandin E1 (PGE_1) to maintain ductal patency in profoundly cyanotic neonates with TOF [47]. Administered as a continuous intravenous infusion at a dose of 0.01–0.1 μg/kg/min, PGE_1 will open and maintain the ductus arteriosus thus providing blood flow until surgical correction or establishment of a systemic to pulmonary shunt. The use of PGE_1 is primarily limited to the first week of life. Administration of PGE_1 to infants presenting after that point is less likely to result in opening of the duct, with success after 2 weeks being rare. The most significant unwanted side effect of PGE_1 infusion is apnea, which often necessitates endotracheal intubation and mechanical ventilation. The majority of other medical treatments are aimed at preventing or treating "TET spells." Beta-blockade is used by some cardiologists, with the theoretical objective of reducing the incidence of spasm of the infundibular muscle of the RVOT. There is conflicting evidence concerning the effectiveness of this therapy [48,49]. The downside of continued use of beta-blockade in TOF patients is that it has been shown to increase the need for inotrope use and temporary pacing following surgical repair [50]. These findings favor earlier surgical intervention for patients who require beta-blockade for paroxysmal spells. Acute medical management for a hypercyanotic patient includes supplemental oxygen, sedation, volume resuscitation, and the alpha-receptor antagonist phenylephrine. Phenylephrine increases systemic resistance through direct vasoconstriction and has been shown to decrease right-to-left shunting, resulting in increased pulmonary blood flow [51,52]. However, any TOF patient who requires such therapy should be referred for urgent surgical palliation or repair.

Surgical Repair

Surgical timing remains a debated topic centered on two issues regarding neonates and TOF. First, should symptomatic neonates and infants below a certain age or size be palliated before complete repair or should all TOF patients have a primary repair regardless of size or age? The second controversy relates to acyanotic neonates and young infants and whether they should be repaired at diagnosis. Proponents of early primary repair offer the following rationales: early repair avoids a longer period of cyanosis that might distress neurologic development; early repair decreases right ventricular hypertrophy; pulmonary artery and pulmonary alveolar development may be adversely affected; any palliative procedure by definition means the patient and family are subjected to multiple procedures [53]. There is evidence demonstrating that early operations, including those in very small neonates can be performed with low mortality [54–61]. However, others have reported increased morbidity with increased requirement for inotropes and prolonged mechanical ventilation after very early repair [62,63]. The reported rate of early reinterventions and reoperations in infants who undergo primary repair under 1 month of age is high [64]. More concerning to advocates of selective staged management of neonates and infants with TOF is the elevated use of a transventricular approach to closure of the VSD and increased use of transannular patch or pulmonary homografts. Reports of repair for patients less than 3 months of age have transannular patch rates at least 50% [63,65], but the use of either a transannular patch or homograft in true neonates (less than 1 month old), range from 84–100% [56,57,61,64]. Also in neonates, the vast majority of VSD repairs are via a transventricular approach. Advocates of selective staged management feel that preserving pulmonary valve function and avoiding transventricular approach to VSD closure outweighs the concerns of delaying primary repair or a staged operation. Within the era of neonatal surgery, the transatrial-transpulmonary approach with selective shunting of symptomatic neonates continues to be advocated with excellent results [66–68]. Evidence shows decreased ventricular arrhythmias and improved right ventricular function with the transatrial-transpulmonary approach

when compared with the transventricular approach [69]. Authors have reported the use of pulmonary valve-sparing techniques in 80% of patients [68]. There are reports of long-term tolerance of significant pulmonary valve regurgitation related to use of the transannular patch based on clinical symptoms [70] and overall mortality [71]. However, the deleterious long-term effects of pulmonary insufficiency (PI) including increased incidence of arrhythmia, decreased right ventricular function, and risk of sudden death have been well documented and are discussed in detail later in this chapter [72–75].

The necessity of a palliative procedure is questioned by advocates of early neonatal repair. There is evidence that the use of selective shunting may positively affect ability to preserve the pulmonary valve. In the authors' series [68], only 40% of previously shunted patients required transannular patch, which compares favorably with the reported rates near 100% if they were repaired primarily. Although we did not demonstrate that the pulmonary annulus grew after placement of the shunt, there is evidence for such growth. In a report from Paris involving 56 TOF patients younger than 6 months of age, eight patients had palliative shunts and went on to complete repair. The Z-score of the pulmonary annulus in these eight patients had increased by a mean of 2.2 and only one of eight infants repaired after shunt required a transannular patch [76]. There was no shunt-related mortality in this series, which reflects the experience of recent series [66,68].

Palliative Procedures

The most common palliative procedure is the modified Blalock-Taussig shunt (MBTS), which has supplanted the classic Blalock-Taussig shunt [77]. While some surgeons still prefer to perform the MBTS via thoracotomy, we use median sternotomy for the following reasons. Median sternotomy allows for the use of cardiopulmonary bypass in cases of hemodynamic collapse or severe hypoxia, allows for examination of the coronary anatomy, and leaves the patient with a single incision after eventual complete repair. The relative comfort of performing a resternotomy that has developed from numerous staged procedures for single-ventricle repair has minimized the rationale of avoiding the sternotomy for MBTS. The majority of procedures are performed without cardiopulmonary bypass. A 3.5- or 4-mm Gore-Tex shunt is anastomosed end to side to the innominate artery and to the ipsilateral branch pulmonary artery. Typically the shunt is placed on the side opposite that of the aortic arch; thus a patient with a left aortic arch receives a right-sided MBTS. Ligation of ductus arteriosus confirms the adequacy of the shunt and may decrease the chances of occurrence of branch pulmonary artery coarctation that can accompany natural constriction of the duct.

A transannular patch without repair of the VSD in small infants with very small pulmonary arteries has been reported with success, but is generally reserved for extreme situations [78,79]. Right ventricular outflow tract and pulmonary valve percutaneous balloon plasty and stenting have also been reported. This has been shown to be helpful in very small infants, and proponents have demonstrated growth of the branch pulmonary arteries [80,81]. However, these reports of pulmonary valve stenting show that effective relief of stenosis is achieved at the cost of irreversible damage to the pulmonary valve [82].

Complete Repair

Anesthetic induction of the patient with TOF is of particular concern as many anesthetic agents cause systemic vasodilation, which can greatly exacerbate any right-to-left shunting, possibly leading to profound hypoxia and potential hemodynamic collapse. The important basic principles include maintaining adequate volume status with a hemoglobin level of at least 10 mg/dL, use of a high inspired oxygen level, and avoidance of inhalational agents as they have a significant vasodilatory affect. Induction of anesthesia with intravenous agents including narcotics [83] and ketamine [84] can minimize unwanted vasodilation. It is also imperative to use extreme care to avoid introducing any air bubbles through the venous lines as the right-to-left shunt may allow these bubbles to reach the systemic circulation, where they can cause myocardial ischemia or stroke [85]. Transesophageal echocardiography should be performed in every patient (if the size of the patient permits) and should be interpreted preoperatively and postoperatively by a pediatric cardiologist.

A median sternotomy is performed and the size of the thymus should be noted before subtotal excision because of the association between TOF and DiGeorge syndrome. If a prior shunt was performed it is carefully isolated following systemic heparinization and aortic and bicaval cannulation. Cardiopulmonary bypass is initiated with moderate hypothermia (28 °C). If a shunt is present, it is ligated proximally and distally and divided to avoid any future tenting of the branch pulmonary artery. If the pulmonary artery is narrowed at the site of the shunt, the shunt is excised from the pulmonary artery and a patch augmentation using fresh autologous pericardium is performed. A left ventricular vent is inserted via the right superior pulmonary vein. The aorta is cross-clamped and cold-blood cardioplegia is delivered in an antegrade fashion through a cardioplegia cannula inserted into the aortic root. The cardioplegia should be readministered every 15–20 minutes or at any sign of cardiac activity. Topical slush saline is placed on the heart in conjunction with the cardioplegia. The cavae are snared, and a generous medial right atriotomy is made (Figure 22.6) [2]. The

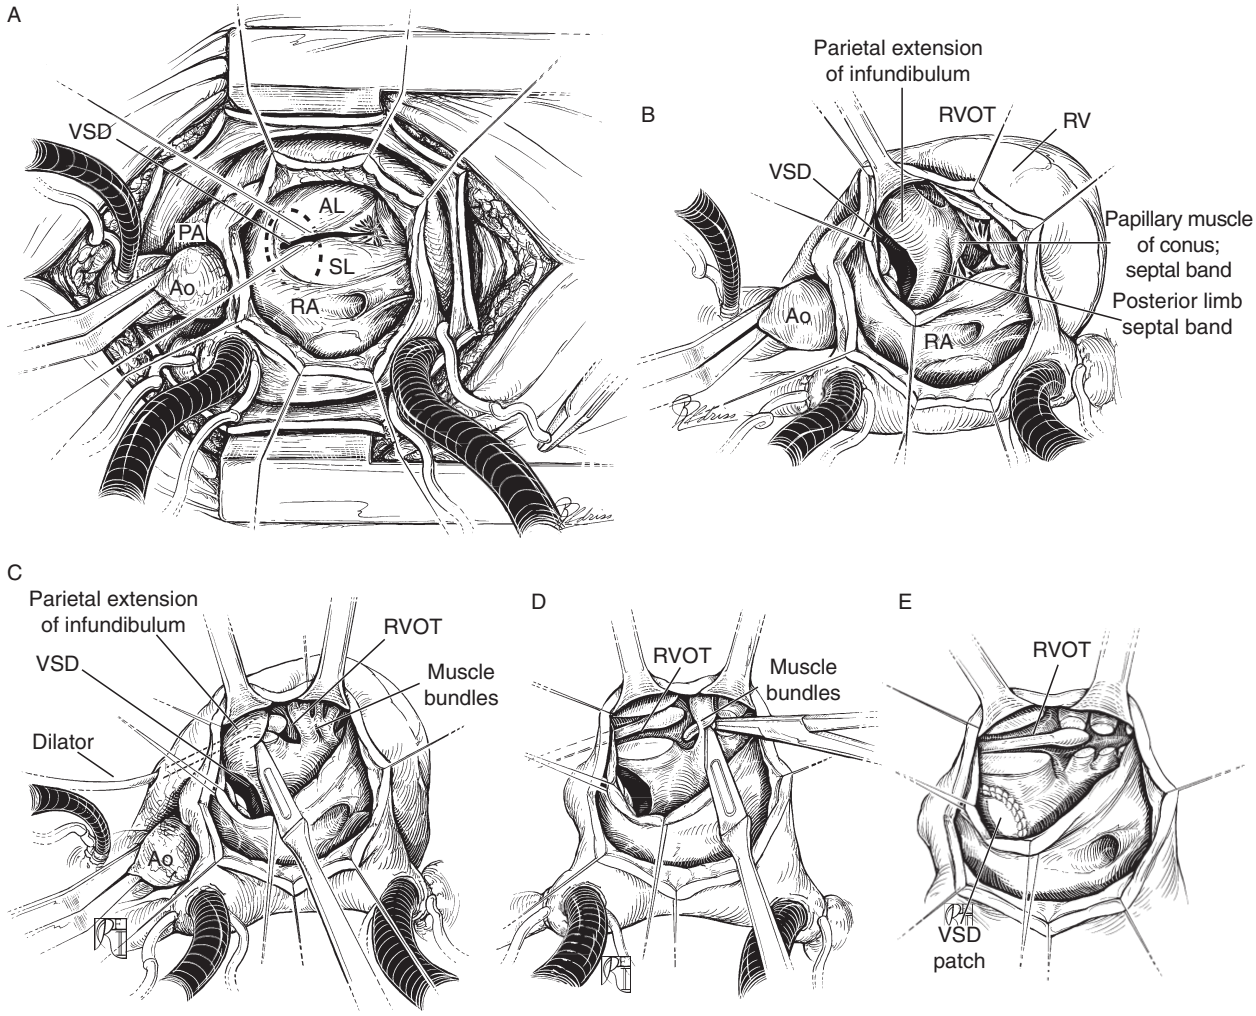

Figure 22.6 The surgical anatomy as viewed through a right atriotomy. The free edge of the atrial wall is retracted with stay sutures. The location of the VSD is denoted by the dashed line. **A,** Stay sutures are placed in the septal and anterior leaflets of the tricuspid valve for retraction. **B,** The tricuspid valve leaflets have been retracted and a single valve retractor is in place to aid exposure. The inferior margin of the VSD can be seen superior to posterior limb of the septal band. **C,** A dilator placed through the pulmonary annulus delineates the course of the right ventricular outflow tract. The parietal extension of the infundibulum is visible at the tip of the dilator. The parietal extension can be resected at its origin from the infundibular septum, dissected up toward the free wall, and amputated at the free wall. **D,** Division of the obstructing muscle bundles along the anterior limb of the septal band. **E,** View through the right atriotomy and tricuspid valve following patch closure of the VSD. (AL, atrial leaflet; Ao, aorta; PA, pulmonary artery; RV, right ventricle; RVOT, right ventricular outflow tract; SL, septal leaflet; VSD, ventricular septal defect.)

RVOT is examined. Resection involves careful excision of any endocardial fibroelastic tissue, which represents areas of turbulent flow. The hypertrophic muscle bundles projecting from the septomarginal and septoparietal bands can be divided or partially excised. Smaller trabecular muscles that are causing obstruction can be completely excised. Care must be taken to avoid excessive resection in the septal portion of the RVOT, which can damage the septal perforating coronary arteries, as well as in the area of the free wall of the right ventricle, which can result in a coronary fistula from the conal branches. The subvalvar apparatus of the tricuspid valve must be carefully noted and preserved during resection. While most of the RVOT resection can be performed through the right atrium and tricuspid valve, additional resection can be performed through the pulmonary valve, if necessary. In the presence of severe tunnel stenosis of the RVOT, a small infundibular incision, approximately 10–12 mm in length, placed immediately below the pulmonary valve annulus, may be required to establish adequate relief of obstruction. This infundibular

incision is closed with a thin-walled (0.4 mm) Gore-Tex patch.

A longitudinal pulmonary arteriotomy is made and carried into the two anterior sinuses in the case of a trileaflet valve or into the lateral sinuses of a vertically oriented bicuspid valve. For a horizontally oriented bicuspid valve, the incision is not bifurcated but rather carried straight up to the annulus, or more accurately, to the right ventricle-pulmonary artery junction. A pulmonary valvotomy is performed using a number 11 blade, dividing the typically partially fused commissures back to the level of the arterial wall, allowing for maximal opening through the preserved annulus. A probe is inserted and if the size is larger than –3 Z score, the annulus is left intact. The pulmonary arteriotomy is then closed with a pantaloon pericardial patch, which maximizes the size of the pulmonary root completely relieving supravalvar obstruction (Figure 22.7) [68]. Inspection of the orifice of the branch pulmonary arteries, especially the left pulmonary artery, should be done as this is frequently stenotic in TOF patients and can be corrected with an extension of the pericardial patch onto the branch PA or a separate patch if necessary.

The VSD is closed by placing a series of interrupted horizontal mattress sutures using 5-0 Ethibond with Teflon pledgets around the circumference of the defect. Superiorly these sutures should be placed close to the aortic annulus to avoid residual defects through the trabeculations. Between the muscle of Lancisi and the tricuspid valve annulus inferiorly, avoiding deep suture bites is critical to avoid damage to the AV node and bundle of His. Several of the sutures are usually placed from the right atrial side of the tricuspid annulus bridging the superiorly and inferiorly placed sutures. A Gore-Tex patch is cut generously to slightly oversize the defect as this avoids potential subaortic narrowing resulting from the anterior malalignment of the VSD. The tricuspid valve is tested and a PFO, which is almost always present, is closed primarily with 5-0 Prolene suture. The PFO is often left open when the repair is performed in the neonatal period. The right atrial incision is closed using two layers of running Prolene suture. The heart is carefully de-aired and the cross-clamp is removed.

After separation from cardiopulmonary bypass, direct measurements of the right ventricle and left ventricle pressures are made using a 21-gauge spinal needle attached to a pressure transducing line. If the right ventricle/left ventricle (RV/LV) pressure ratio is greater than 0.7 [64,68], the transesophageal echocardiography is carefully assessed for level of residual obstruction. If it is predominately at the annulus, then bypass is recommenced and a transannular patch is created. If the stenosis is subvalvar, then only an infundibular patch is inserted starting immediately below the annulus and extending approximately 10–12 mm. Owing to the relatively high incidence of junctional ectopic tachycardia (JET) following TOF repair, regardless of the rhythm after separation from bypass, temporary atrial and ventricular pacing wires are placed.

Results

Mortality

The mortality rate for complete repair of TOF has decreased sharply since the 40% mortality rate initially reported by Dr Lillehei [32]. Between 1955 and 1960, the early mortality rate among 251 patients operated on for TOF at the Mayo

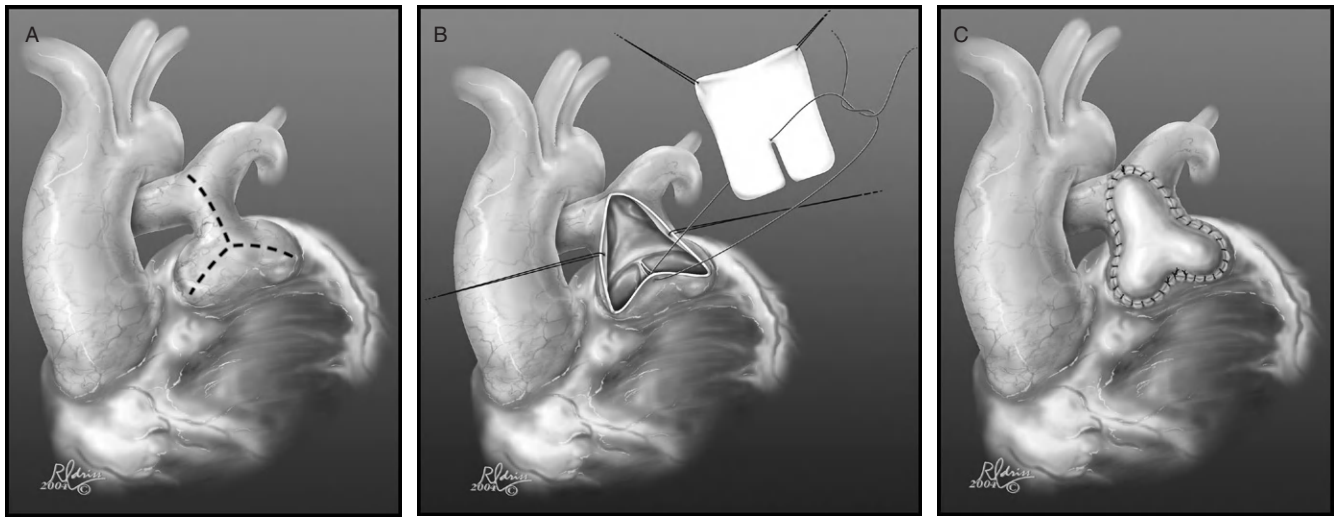

Figure 22.7 A, Pulmonary arteriotomy. **B,** Autologous pantaloon pericardial patch. **C,** Completed pulmonary artery pantaloon patch. (Reproduced with permission from Stewart *et al.* [68].)

clinic was 20% [86]. The mortality rate further decreased to 4.9% among 309 patients operated on at Stanford from 1960 to 1982 [87]. However, the average age at repair of TOF in that era was older. The mean age among 658 patients who underwent repair of TOF between 1958 and 1977 in one large series was 12.2 years [88]. There was a higher mortality initially with the advent of infant and neonatal surgery first championed by Paul Ebert [89,90], Brian Barrett-Boyes [91], and Aldo Castenada [92]. One of the first series of TOF repairs in infants and young children at Boston Children's Hospital between 1972 and 1977 was noteworthy for the excellent long-term results, but also for the 14% early mortality [70]. However, advances made over the last three decades in surgical technique, anesthetic management, and perioperative care have drastically reduced the mortality of infant and neonatal repair of TOF. Roger Mee and colleagues reported a 0.5% hospital mortality among 366 patients with TOF between 1980 and 1991 using a transatrial, transpulmonary approach [67]. There were no mortalities in our series of 102 cases (average age: 5.9 months) at Children's Memorial Hospital in Chicago between 1997 and 2004 [68]. Most recent reports of infant and neonatal TOF have equally low rates of mortality ranging from 0 to 3% [54,57,58,60–63].

The long-term survival rate of patients with TOF is excellent, even for patients who were operated on in the earliest era. The 32-year actuarial survival among 163 patients who had survived 30 days after complete repair of TOF at the Mayo Clinic before 1960 was 86%, with an expected rate of 96% in a control population matched for age and sex [86]. Similarly, a 1997 report on a group of 658 patients with repaired TOF found an 89% 30-year actuarial survival [93].

Morbidity

The most significant complications following repair of TOF are arrhythmias, early reoperation or catheter reintervention, residual VSD, and heart block. Heart block requiring a pacemaker is reported between 0 and 2% and occurs occasionally late after the operation [94]. It is noted that early postoperative transient heart block is a risk factor for the development of late heart block [95]. Other complications include phrenic nerve injury, chylothorax, and delayed sternal closure.

Early Reoperation and Reinterventions

The right ventricle can tolerate the volume load of PI for a number of years, thus reoperation for PI, while being very significant late after repair, is a rare early event. The most common indication for early reoperation after repair of TOF is residual RVOT obstruction. Residual stenosis can be at the infundibular level, valvar level, or in the branch pulmonary arteries. When present in the branch PAs, these are often amenable to catheter-based balloon plasty and/or stent placement. The incidence of reoperation varies greatly with the patient population. The collective experience with electively repaired patients shows that the reoperation rate is relatively low. Mee and colleagues in Australia reported in 1991 a 5- and 10-year freedom from reoperation of 95% [67]. The group from Texas Children's Hospital reported a 3% early reoperative rate [66]. In a series of 90 patients who underwent primary repair of TOF at less than 4 months of age, the reoperation rate was 8%, and 14% required catheter reintervention at a mean follow-up of 4.7 years [61]. Conversely, in a series of primary repair on symptomatic neonates, the reoperative rate has been reported as high as 30% [64]. However, a comparison study of reoperative rates on the RVOT at 20 years for primary repairs versus staged repairs found that the freedom from reoperation is not statistically different [96].

The amount of residual obstruction at the conclusion of initial repair, as assessed by the RV/LV pressure ratio, is directly related to the incidence of reoperation. A study from the University of Alabama, Birmingham in 1982 demonstrated that an RV/LV pressure ratio greater than 0.85 was associated with a 2.5 times increased risk of death and a 7.3 times increased risk of reoperation [97]. But they also showed a decrease in the RV/LV pressure ratio with time, with the greatest reduction seen in those patients with the highest immediate postoperative ratios. In our series, four of seven reoperations were in patients who had an RV/LV pressure ratio between 0.7 and 0.8 [68]. In contrast, a group from Spain reported accepting a RV/LV pressure ratio up to 0.9 in order to preserve more pulmonary valves. Only one of 24 patients required reoperation at one year for annular stenosis, and the group with RV/LV ratios between 0.7 and 0.9 showed a greater reduction in pressure ratio compared with those with RV/LV <0.7 at 32 months follow-up [98].

Other indications for early reoperation include residual VSD, residual ASD, RVOT aneurysm, severe tricuspid regurgitation, heart block, phrenic nerve injury, and chylothorax. Interestingly, while most series report few reoperations for residual VSD, a large series from Germany found that among the 102 reoperations at 12.8 years after repair in 914 patients, half of the reoperations were for residual VSD [99].

Arrhythmias and Sudden Death

Arrhythmias and conduction disturbances are significant both for their prevalence and serious consequences. In fact, the most common cause of mortality late after TOF repair is sudden death, presumably attributable to ventricular arrhythmias [72]. In the early postoperative period, the

most common disturbance is right bundle branch block, which results from RVOT and/or sutures from the VSD repair. In cases where a ventriculotomy is performed, right bundle branch block is seen in up to 90% of patients [100]. In contradistinction, complete heart block is a relatively uncommon complication of TOF repair, with reported incidence being 1–3% [57,59,61,62]. The most common early arrhythmia following repair is JET. The incidence of JET varies greatly based on age at surgery and surgical approach. In a series of patients under 3 months of age undergoing a transventricular repair, 29% had postoperative arrhythmias of which 48% were JET and 17% had some form of supraventricular tachycardia (SVT) [59]. Conversely, in our series of 102 patients repaired at a mean age of 6 months by a transatrial/transpulmonary approach, the incidence of JET was 12% [68]. In another group of patients repaired at a mean age of 1 year by the same approach, the incidence of JET was only 6% [66]. Junctional ectopic tachycardia can result in major hemodynamic instability in the immediate postoperative period. Treatment includes correction of electrolytes, mild hypothermia (33–35 °C), reduction or elimination of catecholaminergic infusions, sedation, and treatment with amiodarone. While 5 mg/kg as a single bolus is recommended by some, we favor multiple boluses of only 1 mg/kg over 20–30 minutes to avoid the negative inotropic effect of amiodarone.

Late arrhythmias after TOF repair include both atrial and ventricular tachycardias (VT). The Alliance for Adult Research in Congenital Cardiology conducted a multi-institutional retrospective study of 556 previously repaired TOF patients and found 43% had a history of arrhythmias [101]. Atrial tachyarrhythmias were present in 20% and ventricular tachyarrhythmias in 15%. This may be an overestimation of the incidence of arrhythmias in a selected population. Sustained SVT was documented in 12% of a cohort of 242 adult patients late after repair [102]. In a multi-institutional study of 793 patients studied at a mean of 21 years after repair, Gatzoulis and colleagues found an incidence of atrial and ventricular tachyarrhythmias of approximately 4% [72]. However, they also found an alarming incidence of sudden death: 2%. Conversely, the incidence of paroxysmal atrial tachyarrhythmias has been found to be as high as one-third of patients [103]. By far the most common type of SVT seen in TOF patients is atrial re-entry tachycardia. The most common site of slow conduction is in the area of the isthmus between the tricuspid valve and the inferior vena cava [104]. Re-entrant circuits also develop in scar areas around atrial incisions. See Chapter 41, *Surgical Therapy of Cardiac Arrhythmias* for a detailed explanation of the mechanisms of re-entry tachycardia. The prevalence of SVT has been shown to be related to older age at surgery, the presence of moderate or severe tricuspid regurgitation, right atrial enlargement, PI, poor right ventricular function, and hypertension [101–105]. While not as life threatening as VTs, supraventricular arrhythmias are perhaps responsible for more morbidity including decreased exercise capacity, heart failure, and stroke. Treatment for atrial arrhythmias includes pharmacologic agents, transcatheter ablation, and surgical ablation. Because of the success with the maze operation in controlling atrial re-entry arrhythmias in patients with congenital heart disease [106,107], we feel that all patients who require reoperation, particularly for pulmonic valve insertion or replacement, should be evaluated for presence of arrhythmias with a 24-hour Holter monitor. If there is any index of suspicion including any history of palpitations, patients should be evaluated by a formal electrophysiologic study to elicit and characterize re-entry pathways in the right or left atrium that can be obliterated with incision, cryotherapy, or radiofrequency ablation at the time of surgery.

The risk factors that have been associated with ventricular arrhythmias include older age at repair, ventriculotomy, transannular patch, severe pulmonary regurgitation, poor right ventricle function, poor left ventricle function, right ventricle enlargement, and elongated QRS duration [72,102,108,109]. The risk of sudden death includes QRS duration greater than 180 msec, older age at repair, severe pulmonary regurgitation, history of sustained VT, and left ventricle systolic dysfunction [72,110].

Long-term Complications Following Repair of Tetralogy of Fallot

The major late complications of repaired TOF result from the deranged physiology of the right ventricle. The long-term effect of volume overload from PI, and tricuspid regurgitation as well as any residual shunts is additive to any pressure load resulting from residual pulmonary stenosis. The sequelae include right ventricular dysfunction, atrial and ventricular arrhythmias, sudden death, late left ventricular dysfunction, and aneurysmal dilation of the aorta. The majority who suffer these complications have been shown to have long-standing PI as the primary etiology. This is directly related to the use of the transannular patch. There have been several studies demonstrating good long-term functional outcomes after repair of TOF with a transannular patch [70,71]. Bacha and colleagues reported long-term outcomes of 45 patients operated on for TOF as infants at Boston Children's Hospital and showed that the functional status as measured by New York Heart Association class was similar for transannular patch and valve-sparing procedures [70]. Kirklin's group at the University of Alabama, Birmingham examined 814 patients and found that the risk of reoperation for PI at 20 years was 7%; they ascribed this low rate of reoperation, despite a significant incidence of PR, to the adaptive properties of

the right ventricle [71]. They also found no difference in New York Heart Association class between transannular patch and valve-sparing approaches. These findings are contradicted by other studies showing the deleterious effects of PI on the right ventricle when more sensitive measurements are made [41,73]. Exercise testing has shown that functional status is impaired in TOF patients with long-term PI [73,111]. Cardiac magnetic resonance cine examination of TOF patients late after repair have demonstrated that PI is closely associated with the transannular patch and that PI results in significant right ventricular dysfunction, even in asymptomatic patients [41,112]. The group at Great Ormond Street has used tissue Doppler assessments of isovolumetric myocardial acceleration to more accurately assess right ventricular function in the face of highly variable loading conditions that exist with PI [113]. They found in a group of 124 patients in which the use of transannular patch highly correlated with PI and PI was associated with both right ventricular and left ventricular dysfunction [113]. The late effect of transannular patch and PI on both right ventricle and patient functional status are further documented by the growing number of reports on the ventricular improvement and symptomatic relief achieved with pulmonary valve insertion late after TOF repair [114–116].

Pulmonary Valve Replacement

Despite reports of functional improvement after pulmonary valve replacement (PVR) in patients with severe PI late after TOF repair, the timing and effect of PVR remains controversial. While no data show overall improvement in survival, in a study of matched cohorts of 82 patients with and without PVR, there were no sudden deaths in the PVR group [117]. The effect of PVR on VT, the substrate for sudden death, is also unclear. One study showed a decrease in the incidence of VT from 23% to 9% after PVR [118] while a matching cohort study of 98 patients showed that PVR did not decrease the incidence of VT or death [119]. The effect of PVR on the duration of the QRS is variable. Therrien reported that PVR stabilized the duration of the QRS while not decreasing it [118]. Others have shown that the QRS decreases early after PVR, and the decrease correlates with the decrease in right ventricular end-diastolic volume (RVEDV) as measured by CMR [120]. Still another report showed only a transient decrease in QRS with an eventual increase in duration to >180 msec. This late increase in QRS duration was more likely for those with a QRS >180 msec before PVR [121]. Pulmonary valve replacement has been shown to improve right ventricular function and to decrease the size of the right ventricle [120,122], but this improvement appears to be limited when the right ventricle has reached a critical size. In an analysis of patients after PVR, there was an improvement in RVEDV and right ventricle end-systolic volume (RVESV); however, no patient with RVEDV >170 mL/m^2 or a RVESD >85 mL/m^2 achieved a normal RVEDV or RVESV while 90% of those with RVEDV <170 mL/m^2 before PVR had normal post-PVR in right ventricular volumes [43].

Because of the myriad of findings after PVR, there are no universally accepted indications. However, most consider that PVR is an important intervention late after TOF repair but that if executed too late, may fail to achieve optimal benefit. Geva and colleagues have recommended general criteria for PVR in patients with moderate to severe PI [123]. The presence of any two of the following represents an indication for PVR: RVEDD index >160 mL/m^2; RVESD index >70 mL/m^2; LVEDV index >65 mL/m^2; RVEF <45%; RVOT aneurysm; clinical symptoms or signs including syncope and VT [123]. These indications will certainly evolve as more data are analyzed.

The technical aspects of PVR include homograft replacement, valved conduit replacement, and bioprosthetic valve insertion in the orthotopic location with the creation of RVOT hood using Gore-Tex or heterograft pericardium [124–126]. All of these techniques have been successful without clear advantage of any particular technique. Others have used stentless porcine valves for RVOT reconstruction with success [127], and there are reports of mechanical valves being used for PVR, though most avoid these valves because of the risk of thrombosis and indication for anticoagulation [128]. An alternative method for PVR involves the percutaneous insertion of a bovine jugular valve sewn to an expandable stent [129]. This technique, introduced by Bonhoeffer, has the clear advantage of avoiding a redo sternotomy. At the present time the approved indications limit its use to circumstances of failure (obstruction or regurgitation) of a previously implanted conduit (with some constraints related to minimum and maximum size of the RVOT conduit). The risk of coronary artery compression is also present with percutaneous PVR. The use of percutaneous PVR will certainly become more prevalent as the engineering of the devices improves. The indications for percutaneous PVR should be the same as for surgical PVR.

Neurological Outcomes

Evaluations of children with repaired TOF have demonstrated inferior full-scale IQ than the general age-matched population [130]. However, when repaired TOF children were stratified by presence of a genetic lesion or syndrome, those without any identified defects had scores within the normal limits for age [131]. It has also been recognized that the incidence of stroke is higher in adults with repaired TOF than the general population, though no clear etiology for this finding has been demonstrated [132].

Aortic Complications

Aortic valve and aortic root complications have become well recognized late after TOF repair. In a study of 59 patients, Zahka and colleagues evaluated PI at a mean of 18 years after repair and noted that 21% of patients had important aortic regurgitation [133]. This finding has been reported by others late after repair [134], but has been shown to begin in childhood and to be associated with a high level of elastic fiber fragmentation seen in the aorta of children with TOF [135]. Another study of the autopsy specimens from patients with TOF found that the aorta had elastic fragmentation in 59%, medionecrosis in 29%, cystic medial necrosis in 35%, and fibrosis in 82% [136]. These aorta histologic derangements can lead to the development of aortic aneurysms [137] and aortic dissection [138] late after TOF repair. These aneurysms require surgical intervention with the same criteria as aneurysms in nontetralogy patients [139].

Special Circumstances

Tetralogy of Fallot with Absent Pulmonary Valve

Approximately 2.5% of cases of TOF have a unique variant of the morphologic features, characterized by near absence of the pulmonary valve leaflets [140]. Rather than the semilunar cusps of a more typical pulmonary valve, these valves have very rudimentary leaflets, completely lacking three-dimensional cusp-like anatomy. In addition to having limited mobility, these cusps are centrally deficient so that there is a large coaptation gap. The combination of annular hypoplasia, leaflet immobility, and the central deficiency of valvar tissue create the anatomic substrate for combined pulmonary stenosis and insufficiency. The infundibulum tends to be somewhat elongated and tubular, and muscular right ventricular outflow obstruction is not commonly a major element. In some cases the main pulmonary trunk and central right and left branch pulmonary arteries are markedly dilated (Figure 22.8) [2]. The aneurysmal features of the central pulmonary arteries may extend into the pulmonary hilum, in which case only segmental branches can be identified emanating from the bulbous central aneurysm. An important feature of these cases is compression of the tracheal-bronchial tree by the enlarged central pulmonary arteries. In the most extreme instances, severe respiratory distress is present from birth. The name "tetralogy of Fallot with absent pulmonary valve syndrome" has been applied, in recognition of the unique presentation and pathophysiology. Anatomically, there is complete absence of a patent ductus or ductal ligament in the vast majority of cases, and this has been invoked as a consequential stimulus accounting for the in utero development of the aneurysmal pathology of the central pulmonary arteries. These infants are frequently ventilator-dependent at birth and require early intervention. Those with less severe symptoms might allow for elective repair in the first 6 months of life. The classic repair involves a homograft valve replacement, closure of the VSD, and pulmonary arterioplasty to reduce their size and relieve bronchial compression. Alternatives to this repair now include a transannular patch without a homograft valve. The rationale for such an approach relates to a significantly longer interval before a required reoperation as any infant will outgrow a homograft within the first few years of life [141]. In cases where the bronchial compression cannot be ameliorated by a pulmonary reduction arterioplasty, the addition of the Lecompte maneuver to the repair has been reported. By transferring the dilated branch pulmonary arteries anterior

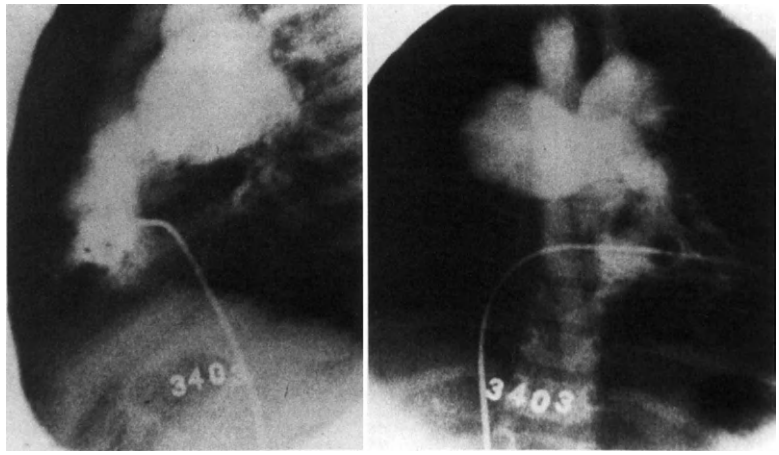

Figure 22.8 Angiogram in a patient with tetralogy of Fallot and absent pulmonary valve. There is marked aneurysmal dilatation of the main, right, and left pulmonary arteries and absent pulmonary valve.

to the aorta and thus away from the bronchi, the Lecompte maneuver has been shown to provide substantial relief from bronchial compression [142]. Others have replaced the entire proximal pulmonary artery, including the dilated branches, with a pulmonary homograft that includes the branch pulmonary arteries [143].

Mortality from repair of TOF with absent pulmonary valve is approximately 5% [144,145] and more often than not occurs in the most critically ill infants with substantial pulmonary disease related to bronchial compression and persistent bronchial malacia.

Tetralogy of Fallot and Atrioventricular Septal Defect

After ASD and PDA, the condition most commonly associated with TOF is complete AVSD. The combination of TOF and AVSD (TOF-AVSD) occurs in approximately 3% of all TOF cases. While less than 10% of patients with TOF have trisomy 21, the majority of TOF-AVSD patients have trisomy 21, similar to isolated AVSD [146]. Unlike isolated AVSD, the incidence of early pulmonary hypertension is limited by the protective effects of RVOT obstruction. The associated AVSD is usually Rastelli type C, with an absence of cordal attachments from the anterior bridging leaflet to the crest of the ventricular septum. Repair is usually undertaken between 4 and 6 months of age. Using a transatrial approach, a two-patch technique is most commonly used with a modified VSD patch in the shape of a comma [147]. This patch combines the geometry of the crescentic VSD patch of an isolated AVSD, which extends under the posterior bridging leaflet, with that of the large round patch of a typical TOF anterior malalignment VSD extending under the anterior bridging leaflet. The RVOT obstruction is treated as in isolated TOF. Historically, TOF-AVSD has a higher morbidity and a mortality of up to 10%, but more recent series have shown a substantial reduction in both, including a recent report with no mortality in 20 patients [148].

Conclusion

Tetralogy of Fallot is the most common cyanotic congenital heart lesion. Surgical repair has a high rate of success, and long-term survival with excellent functional outcome has been well demonstrated. While there is general consensus that repair in infancy is superior, controversy persists regarding neonatal repair versus staged repair. Late complications include right ventricular dysfunction, atrial and ventricular arrhythmias, and sudden death. The effectiveness of late pulmonary valve repair in ameliorating these complications is being actively studied, and intervention criteria are evolving.
