CHAPTER 23

Surgical Treatment of Pulmonary Atresia with Ventricular Septal Defect

Vadiyala Mohan Reddy and Frank L. Hanley

Lucile Packard Children's Hospital, Stanford University, Stanford, CA, USA

Introduction

Pulmonary atresia with ventricular septal defect (PA-VSD) is perhaps best characterized as being at the extreme end of tetralogy of Fallot and differs from regular tetralogy of Fallot in having obligatory extracardiac sources of pulmonary blood flow. Within PA-VSD is a spectrum of lesions distinguished by a dramatic heterogeneity of pulmonary blood supply [1–3], which makes it difficult to characterize the exact incidence of each of these subsets.

Somewhere between 35% and 70% of patients with PA-VSD have a "duct-dependent" pulmonary circulation in which blood supply to the lungs is entirely through true pulmonary arteries supplied via the ductus arteriosus. The remaining 30–65% of patients, who constitute perhaps the most challenging subset of patients with this anomaly, derive pulmonary blood flow entirely or in large part from major aortopulmonary collateral arteries (MAPCAs) [4,5]. These collaterals, which are thought to arise from the embryonic splanchnic plexus, can originate from the aorta, the subclavian or carotid arteries, the coronaries, or the bronchial arteries. Each collateral may supply as little as one lung segment or as much as an entire lung and may be characterized by extrapulmonary and intraparenchymal stenoses. In such patients, true pulmonary arteries are typically either hypoplastic or absent altogether [1–3,6,7].

Although variations in pulmonary blood supply constitute a spectrum, it is practical to consider pulmonary blood flow in patients with pulmonary atresia as either "duct-dependent" or "MAPCA-dependent" because the timing and technique of surgical management differ across this division. Several reports have looked at patients with tetralogy of Fallot, pulmonary atresia, and hypoplastic confluent pulmonary arteries as a separate category of patients [8]. However, these patients almost always have collaterals contributing to pulmonary blood flow by feeding the true pulmonary arteries.

Another important morphologic feature that differs among patients with pulmonary atresia is the form of atresia: the pulmonary arteries may be separated from the right ventricle by a long-segment atresia or, occasionally, by an imperforate membrane. The primary surgical relevance of this difference relates to the method of right ventricular outflow tract reconstruction. Whereas membranous atresia may be repaired with an outflow tract patch and valvotomy or resection of the atretic valve, long-segment atresia generally requires creation or implantation of a conduit.

The cardiac morphology in these patients is almost always similar to tetralogy of Fallot with a single conoventricular type of ventricular septal defect and anterior malaligned conal septum with aortic override. The presence of an atrial-septal communication, coronary anomalies, and left superior vena cava is similar to tetralogy of Fallot. The incidence of right aortic arch and retroaortic innominate vein seems to be higher in our experience. In a small percentage of patients there may be communication between the pulmonary arteries and the coronary arteries, which provide a source of pulmonary blood flow.

Clinical Features

Pulmonary atresia with ventricular septal defect accounts for approximately 1–2% of children born with congenital heart defects. A prevalence of 0.07 per 1000 live births was reported in one study [9] where 1.4% of all children born with congenital heart disease and 20.3% of all children born

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

with tetralogy of Fallot had PA-VSD. The risk of PA-VSD is higher in siblings (2.5–3%) and in children of adults with tetralogy of Fallot (1.2–8.3%).

The incidence of extracardiac anomalies is significant, and the common associations are 22q deletion syndromes, DiGeorge syndrome, VATER (vertebrae, anus, trachea, esophagus, and renal) syndrome, and Alagille syndrome. There is also a relatively high incidence of bronchus suis (right upper-lobe bronchus originating from the trachea). Often the tracheobronchial compression may result from a large aorta, especially with a right aortic arch and right descending aorta. Commonly associated cardiac anomalies include atrial septal defects (ASDs), multiple ventricular septal defects, coronary artery abnormalities, left superior vena cava, and retroaortic innominate vein. Clinical presentation is variable because of the unpredictable nature of the pulmonary blood supply.

A predictable patient population is the one in which there are duct-dependent, confluent, and normal pulmonary arteries. Patients become cyanotic as the duct starts to close and require resuscitation with prostaglandin (PGE) if they have not been diagnosed prenatally. In patients with MAPCAs, cyanosis is the most common clinical presentation, and many of these infants are asymptomatic until they become progressively more cyanotic. However, some infants may present with signs of pulmonary overcirculation and congestive heart failure (CHF). Cyanotic spells are uncommon but may occur probably owing to a drop in systemic vascular resistance resulting in decreased pulmonary blood flow. In late-presenting patients previously undiagnosed, clubbing and polycythemia may be present, and sometimes stroke or cerebral abscess may be presenting features.

Increasingly with widespread use of fetal echocardiography as a prenatal screening modality, more and more children born with congenital heart disease are diagnosed prenatally. Pulmonary atresia with ventricular septal defect is relatively easy to diagnose in the fetus, although it is difficult to identify the sources of pulmonary blood flow. Nevertheless, if the ductus arteriosus is not seen in a fetus with PA-VSD, then the likelihood of MAPCAs is high. All prenatally diagnosed neonates with this condition should undergo a thorough diagnostic evaluation postnatally.

Diagnostic Evaluation

In the current era, a chest X-ray and electrocardiogram are probably less useful as diagnostic tools and more useful in patient management. Echocardiography is useful for complete delineation of the intracardiac anatomy and identifying any associated anomalies, such as confluent pulmonary arteries, duct-dependent circulation, ASDs, multiple ventricular septal defects, left superior vena cava, retroaortic innominate, and coronary anomalies. Especially in neonates and infants, a thorough echocardiographic evaluation can identify patients who will need further investigation to identify the sources of pulmonary blood flow. However, older infants or children with PA-VSD will need additional studies to evaluate the pulmonary circulation.

It is essential to determine all sources of pulmonary blood flow in all patients before surgery. The pressure in each collateral needs to be measured, and the blood flow to all segments of the lung should be defined. Cardiac catheterization and angiography is currently our standard to evaluate these sources and the health of the pulmonary microvasculature. Often direct injection and catheter entry into each collateral is necessary. The true pulmonary arteries can be defined if the patient has a patent ductus arteriosus or if a collateral is communicating with them. Occasionally pulmonary venous wedge angiography may be necessary to define the true pulmonary arteries and/or the blood supply to some segments of the lung. If dual supply to a lobe or some segments is suspected it is important to determine the exact anatomy and the reliability of the connection between the true pulmonary arteries and the collaterals. In 10–30% of patients, true pulmonary arteries are completely absent.

Computed tomographic (CT) angiography and magnetic resonance imaging (MRI) are increasingly being used to define the collateral anatomy. Indeed, in our institution all neonates with PA-VSD undergo CT angiography to identify the sources of pulmonary blood flow and serve as a road map for cardiac catheterization before surgical intervention. With the current level of sophistication, these modalities have the advantage of being less invasive and providing a three-dimensional reconstruction of the pulmonary blood supply. This detail can be useful in planning the dissection and rerouting of the collaterals for unifocalization. However, they do not provide the hemodynamic data.

In patients who have undergone previous palliation or unifocalization but not intracardiac repair, cardiac catheterization is essential. In these patients, the pressures in the collaterals and the calculation of pulmonary-to-systemic blood flow ratio (Qp:Qs) together with the morphology is needed to determine if complete repair can be performed. If the Qp:Qs is greater than 2:1 then a complete repair can be safely performed. However, a lower Qp:Qs does not rule out complete repair if the collaterals are well developed or have grown well from previous palliation but have surgically treatable stenosis accounting for the low Qp:Qs ratio. During cardiac catheterization reactivity of the pulmonary vascular bed can also be tested with oxygen and inhaled nitric oxide.

Surgical Management

Pulmonary atresia with ventricular septal defect with duct-dependent circulation was initially managed by palliation with a systemic-pulmonary arterial shunt [10]. In 1954

Lillehei reported the use of a technique for repairing PA by anastomosing the pulmonary artery directly to an infundibulotomy [11]. Subsequently, repair using a nonvalved conduit was first reported in 1965, and repair using a valved allograft conduit was first reported in 1966 [12].

Because an enormous variety of lesions exists within the spectrum of PA-VSD, particularly with regard to pulmonary artery size, origin, course, and site of obstruction, a convenient scheme to divide PA-VSD patients into anatomic subtypes may be used for operative planning:

- **Group 1:** in this group, the patients all have large-sized duct-dependent pulmonary arteries that connect to all bronchopulmonary segments and arborize normally. It is rare to discover diminutive PAs in this group of patients.
- **Group 2:** this group of PA-VSD patients consists of infants with diminutive pulmonary arteries that supply some or all lung segments, while a variable number of MAPCAs feed the hypoplastic pulmonary arteries or are the sole supply to some segments.
- **Group 3:** in this group, all bronchopulmonary segments are supplied by MAPCAs. These patients have no true pulmonary arteries that course through the mediastinum. This group represents the most severe form of PA-VSD and has traditionally required multiple staged operations to unifocalize the MAPCAs into the pulmonary arterial system.

As with simple tetralogy of Fallot, for patients in group 1 (duct-dependent normal pulmonary arteries) the issue of palliation versus primary complete repair in the neonatal period remains purely an institution- and surgeon-dependent choice. Our bias is to repair and not perform systemic-to-pulmonary artery shunt with rare exceptions. Older age at repair was found by Kirklin *et al*. [13] to be the most important incremental risk factor for death after repair of tetralogy with PA in the constant hazard phase.

In contrast, the management of group 2 and 3 patients with PA-VSD and MAPCA-dependent pulmonary blood flow is much more controversial. MAPCAs are highly variable in terms of number, size, origin, course, arborization, and structure. They may constitute the sole source of pulmonary blood flow or may supply as little as a single lung segment. Until the mid-1970s medical management was considered the only option, with surgical treatment reserved for palliation, which generally consisted of one or more systemic-pulmonary arterial or systemic-collateral shunts, or with right ventricular outflow reconstruction and ligation of MAPCAs [14–17]. Based on the morphologic and physiologic studies of the variable pulmonary blood supply, Haworth and Macartney postulated that pulmonary blood supply in these patients might be normalized by unifocalizing the individual pulmonary arteries and MAPCAs to a single source [2,18].

Since then, a number of surgeons and institutions have developed strategies for the management of this lesion. Most of these have been based on the concept of staged unifocalization, with the initial phase(s) of management typically designed to increase flow to the true pulmonary arteries in an effort to stimulate growth [19–25]. These strategies have served to advance the field and have provided good results for a select group of patients. However, very few if any have cohorts of infants, and most leave a substantial proportion of patients without complete repair. As Bull and colleagues [26] observed in their article, "*Infancy is the period of greatest attrition for complex pulmonary atresia, without and with attempts at palliation ... any surgical focus aiming to make an impact on the overall mortality of this condition must alter the pattern of attrition in infancy*." Most reports do not address this most difficult group of patients. Taking into account natural attrition, which is highest in infancy [26], it is logical to conclude that only 20–30% of a cohort of newborns with tetralogy of Fallot and MAPCAs will achieve complete repair with acceptable right ventricular hemodynamics if a delayed, staged approach is taken.

The definitive goal of surgical therapy in PA-VSD with MAPCAs is to normalize circulatory physiology. Among patients surviving complete repair, the most important physiologic indicator of outcome is peak right ventricular pressure, with lower pressures being more favorable [13,27]. For a right ventricle pumping a single cardiac output, peak pressure is a direct function of pulmonary vascular input impedance, which is generally calculated as resistance. In addition to vascular resistance, which is inversely related to the total cross-sectional area of the distal pulmonary vascular bed, pulmonary arterial input impedance is also influenced by pulse-wave propagation characteristics and the presence or absence of arterial stenoses.

Given the importance of right ventricular pressure in predicting outcome, the most reliable means of ensuring that patients receive the optimal benefit from surgical therapy is to make every effort to minimize right ventricular afterload. This principle forms the basis for early complete unifocalization and repair in infancy. In patients with repaired tetralogy of Fallot and PA, the number of lung segments supplied by the pulmonary arterial system has been found to correlate strongly with pulmonary arterial pressure and calculated pulmonary vascular resistance [27]. Thus, in patients with multifocal pulmonary blood supply, it is critical to incorporate as many lung segments as possible into the unifocalized pulmonary vascular bed. In addition we have to ensure that resistance in a given pulmonary segment is as low as possible, which is largely a function of the health of the microvasculature. Presumably, the microvasculature of the lung in patients with MAPCAs is in its healthiest state at birth. The natural history of MAPCAs often follows a course of progressive stenosis and occlusion, sometimes precluding access to a given

segment of lung at the time of unifocalization. Even if a severely stenosed collateral can be incorporated into the unifocalization, chronic hypoperfusion may lead to distal hypoplasia of the pulmonary vasculature and underdevelopment of alveoli [3]. Also, iatrogenic occlusion can occur when MAPCAs are unifocalized in stages using nonviable conduits, sometimes resulting in loss of segments. On the other hand, unrestricted flow through large collaterals without protective stenoses can lead to pulmonary vascular obstructive disease, which also effectively raises resistance. As experimental studies have shown, pulmonary vascular function and structure are altered after as little as 4 weeks of postnatal pulmonary hypertension with high pulmonary blood flow [28]. Similarly, staged unifocalization utilizing systemic-pulmonary arterial shunts may result in pulmonary vascular obstructive disease without necessarily stimulating compensatory flow-related growth [29]. Injuries to the distal pulmonary vasculature owing to both hypoperfusion and perfusion at systemic pressures are progressive, time-related processes. Thus, one of the keys to optimizing the health of the pulmonary vasculature, and hence the entire right heart complex, is to normalize the pulmonary circulation as early in life as possible, removing the pulmonary vascular bed from exposure to the inevitable hemodynamic vagaries associated with MAPCAs.

It is also important to preserve the growth potential of the pulmonary vascular bed. One means of accomplishing this goal is by maximizing the use of native pulmonary arterial tissue in the reconstruction and avoiding prosthetic material, especially circumferential conduits. Moreover, if the aim is to repair patients at as young an age as possible, preferably early infancy, growth potential is an important concern. Non-native tissue lacks such growth potential and is also susceptible to acquired stenosis and/or calcification. Moreover, although the mechanics of the pulmonary vasculature and its coupling with the right ventricle are not yet understood in their full complexity, especially in the context of the heterogeneous arborization and structural anomalies characteristic of tetralogy of Fallot with MAPCAs, this may also be an important issue in evaluating the health of the pulmonary circulation [30,31]. When circumferential conduits are employed in the central and hilar reconstruction of the pulmonary vasculature, the mechanical efficiency of right ventricle-pulmonary arterial coupling is likely to be impaired. Large pericardial manifolds or synthetic conduits, regularly incorporated into the reconstruction in many approaches to staged unifocalization [20–23,32,33], may produce extensive compliance and diameter mismatches in the pulmonary vascular bed, which can decrease the efficiency of right ventricle-pulmonary arterial coupling and predispose to shear stress-related vascular changes at anastomotic junctions [30,34].

There are other factors to consider in defining therapeutic goals of management for tetralogy of Fallot with MAPCAs. As discussed in Chapter 22, *Tetralogy of Fallot*, there are several benefits to early normalization of the circulation other than those affecting the pulmonary vasculature per se, including avoidance of right ventricular hypertrophy and fibrosis, avoidance of cyanotic spells and minimization of the consequences of cyanosis and polycythemia, and optimal preservation of left ventricular and aortic valvar function.

In light of the poor natural history of tetralogy of Fallot with MAPCAs and the inadequacy of staged approaches for achieving successful complete repair in the majority of patients, a strategy for managing this lesion that is founded on the principle of early total repair with one-stage unifocalization of all lung segments and maintenance of native tissue continuity seems appealing [35]. The aim of this strategy is to provide complete repair with optimum results for as many patients as possible. Keeping in mind the therapeutic goals outlined above, a complete repair in early infancy may be the ideal approach. This allows for early normalization of cardiovascular physiology, with preservation of the pulmonary vascular bed, recruitment of all lung segments, alleviation of cyanosis, and prevention of other cardiac sequelae. By performing the repair in a single stage, the number of operations required can be minimized and a greater proportion of patients is likely to be treated successfully.

The decision whether to close the ventricular septal defect at the time of unifocalization is critical to successful repair. An incorrect decision may lead to substantial morbidity, if not death. With respect to this issue, one-stage unifocalization differs significantly from staged approaches, as catheterization and angiographic data are not available following unifocalization but before closure of the ventricular septal defect. In several reports of staged unifocalization, criteria for ventricular septal defect closure based largely on angiographic measurement of the reconstructed pulmonary arteries and measurement of pulmonary vascular resistance have been suggested [21,23,27]. In patients undergoing one-stage unifocalization, such methods are not applicable, and the decision must be made intraoperatively. Angiographic measurements of the collaterals and pulmonary arteries preoperatively can be performed to estimate a neopulmonary artery index, which is the sum of the indexed cross-sectional areas of all vessels unifocalized [36]. Although we have found this method to be helpful in defining a neopulmonary artery index above which all patients can undergo closure of the ventricular septal defect ($200\,mm^2/m^2$), it is of little help in predicting suitability for closure in patients below this level. More useful is an intraoperative pulmonary flow study to estimate the resistance of the unifocalized pulmonary arterial bed [36].

Techniques of Repair

PA-VSD with Duct-Dependent Pulmonary Blood Flow

Exposure of the heart and great vessels and the initiation of cardiopulmonary bypass are performed in the same manner as described for tetralogy with pulmonary stenosis. Inevitably, right ventriculotomy is a necessary component of complete repair. Therefore, the ventricular septal defect may be closed and infundibular myectomy performed through an incision in the infundibulum rather than via a transatrial-transpulmonary approach. As such, a vertical incision is made in the right ventricular infundibulum, and the ventricular septal defect is exposed. Muscle bands bordering the incision may be resected both to ensure an unobstructed subpulmonary region and to aid in exposure. The ventricular septal defect is closed with an autologous pericardial patch using interrupted pledgeted sutures for tetralogy with pulmonary stenosis as described in Chapter 22, *Tetralogy of Fallot*. After closure of the defect, the right ventricular outflow reconstruction is completed. In the majority of cases, a valved homograft conduit must be used to restore right ventricle–pulmonary arterial continuity. A nonvalved conduit, transannular patch with a monocusp valve, or valved conduits other than homografts can also be used. (Refer to Chapter 22, *Tetralogy of Fallot*, for more details.)

PA-VSD with MAPCA-Dependent Pulmonary Blood Flow

Surgical strategy can be categorized into four groups on the basis of morphologic variations in pulmonary blood supply:

- **Strategy A:** in patients where the size of the MAPCAs is adequate, the stenotic segments can be approached through sternotomy, and the distal bed is healthy, a complete unifocalization and intracardiac repair can be performed in one stage (Figure 23.1) [37].

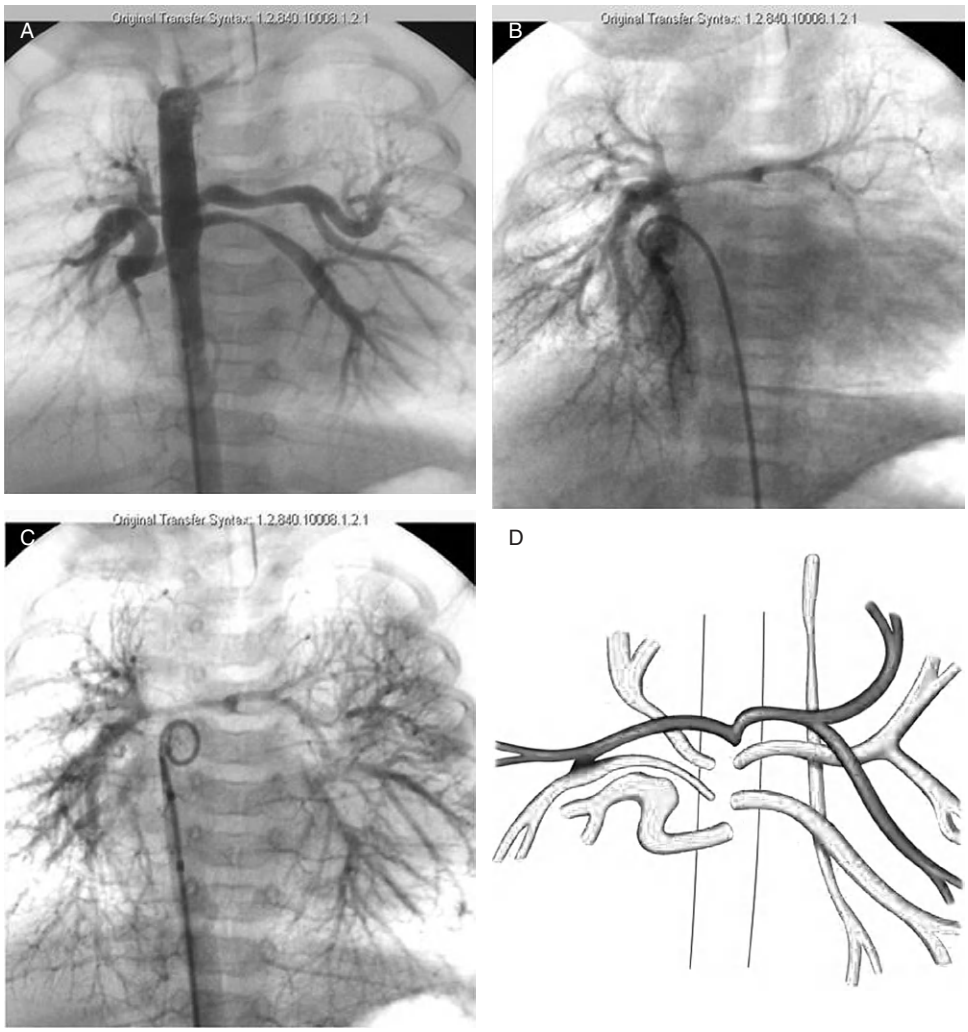

Figure 23.1 Surgical strategy A: one-stage unifocalization and intracardiac repair. **A–D** Representation of the anatomy conducive to a one-stage unifocalization and complete repair. These patients have well developed MAPCAs without significant distal stenoses. Light gray in **D** denotes MAPCAs, which are pulmonary arteries derived from the aorta. Dark gray denotes the main pulmonary arteries, which are undeveloped. (Reproduced with permission from Malhotra *et al.* [37].)

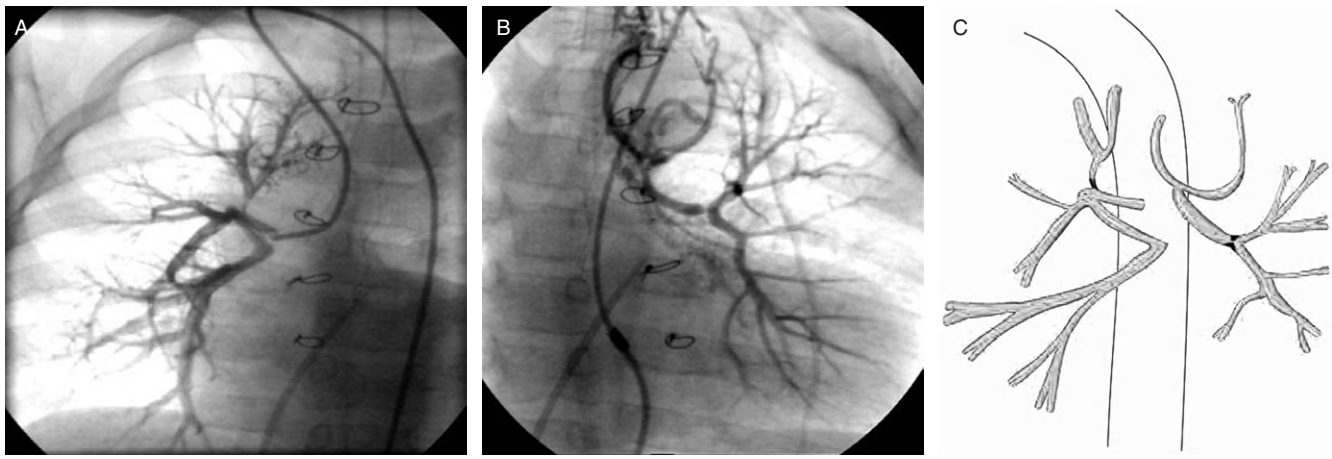

Figure 23.2 Surgical strategy B: one-stage unifocalization with shunt. The pulmonary angiograms (**A,B**) and diagram (**C**) depict small to moderate sized collaterals with proximal stenoses. This patient subgroup is amenable to one-stage complete unifocalization. However, intracardiac repair must be deferred because of elevated pulmonary arterial resistance. (Reproduced with permission from Malhotra *et al.* [37].)

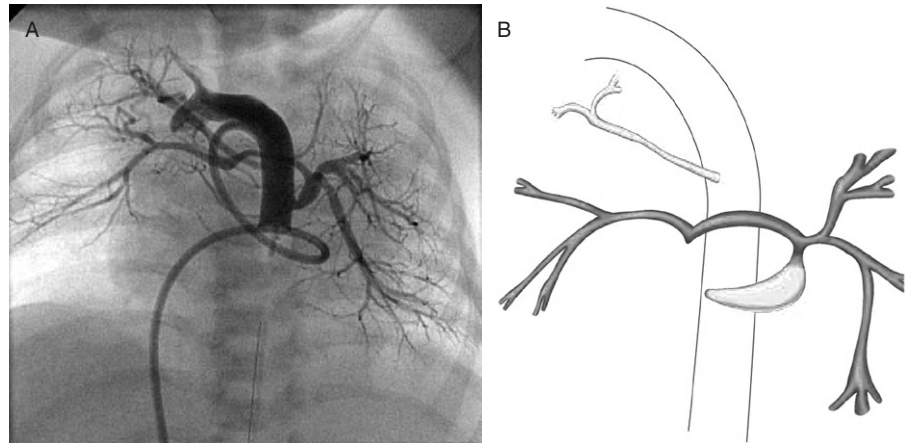

Figure 23.3 Surgical strategy C: aortopulmonary window. **A,B,** The morphology depicted is that of a well arborizing but hypoplastic true pulmonary arterial tree and poorly developed collaterals. This subgroup requires an initial aortopulmonary window to induce PA growth before completing repair. (Reproduced with permission from Malhotra *et al*. [37].)

- **Strategy B:** in patients where the MAPCAs are hypoplastic, the stenotic segments can be approached through sternotomy, and the distal bed is hypoplastic, a complete unifocalization can be performed in one stage but intracardiac repair is not feasible (Figure 23.2) [37].
- **Strategy C:** in patients where the true pulmonary arteries including the intraparenchymal vessels are hypoplastic but supply a majority of the lung segments (approximately 80%), an aortopulmonary window can be created and the collaterals feeding the true PAs can be ligated (Figure 23.3) [37].
- **Strategy D:** in patients where the MAPCAs have distal segmental stenotic areas that cannot be approached through sternotomy, a staged unifocalization through thoracotomy can be performed (Figure 23.4) [37].

Strategy A: Complete Unifocalization and Intracardiac Repair

The approach to one-stage unifocalization of pulmonary blood supply in tetralogy of Fallot with MAPCAs follows several basic principles: it is essential to control all collaterals before commencing cardiopulmonary bypass and to perform native tissue-tissue reconstruction whenever possible. A number of important techniques can aid in achieving these goals [35]. The mediastinum is entered through a median sternotomy, which is extended and retracted widely to improve exposure. Other investigators have described the use of a bilateral transsternal thoracotomy, which will also provide good exposure [38]. Collaterals are identified and dissected using a variety of approaches.

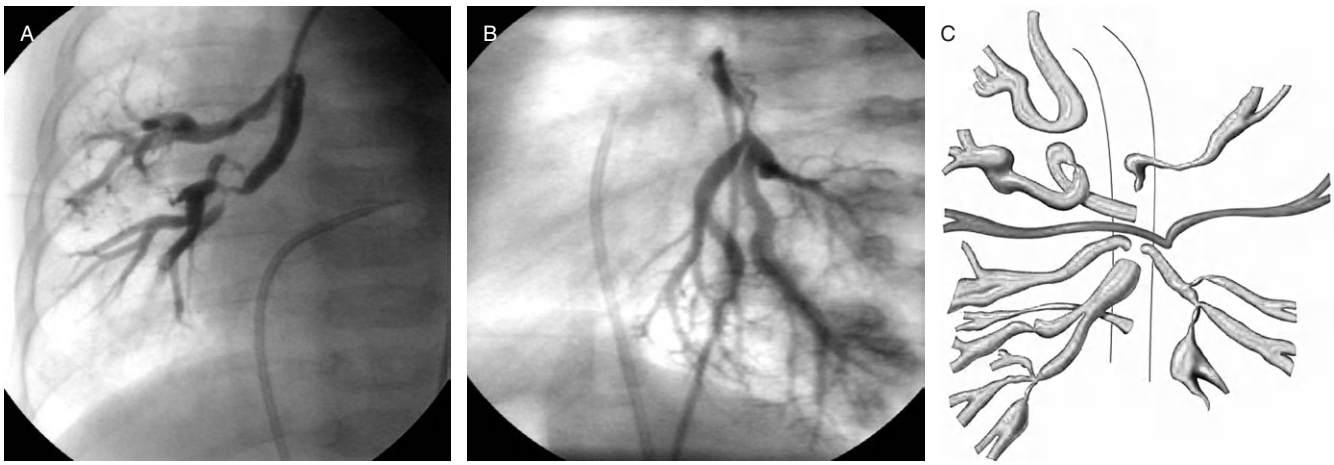

Figure 23.4 Surgical strategy D: staged thoracotomy. **A–C,** The dominant collateral system depicted has multiple stenoses at the segmental level. Sequential unilateral unifocalizations are required because of the distal extent of the obstructive lesions. Light gray denotes MAPCAs which are pulmonary arteries derived from the aorta. (Reproduced with permission from Malhotra *et al.* [37].)

Both pleural spaces are opened widely anterior to the phrenic nerves and the lungs are lifted out of their respective pleural cavities, allowing identification of collaterals at their aortic origins. Additional collaterals from the upper descending aorta are identified and dissected in the subcarinal space (between the tracheobronchial angle and the roof of the left atrium) by approaching between the right superior vena cava and the aorta (Figure 23.5) [35]. The floor of the pericardial reflection in the transverse sinus is opened and the posterior mediastinal soft tissues dissected to expose the aortic segment and the collaterals in this region. This is an important maneuver for gaining access to MAPCAs, which often arise from this location, and for providing a direct pathway for rerouting of MAPCAs to facilitate tissue-tissue anastomoses [35]. Collaterals arising from the aortic arch, brachiocephalic vessels, or coronary arteries are also exposed and dissected. To achieve controlled perfusion, collaterals are controlled before cardiopulmonary bypass and ligated at their origin before or immediately after commencing bypass.

As many collaterals as possible are ligated, mobilized, and unifocalized without cardiopulmonary bypass. Arterial oxygen saturation is followed with the ligation of each collateral, and it is possible to proceed with unifocalization off bypass until the cyanosis approaches a compromising level. At this point, partial cardiopulmonary bypass is instituted with the heart beating, and the remaining collaterals are unifocalized. The patient is cooled to 25°C and a calcium-supplemented blood prime is used to maintain normal cardiac function. During the unifocalization process, emphasis is placed on avoiding nonviable conduits in the periphery and achieving unifocalization by native tissue-tissue anastomosis. Important concepts in

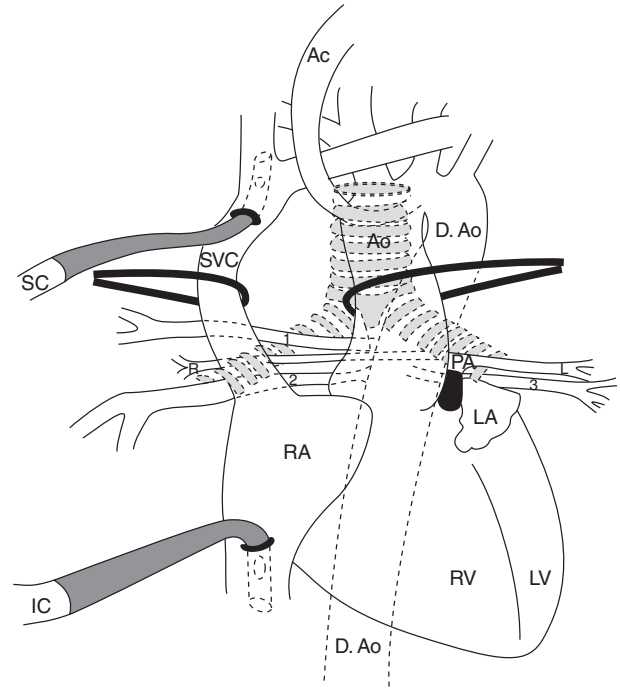

Figure 23.5 Transverse sinus approach for the dissection, rerouting, and unifocalization of the major AP collaterals. achieving this type of unifocalization are flexibility regarding reconstruction, aggressive mobilization, maximizing length of the MAPCAs, and creative rerouting. Avenues for collateral rerouting are developed by opening the pleura on both sides posterior to the phrenic nerves in the hilar regions and by opening the subcarinal space through the transverse sinus. To meet the objective of complete unifocalization without peripheral conduits and with maximization of native tissue-tissue anastomosis, the following peripheral and central reconstructive techniques are employed (Figure 23.6):

- end-to-side or oblique end-to-side anastomosis of collaterals to other collaterals or to central pulmonary arteries (A);
- side-to-side or long onlay anastomosis of collaterals to the central pulmonary arteries (B);
- allograft patch augmentation of distal collateral stenoses (C);
- end-to-end or end-to-side anastomosis of collaterals to a central conduit (D);
- anastomosis of a descending aortic button giving off multiple unobstructed collaterals to true pulmonary arteries (E);
- allograft patch augmentation of the reconstructed central pulmonary arteries (F).

These techniques are used as necessary in a given patient and frequently combined, depending on the particular anatomy. Figure 23.7 [35] is an example of complex reconstruction using several of these methods. Direct tissue-tissue anastomoses are achieved by bringing collaterals through the transverse sinus, or below or above the lung hilum, utilizing as much of the collateral length as possible. Collateral length is given the highest priority so that tissue-tissue anastomosis can be achieved. For example, if a discrete stenosis is present in the mid-portion of a collateral, the entire collateral is still used, and the stenosis is relieved by side-to-side reconstruction with another collateral

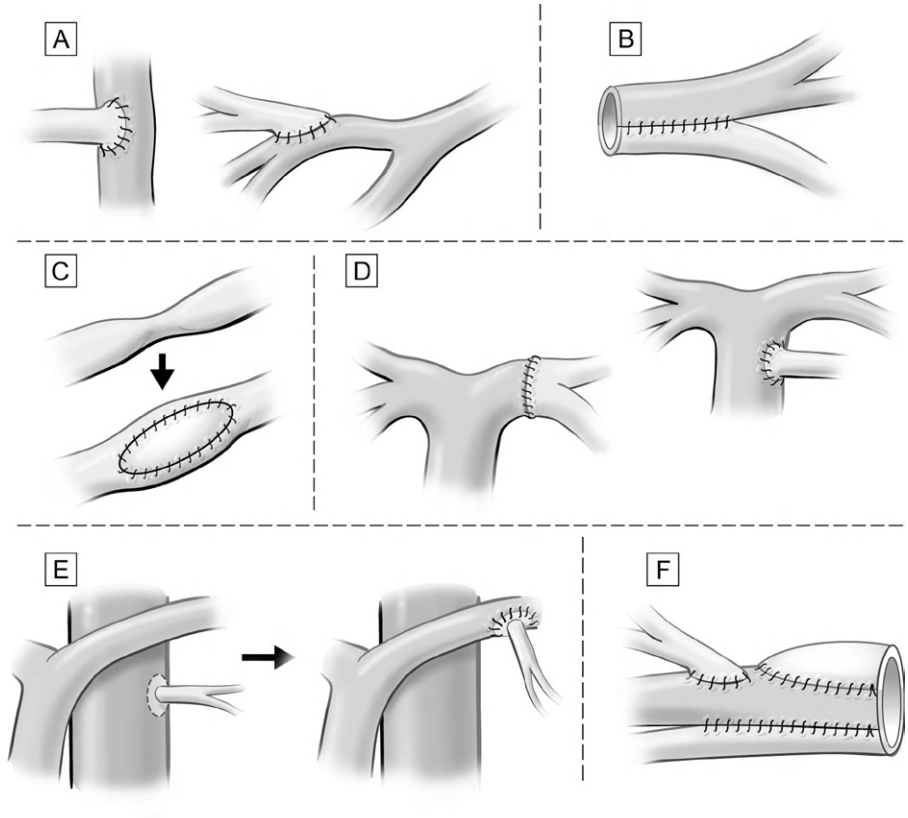

Figure 23.6 Techniques of unifocalization. (AO, aorta; COR, coronary collateral; IA, innominate artery; LPA, left pulmonary artery; RPA, right pulmonary artery; 1, large and tortuous major AP collateral arising from the carotid artery; 2 and 3, major AP collaterals arising from the descending aorta. *Site of ligation and division of the major AP collaterals.) **B,** A-A′, D-D′, E-E′, the major AP collaterals are filleted open along the broken lines; B-B′, the true right and left pulmonary arteries are filleted open from hilum to hilum. **C,** A-A′ to B-B′, major AP collateral 1 is filleted open along its length all the way to the hilum and is anastomosed to the true pulmonary arteries, thereby augmenting the pulmonary arteries from hilum to hilum; C-C′ to D-D′ and F-F′ to E-E′, major AP collaterals 2 and 3 are anastomosed to the augmented true pulmonary arteries in an end-to-side fashion. Unifocalization and central pulmonary artery reconstruction are thus achieved without the need for non-native material. (Reproduced with permission from Reddy *et al.* [35].)

or true pulmonary artery, or by patch augmentation if necessary. All collaterals are incorporated into the reconstruction using these methods, including those that provide dual supply to a lung segment along with a true pulmonary artery, to build up the neopulmonary arteries with as much native tissue as possible.

In patients undergoing complete repair, blood flow to the unifocalized pulmonary arteries is provided via an aortic allograft valved conduit from the right ventricle to the central pulmonary arteries. Following unifocalization, the distal end of the allograft conduit is anastomosed to the central pulmonary arteries. If necessary, allograft tissue from the conduit can be extended distally to help augment the central branch pulmonary arteries. Before completing the proximal anastomosis, intracardiac repair is performed. The aorta is cross-clamped, and cardioplegia is administered. A longitudinal ventriculotomy is made in the right ventricular infundibulum and the hypertrophied muscle bundles are resected. In patients undergoing closure of the ventricular septal defect, this is performed with an autologous pericardial patch fixed in glutaraldehyde or a prosthetic patch using continuous or interrupted pledgeted

sutures. The right atrium is opened to inspect the atrial septum. If an ASD or patent foramen ovale is present, it is closed partially to leave a small unidirectional interatrial communication for decompression of the right heart in the event of postoperative right ventricular dysfunction. In some cases with intact atrial septum, a small one-way interatrial communication is created. Following this the aortic cross-clamp is removed. During the rewarming period the right ventricular outflow tract reconstruction is completed by anastomosing the proximal conduit to the infundibulotomy.

In the vast majority of patients the ventricular septal defect can be closed based on the preoperative data. However, when in doubt, a pulmonary flow study can be performed [38] with the patient still on cardiopulmonary bypass. A pulmonary arterial catheter and perfusion cannula are placed into the reconstructed neopulmonary arterial system. While venting the left atrium vigorously, the lungs are perfused from the bypass pump with gradually increasing flow equivalent to at least one cardiac index ($2.5\,L/min/m^2$). In both laboratory and clinical studies, we have found this method to predict reliably mean pulmonary arterial pressure with the ventricular septal defect closed [38]. If the mean pulmonary arterial pressure is ≤25 mmHg in infants, the ventricular septal defect is usually closed. Otherwise, the defect is typically left open. In such situations in our early experience the authors performed a right ventricle-to-pulmonary artery conduit and left the ventricular septal defect open. However, the authors favor an aortopulmonary shunt instead. This avoids the need to cross-clamp and do a ventriculotomy, and the reconstructed pulmonary arterial suture lines are not exposed to systemic pressures, which can result in significant bleeding problems in some. Some groups have advocated the use of a fenestrated ventricular septal defect or its variations.

After separation from cardiopulmonary bypass, aortic, pulmonary arterial, and atrial pressures are measured continuously. Transesophageal echocardiography is performed to ensure that there are no significant residual defects. Bilateral pleural and mediastinal tube drains are placed and the sternum is closed. If bleeding or ventilation is an issue, the sternum is left open electively and the skin incision is closed with a Silastic patch. The sternum is then closed on the second or third postoperative day.

Strategy B: Complete Unifocalization to a Systemic-Pulmonary Artery Shunt

In this group of patients a complete unifocalization is performed using the same techniques as described earlier but the pulmonary blood flow is provided by constructing a central systemic-pulmonary artery shunt. The authors' preference is to place a Gore-Tex tube graft from the ascending aorta to the unifocalized neopulmonary arteries. The shunt is anastomosed using 7/0 or 6/0 polypropylene monofilament suture. The length of the shunt should be optimal without any kinks. The diameter of the shunt is determined by the quality of distal pulmonary bed and size of the patient. If the distal pulmonary bed is hypoplastic, a larger shunt may be necessary. To err on the larger side appears to be a safer option in this group of patients to allow for growth of the pulmonary bed with more flow. However, it is important to avoid excessive pulmonary flow resulting in low systemic output and pulmonary congestion. It may be necessary to reduce the size of the shunt by using hemoclips if the pulmonary blood is excessive resulting in hemodynamic compromise.

Strategy C: Creation of an Aortopulmonary Window

Creation of an aortopulmonary window involves direct anastomosis of the hypoplastic main pulmonary artery to the ascending aorta [39,40]. Through a median sternotomy approach the great arteries are carefully dissected. The main pulmonary artery is mobilized to its origin at the right ventricular infundibulum (Figure 23.8) [40]. The proximal left and right main pulmonary arteries are also adequately mobilized. Temporary neurovascular clips are placed on the branch pulmonary arteries, and the most proximal extent of the main pulmonary artery is divided as closely as possible to its infundibular origin. If needed, the proximal margin is oversewn or occluded with a surgical clip. The best location for the anastomosis of the hypoplastic main pulmonary artery to the aorta is generally to the left posterolateral aspect of the ascending aorta. Careful positioning is critical to avoid stretching and distorting the right pulmonary artery branch where it passes behind the ascending aorta. In occasional cases the pulmonary artery is better positioned by being anastomosed superiorly to the underside of the aortic arch. This decision may be heavily influenced by the anatomy of the ascending aorta and aortic arch, which can be quite variable in these patients.

The goal of a surgical aortopulmonary window is to create the largest anastomosis possible between the aorta and the diminutive main pulmonary artery trunk. The proximal end of the divided main pulmonary artery is spatulated at its open end with a longitudinal incision approximately twice the diameter of the main pulmonary artery. The incision is made on the aspect of the pulmonary artery directly adjacent to the aorta. Patients are given 150–200 units/kg of heparin before the pulmonary arteries are clamped. At completion of the anastomosis, the temporary neurovascular clips are removed from the pulmonary arteries and the partial-occluding aortic clamp is released. Diastolic blood pressure and systemic arterial saturations must be carefully monitored. Typically, the diastolic blood pressure drops by 5–10 mmHg, and the systemic arterial oxygen saturations rise by 5–10%. The heparin is not reversed. After hemodynamic stability has been ensured, the sternotomy incision is closed. Cardiopulmonary bypass

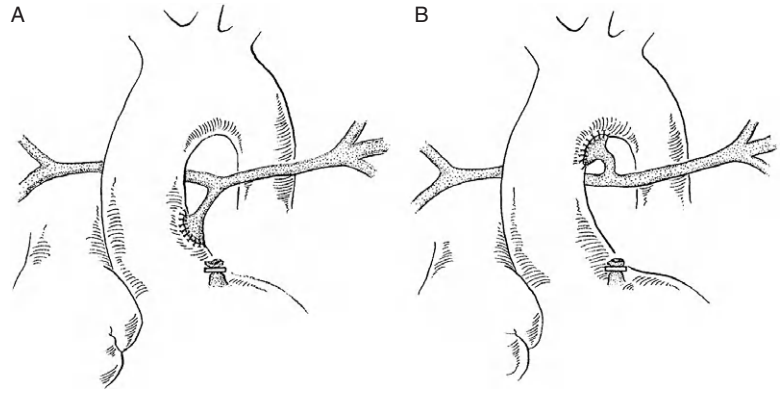

Figure 23.8 Surgical aortopulmonary window. Ideal location for anastomosis varies according to patient-specific anatomic variables and may be dictated not only by pulmonary artery anatomy but also by aortic size and position. **A,** Most common anastomotic position at left posterolateral aspect of ascending aorta, just above sinotubular junction. **B,** Less commonly, pulmonary artery confluence has better positional lie when located superiorly to undersurface of aortic arch. (Reproduced with permission from Rodefeld *et al.* [40].)

in general is not required unless the patient is severely cyanotic or hemodynamically unstable.

Strategy D: Staged Thoracotomy Unifocalization to a Systemic-Pulmonary Artery Shunt

In patients where MAPCAs are the predominant supply to the lungs but significant distal segmental stenoses are present that are not amenable for unifocalization through sternotomy, the strategy of traditional thoracotomy and unifocalization to a systemic-pulmonary artery shunt is most appropriate. Because the operation is typically performed without cardiopulmonary bypass, a posterolateral thoracotomy (through the fourth or fifth intercostal space) is performed on the side that has the worst morphology of MAPCAs so that patient's oxygenation is not affected significantly during the procedure. All the MAPCAs are dissected and controlled and then unifocalized applying the same principles as through the midline. Once the unifocalization is complete, the neopulmonary arteries are connected to the aorta or the subclavian artery using an expanded polytetrafluoroethylene (ePTFE) shunt. The unifocalized neopulmonary artery is brought close to the hilum and as close as possible centrally to facilitate later completion from the midline. The authors prefer an aortopulmonary shunt because of the ease of taking it down during the completion phase.

Postoperative Management

The postoperative management of these patients in general should follow the same principles involved in managing a complex cardiac patient following prolonged cardiopulmonary bypass. However, PA-VSD patients are prone to a certain set of special postoperative challenges. Pulmonary parenchymal reperfusion injury, parenchymal hemorrhage, and bronchospasm are commonly seen. Reperfusion injury is often seen in the regions that are underperfused preoperatively. This can result in opacification of an entire lobe or whole lung. All of these factors can sometimes make ventilating patients a challenge. A strategy of permissive hypercarbia and high positive end-expiratory pressure (PEEP) is often effective. Occasionally a ventilator may be employed and rarely venovenous extracorporeal membrane oxygenation (ECMO) may be needed until the lungs recover. It is important to restrain from escalating ventilatory peak pressures, for this can certainly result in further lung damage. Pulmonary parenchymal hemorrhage is self-resolving over time, but any coagulopathy should be promptly treated. Hemorrhage into the bronchial tree is not uncommon and usually should be managed with bronchoscopy and pulmonary toilet as indicated. Patients with bronchus suis also often need bronchoscopy for effective pulmonary toilet. Bronchospasm is often seen in the early postoperative period, especially in younger infants, possibly because of extensive dissection around the tracheobronchial tree. This usually resolves after the initial few days during which time broncholytic agents may be required. In patients who fail to extubate, phrenic nerve injury and any tracheobronchial compression should be entertained.

Postoperatively these patients require modest doses of dopamine, milrinone and calcium infusions, and sometimes epinephrine. In general in the first 48 hours after surgery the patients are well sedated and often paralyzed. Because all patients routinely have a right ventricular or pulmonary arterial catheter to monitor pressure, it is easy to observe the reactivity of pulmonary vasculature and use nitric oxide if indicated.

Bleeding can be another significant problem in the perioperative period. In the authors' experience, bleeding

problems can be minimized with the use of small needles on 7/0 or 8/0 polypropylene suture and the routine use of epsilon-aminocaproic acid. If bleeding is still a concern at the end of the operation, the sternum can be left open and the mediastinum packed with thrombin-soaked Gelfoam and gauze. With this approach the risks of tamponade and re-exploration for bleeding are minimized.

Follow-Up Evaluation

At the time of discharge, in addition to the routine investigations, all patients undergo a lung perfusion scan to obtain a baseline distribution of blood to the right and left lungs and to various regions within each lung. Subsequently patients are followed closely by the cardiologist with echocardiograms and periodic lung perfusion scans. If there is clinical and echocardiographic suspicion of elevated right ventricular pressures, right ventricular dilatation, and/or depressed right ventricular function, a cardiac catheterization is performed. Nearly 30% of the patients will require additional pulmonary arterioplasty or balloon dilatation to keep the right ventricular pressure low and to encourage growth of the distal pulmonary bed by avoiding maldistribution of blood within the lungs. In this regard, the lung perfusion scan is also very important. Even in the presence of low right ventricular pressures, if there is gross maldistribution of blood between the right and left lungs or within each lung, a cardiac catheterization is performed to evaluate whether further intervention is needed to correct the stenotic areas in the reconstructed pulmonary arteries.

In patients with open ventricular septal defect, a cardiac catheterization is performed 3–4 months after unifocalization to assess the feasibility of repair. If the Qp:Qs ratio is more than 2:1 the ventricular septal defect can be closed safely. If not, the pulmonary arterial system is assessed with the goal of addressing any residual stenotic lesions that can be addressed by balloon dilation or surgery. The authors strongly discourage the use of stents in the pulmonary arterial system unless the goal is for future palliation only or if the stenoses cannot be approached by thoracotomy. Even after hemodynamically good repair, these patients should be closely followed to preserve right ventricular function with timely intervention for conduit changes or pulmonary arterioplasty.

Outcomes

In the current era, the outcomes for PA-VSD and confluent normally arborizing pulmonary arteries are almost as good as for regular tetralogy of Fallot except that these patients require multiple conduit changes over their life span; these are best considered along with tetralogy of Fallot. This section will focus on outcomes in patients with PA-VSD and MAPCAs.

Although there are numerous reports of early outcomes [19,20,22–25,32,33,35] there are very few reports of midterm [41] to long-term outcomes. This is because programmatic surgical unifocalization strategy was adopted in very few centers, and most of the cohorts include only older patients, often with preselected patients. Further, while the strategy of staged unifocalization has yielded good results in select patients [23,32,33], many of these programs did not initiate surgical treatment in early infancy when the attrition rate for infants born with PA-VSD is the highest.

In addition the variability of MAPCAs makes it difficult to compare results between institutions and between various approaches. The fact that many reports do not segregate the data of different patient groups further compounds the problem by making it difficult to discern the mortality, morbidity, and outcomes of different groups. For instance patients with hypoplastic central pulmonary arteries with a normally arborizing, good-sized intraparenchymal system would require patch augmentation of the central intrapericardial branch pulmonary arteries along with a conduit placement; in these patients the outcomes are almost as good as in tetralogy of Fallot with normal-sized central pulmonary arteries. Conversely, if the intraparenchymal pulmonary arteries are also hypoplastic, then the surgical management and results will change significantly. Patients with MAPCAs as the predominant source of pulmonary blood flow who require unifocalization of the collaterals also will have different outcomes.

Cho and Puga and associates [42] included all forms of PA-VSD in reviewing the Mayo clinic experience in 495 patients from 1977 to 1999. They reported that the presence of MAPCAs is a risk factor for mortality in unrepaired patients. In patients who were palliated with shunts and/or unifocalization but did not undergo complete repair, early mortality was 16.3% and late mortality was 23.1%. In patients who underwent complete repair (median age, 11.3 years), early mortality was 4.5% and late mortality was 16%. In 6.6% of patients the ventricular septal defects had to be reopened because of high right ventricle pressures. The risk factors for mortality at a mean follow-up of 11.4 years (standard deviation, 7.5 years) were male sex, nonconfluent central pulmonary arteries, reopening of the ventricular septal defect, and, surprisingly, postrepair conduit change. Actuarial survival at 20 years was 75%. At 22 years following initiation of PA-VSD management, 32.3% of the cohort and 27.6% of the survivors remained unrepaired.

In another report from Australia, the outcomes of staged unifocalization were evaluated in a cohort of 82 patients [43]. Approximately 65% were able to undergo complete repair, and overall survival at 12 years after complete repair was 51% (standard deviation, 14%).

A report from Toronto [44], examined a cohort of 185 surgical patients between 1975 and 2004 with only 53 patients having MAPCAs. Overall survival for the entire

group at 10 years from the time of initial operation was 71%. Risk factors for death included younger age at surgery, earlier birth cohort, fewer bronchopulmonary segments supplied by native pulmonary arteries, and initial palliation with systemic-pulmonary artery shunt. Another report from Tokyo [45] is much more encouraging for staged unifocalization, with 7-year survival of 91.3% in the cohort of patients receiving late repair. Nevertheless, the patients' age in this group at first unifocalization was 3.9 years, again suggesting that many of the unifocalization programs do not initiate surgical management in early infancy where the attrition rate is high.

Between July 1992 and December 2007, the authors performed unifocalization procedures in 338 patients with PA-VSD and MAPCAs. The median age of the patients was 7.7 months (range, 10 days to 39 years; 65% of patients were infants). The median number of collateral arteries in these patients was 4 (range, 1 to 7). Collaterals supplied a median of 16.5 lung segments (range, 4 to 20), and 23.5% of patients had complete absence of true pulmonary arteries. Complete single-stage unifocalization and intracardiac repair was performed in 196 patients (58%), complete unifocalization to shunt or right ventricular conduit in 64 patients (19%), an aortopulmonary window in 37 patients (11%), and staged unifocalization via thoracotomy in 41 patients (12%). During this period complete repair was eventually achieved in 90% of the patients with perioperative right ventricle/left ventricle pressure ratio of 0.41 ± 0.12. In patients operated on since 1999, the ratio was 0.37 ± 0.11.

Overall early mortality was 5.6%. The mortality was lowest in patients with complete unifocalization and repair (3%; 6/96). Mortality with complete unifocalization to a shunt or conduit was 7.8% (5/64), with aortopulmonary window was 10.8% (4/37), and with staged thoracotomies was 10% (4/41).

Since 1999, overall mortality decreased to 2.3%. As the majority of patients were infants, conduit changes were required earlier and have been performed in 20% of the patients. In addition 22.6% of patients have undergone surgical reintervention for unifocalized pulmonary artery stenosis. Catheter intervention, predominantly balloon dilation, was performed in 19.7% of patients; in the majority of these patients, stenosis was addressed at the time of subsequent surgery. The authors have observed definitive growth in the unifocalized collaterals, also substantiated by the continued low right ventricle/pulmonary artery ratio of 0.37 ± 0.11.

Mid to late mortality was observed in 7.1% of patients (8.3% between 1992 and 1998; and 6.2% between 1999 and 2005). Late mortality was lowest in patients with complete unifocalization and repair (3%; 6/96). The mortality with complete unifocalization to a shunt or conduit was 10.4% (6/64), with aortopulmonary window was 13.5% (5/37), and with staged thoracotomies was 17% (7/41).

Total cumulative mortality was 12.7% (43/338) despite the fact that the majority of patients were infants and underwent complete unifocalization. At 10 years the actuarial survival for the whole group was 85.5%. Analysis of the data showed risk factors to be: year of surgery, and patients with both DiGeorge syndrome and gastroesophageal reflux.

More recently institutions that have adopted a programmatic approach to PA-VSD and MAPCAs have reported encouraging results.

CHAPTER 24

Ventricular to Pulmonary Artery Conduits

Valve pathology in infants and children poses numerous challenges to the pediatric cardiologist and cardiovascular surgeon. Valve reconstruction is the goal of all surgical intervention because restoration of anatomy and physiology employs native tissue that allows for growth and potentially better long-term outcome. When repair fails, or is not feasible, valve replacement becomes inevitable [1]. The valve pathology, patient size, and the requirement for growth all interrelate making valve replacement in neonates, infants, and children a challenging surgical procedure.

The pulmonary valve is the most common valve replaced in the congenital population. We have replaced more than 800 pulmonary valves in the past 25 years at our institution. Reconstruction of the right ventricular outflow tract (RVOT) is performed in patients with congenital heart disease when there is discontinuity between the right ventricle (RV) and the branch pulmonary arteries (PA) or in whom significant pulmonary valve stenosis or insufficiency is present. In 1964, Gian Rastelli and coworkers inserted a pericardial nonvalved tube as the first right ventricle-to-pulmonary artery (RV-PA) conduit in a child with pulmonary atresia [2]. Ross and Somerville [3] introduced the aortic valved allograft for RVOT reconstruction in 1966.

The extracardiac conduit has permitted routine repair of congenital anomalies that involve pulmonary atresia or hypoplasia of the RVOT. Such lesions include complex forms of tetralogy of Fallot (with or without pulmonary atresia), truncus arteriosus, pulmonary atresia without ventricular septal defect (VSD), transposition of the great arteries, VSD with pulmonary stenosis or atresia, certain subtypes of double outlet right ventricle, as well as pulmonary autograft replacement of the aortic root in the Ross operation. Many of these anomalies are routinely corrected in neonates—the most challenging environment for any prosthesis selected for RVOT reconstruction.

The porcine valve Dacron conduit was favored through the 1970s and early 1980s, but late obstructive complications, particularly the development of neointimal peel formation within the Dacron tube led to abandonment of this prosthesis [4]. The cryopreserved allograft (aortic and pulmonary) subsequently became the conduit of choice for RVOT reconstruction from the mid 1980s to the late 1990s. Development of cryopreservation techniques considerably improved availability and durability of allografts resulting in increased clinical use. Numerous valved conduits have since been introduced including aortic xenografts in Dacron tubes, stented bovine pericardial or porcine xenografts in pericardial tubes, glutaraldehyde fixed aortic and pulmonary roots, aortic and pulmonary allografts, and bovine jugular vein conduits [5–10].

In the following pages we will review monocusp reconstruction following transannular RVOT reconstruction, the various RV-PA conduits, isolated pulmonary valve replacement in older patients including transcatheter pulmonary valves, and finally the indications for intervention and reintervention on the RVOT in older patients who have had previous surgical and nonsurgical intervention.

Polytetrafluoroethylene Monocusp Right Ventricular Outflow Tract Reconstruction

Tetralogy of Fallot patients with significant pulmonary valve annulus and/or leaflet hypoplasia historically have been treated in one of two ways: 1) transannular patch or 2) valved conduit insertion. The transannular patch immediately relieves RV hypertension and enhances RV growth proportionally with patient growth, and reoperation for RVOT stenosis is generally uncommon. The disadvantage of transannular patching is acute pulmonary insufficiency (PI) resulting in sudden hemodynamic conversion of an

obstructed pressure-loaded RV to a volume-loaded RV, which causes temporary and/or delayed RV dysfunction. Chronic RV volume overload can lead to late biventricular dysfunction and tricuspid insufficiency necessitating the need for pulmonary valve insertion [11,12].

The initial advantage of a valved conduit is immediate pulmonary valve competency. Conduit insertion is particularly useful in patients who have peripheral unrepaired pulmonary stenosis or elevated pulmonary vascular resistance (PVR >4 Wood units). The disadvantages of currently available valved conduits are their structural deterioration secondary to calcification, shrinkage, and lack of growth resulting in early and late valve dysfunction. These unsolved problems are manifested by the allograft conduit (AC) that became popular in the United States during the mid 1980s. Pulmonary allografts remain popular at present despite freedom from reoperation of 50% at 5 years in patients undergoing a non-Ross RVOT conduit insertion [10,12].

An attractive alternative strategy has been the concept of a monocusp RVOT patch reconstruction, which in certain patient populations has the potential advantages lacking in patients who require a transannular patch without pulmonary valve reconstruction or placement of a valved conduit that may interrupt RV-PA continuity. A monocusp valve can be placed in any sized patient when the monocusp leaflet is tailor-made to fit the RVOT that is being enlarged by a transannular outflow patch, is less expensive, and usually lasts longer than a valved conduit in an infant. The monocusp RVOT patch can be constructed with autologous or bovine pericardium [13,14], allograft pulmonary valve cusp [15], or a polytetrafluoroethylene (PTFE) membrane (0.1 mm PTFE cusp; W.L. Gore & Associates, Inc, Flagstaff, AR; off-label use) traditionally employed as a pericardial substitute [16–20]. Each of these materials have demonstrated good immediate postoperative valve competency and reduced early PI [17,19–21].

In 1993, Yamagishi and Kurosawa [18] and Oku and colleagues [19] independently introduced 0.1 mm PTFE pericardial membrane as readily available material with good handling characteristics for monocusp valve construction and found it superior when compared to biologic leaflet materials. Our animal studies suggest that 0.1 mm PTFE functioned as well as or better than fresh or glutaraldehyde-treated pericardium. Clinical application of this material in our patients with tetralogy of Fallot in whom transannular patching was necessary resulted in improved perioperative RV function as evidenced by a lower postoperative central venous pressure, less need for postoperative inotropic agents, less chest tube drainage, and a decreased intensive care unit (ICU) and hospital stay [22]. The PTFE membrane is now our material of choice for a monocusp construction and has been used in more than 250 patients with a wide range of RVOT obstructive and regurgitation defects. We particularly value its use in the small infant undergoing primary tetralogy of Fallot repair with and without pulmonary atresia in whom transannular patching is necessary.

Construction of a pericardial or PTFE monocusp is simple, relatively inexpensive, and reproducible. Allograft pulmonary valve cusps are considerably more expensive in the United States and may be difficult to custom fit into the RVOT. The potential disadvantage of a monocusp patch in comparison with insertion of a pulmonary valve or valved conduit is that PI may recur more quickly in some patients if the monocusp leaflet sticks in the open position as has been reported with some biologic monocusps [17,20,21]. Recurrent stenosis at the level of the monocusp valve is rarely seen with monocusp leaflet material of any type. The major advantage of the 0.1 mm PTFE is that it does not allow tissue ingrowth and remains mobile (functional) for a much longer period.

The technique of monocusp insertion at our institution has remained relatively constant over the last 16 years. The length and width of the monocusp leaflet are determined and the 0.1 mm PTFE membrane is sewn into the RVOT. To ensure monocusp leaflet coaptation to the conal septum and/or residual pulmonary leaflet tissue, the width and length of the patch is kept mildly redundant. A second patch of 0.4 mm PTFE is sewn across the entire RVOT onto the main PA with the second suture line. Patients with defects that include an intact pulmonary valve annulus are evaluated following pulmonary valvotomy. The annulus diameter is measured with a Hegar dilator and if the annular Z value was ≥–2, then transannular patching is not performed. In patients with moderate-to-severe annular hypoplasia (Z score <–2), or postvalvotomy RVOT gradient >30 mmHg and/or RV pressure >80% of systemic pressure, transannular patch repair with a monocusp valve insertion is used (Figures 24.1–24.3).

The PTFE monocusp with separate RVOT patch has been useful for our patients with tetralogy of Fallot or pulmonary atresia with VSD who require a transannular patch (35–40% of our tetralogy series) and in patients requiring a second RVOT procedure after failed initial conduit reconstruction. The monocusp valve has functioned well in most patients for the first 3–4 years and for up to 10–12 years in some patients. While the majority of patients developed some pulmonary regurgitation as the RV outflow tract grows, recurrent outflow obstruction at the leaflet level has not been observed. Another important indication for PTFE monocusp reconstruction is primary AC failure because inserting a second AC has been associated with accelerated structural failure [12].

The PTFE monocusp can be expected to retain adequate function in the early to mid postoperative period. The only anticoagulant used is aspirin (10 mg/kg day, up to a limit of 80 mg/day).

From 1994 through 2006, 192 patients (mean age 3.3 ± 5.0 years) underwent RVOT reconstruction with a PTFE monocusp valve (192 patients; 202 implants), mean interval (4 to 9 ± 3.1 years) (range, 6 months to 12 years). The series was divided into three groups: patients undergoing initial repair of tetralogy or pulmonary atresia with VSD (group I); patients undergoing redo RVOT procedure (group II); and patients undergoing complex initial repair (group III).

There were four early and five late deaths (9 of 192 patients; 5%). The difference between the preoperative and postoperative peak RVOT gradients for the 192 patients was significant (71.2 versus 23.1; $p < .0001$). Twenty-five patients (13%) developed mild-to-moderate RVOT stenosis at one or more locations proximal and/or distal to the monocusp valve but not at the monocusp valve (mean gradient, 44.7 ± 20.3 mmHg). Freedom from increased PI greater than moderate was 86% at 1 year, 68% at 5 years, and 48% at 10 years (Figure 24.4) [23]. Twenty-five patients have undergone 35 PTFE monocusp reoperations 4.2 ± 3.1 years (range; 3 months to 10 years) after initial repair. Kaplan-Meier freedom from reoperation was 96% at 1 year, 89% at 5 years, and 82% at 10 years following surgery (Figure 24.5) [23]. Freedom from reoperation in group II (69%) was significantly higher when compared with group I (88%; $p = .01$) and group III (90%; $p = .02$) while there was no observed difference between groups I and III.

Several bicuspid PTFE reconstructions, conduits, and a folding monocusp PTFE leaflet have been recently introduced. Most incorporate a 0.1 mm pericardial PTFE membrane that is used "off label" for leaflet construction as described earlier [22,23]. Early results with these new modifications seem promising, but longer follow-up will be necessary to evaluate their durability.

Quintessenza and colleagues described a bicuspid RVOT outflow reconstruction [24]. Their early results (3 years) with the 0.1 mm PTFE are considerably better than those obtained with the 0.6 mm PTFE followed for up to 8 years. Nunn and colleagues described a folding monocusp using 0.1 mm PTFE and demonstrated less regurgitation across the RVOT at the expense of a higher gradient at mid-term follow-up than obtained with a simple horizontal monocusp [25]. Morell and colleagues have described a PTFE tube with a bicuspid PTFE valve constructed in the conduit [26]. Their initial results have been satisfactory in spite their short follow-up (<1 year).

Allograft Conduits

Cryopreserved pulmonary allografts were the "gold standard" in the United States from the mid-1980s through the late 1990s [5,6,10]. In most centers, pulmonary ACs were favored over aortic allografts as they are less prone to dysfunction and calcification [27]. The higher elastin content of aortic allografts may increase their propensity for early dense calcification and adherence to adjacent structures making conduit removal or revision challenging. In some patients, extracardiac pulmonary ACs are prone to significant valve regurgitation within months of insertion or can develop shrinkage leading to late conduit stenosis [12]. However, pulmonary allograft performance and longevity is significantly improved in the Ross operation because many of the patients are older and the oversized pulmonary allograft is inserted into the orthotopic position, which may alleviate the turbulent flow seen in extracardiac valved conduits.

The evaluation of AC durability is critical in determining the choice of prosthesis for pulmonary valve replacement. Forbess *et al*. [5] evaluated 185 consecutive pulmonary AC implanted at a single institution over 14 years in three separate age groups. Their univariate analysis demonstrated that smaller allograft size (<14 mm),

younger aged patients (<1 year), and diagnosis of truncus arteriosus were all risk factors for conduit failure while allograft size was the only predictor of failure in the multivariate analysis. Ross aortic valve replacement (AVR)-related implants had the best outcome with a 5-year AC survival of 94% (Figure 24.6) [5], while non-Ross AC implants in children >10 years of age had a 5-year graft survival of 76% (Figure 24.7) [5].

Dearani *et al*. published the largest series of pulmonary valve replacement and RV-PA conduits from the Mayo Clinic [6]. They described 1270 RVOT procedures in 1095 patients undergoing RV-PA conduit or pulmonary valve replacement over a 37-year period. The operative mortality was 3.7% in the most recent decade. Mean follow-up for the entire series was 10.9 years with a maximum of 29 years. Three types of conduits were implanted: 730 porcine valved Dacron conduits, 239 homografts, and 126 nonvalved conduits. Risk factors for conduit failure included pulmonary allografts, younger age (<4 years) at initial operation, and smaller conduit size (<19 mm) [6]. Survivorship free of reoperation for conduit failure was 84.1% ± 1.4% at 5 years, 55.5% ± 2.0% at 10 years, 39.6% ± 2.2% at 15 years, and 31.9% ± 2.7% at 20 years. In their series comparing the AC with the Dacron tube with a porcine xenograft they found the AC was less durable.

At our institution, 117 non-Ross patients received cryopreserved ACs (94 pulmonary and 23 aortic) between January 1985 and December 2003 for RVOT construction [30]. Ages ranged from 6 days to 43 years (mean, 8 months), and there were 57 children (49%) younger than 12 months of age. There were no device-related deaths. Overall patient survival was 80% at 15 years. Freedom from AC failure (valve explantation, balloon dilatation) was 60% at 5 years and 43% at 15 years; freedom from AC failure was worse in infants (42% at 5 years and 34% at 15 years). Freedom from AC dysfunction (AC stenosis >40 mmHg and AC insufficiency more than moderate) was 40% at 5 years and 23% at 15 years; freedom from dysfunction was worse in infants (21% at 5 years and 16% at 15 years).

Univariate analysis identified younger age, smaller AC, diagnosis of truncus arteriosus, and presence of aortic AC as risk factors for AC dysfunction and failure. Multivariate analysis identified smaller AC size and the presence of truncus arteriosus as risk factors for AC dysfunction and failure (Figure 24.8 and Figure 24.9) [28]. A comparison of some published series of AC used for RVOT reconstruction is shown in Table 24.1 [7,8,10,28–34,72].

Pulmonary Allografts in Ross Aortic Valve Replacement Patients

In our experience the durability of RVOT reconstruction with a pulmonary AC in patients undergoing the Ross AVR is improved secondary to older age at implant, orthotopic positioning, and the ability to oversize the AC [35].

From 1993 at our institution, pulmonary allografts have been the RV-PA conduit of our choice for reconstruction in Ross AVR operation and remain so today with the exception of children younger than 5 years of age where the Contegra® conduit (Medtronic; Minneapolis, MN) is favored [35,36].

Aortic allografts calcify more quickly than pulmonary ACs when placed in the RVOT [8,10]. This is linked to the higher elastin content of the aortic AC wall [11]. The AC size was found to be a significant mechanical risk factor that influenced durability in many studies [5,8,36]. Our results

are consistent with this observation as allograft diameter was found to be an independent predictor of late stenosis. This is especially true in the pediatric Ross AVR population. Children younger than 5 years of age have an accelerated growth and can quickly outgrow their valve conduit. For this reason, we aggressively oversize the implanted allograft in Ross AVR patients, regardless of the patients' pulmonary annulus size because size rather than patient age is the most important predictor for pulmonary allograft failure (defined as the need for graft replacement) [36].

Between June 1993 and May 2007, 183 consecutive patients at our institution underwent Ross AVR with RVOT reconstruction using a cryopreserved pulmonary allograft (n = 156), decellularized pulmonary homograft (n = 22), and bovine jugular vein conduit (n = 5). Ages ranged between 1 month and 61 years (mean age, 23.3 ± 15.2 years). Three patients (2%) died (two early and one late), 24 patients (13%) had a peak systolic RVOT gradient exceeding 20 mmHg, 5 (3%) had a gradient exceeding 40 mmHg, and 7 (4%) had more than 2+ PI. Eight patients (4%) underwent conduit replacement for RV dysfunction. Freedom from RVOT reoperation at 10 years is 96%. Freedom from RV conduit failure and dysfunction was 98% and 96% at 5 years and 96% and 93% at 10 years, respectively. Independent predictors of pulmonary allograft RV-PA conduit dysfunction are smaller (<14 mm) RVOT conduit size ($p = .03$) and follow-up exceeding 5 years ($p = .05$) (Figure 24.10) [35]. The most logical reasons for the superior performance of the allograft in Ross AVR patients are 1) orthotopic conduit position, 2) older implant age, and 3) the use an oversized homograft [35].

During the last decade demand has increased for a RV-PA conduit more durable than ACs for non-Ross RVOT reconstruction has increased [28,37]. In late 1999, we began implanting the bovine jugular vein conduit (Contegra® BJVC, Medtronic, Minneapolis, MN), porcine stentless aortic root xenograft (Freestyle™, Medtronic), and the new decellularized pulmonary allograft (SynerGraft®, CyroLife, Kennesaw, GA) for non-Ross RVOT reconstruction [37–40].

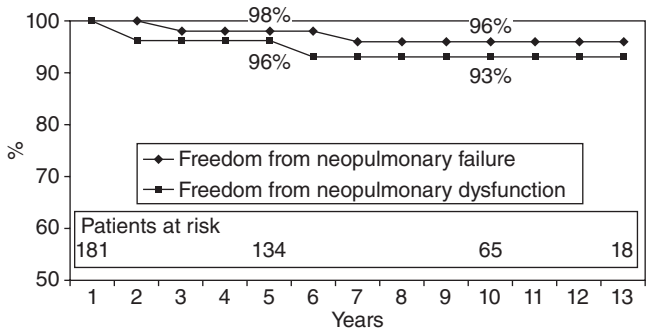

Figure 24.10 Kaplan-Meier freedom from neopulmonary conduit failure and dysfunction in patients following Ross aortic valve replacement. (Reproduced with permission from Brown *et al.* [35].)

Bovine Jugular Venous Valved Conduit

The limited availability and durability of ACs, especially in smaller sizes, supported the search for an alternative prosthesis to reconstruct the RVOT in patients with congenital heart disease (pulmonary allografts work well in Ross patients). In 1999, the Contegra BJVC was introduced as a potential alternative to allografts for RVOT reconstruction. The BJVC is a low-pressure, buffered glutaraldehyde fixed section of bovine jugular vein (12–15 cm in length and 12–22 mm in diameter). The three-cusp naturally occurring venous valves are in the center of the conduit, which possesses natural sinuses. The conduit wall is compliant with excellent suturability (Plate 24.1, see plate section opposite p. 594).

Early animal studies by Ichikawa and colleagues [41] and by our group [42] reported excellent results demonstrating good leaflet preservation and freedom from significant structural degeneration and valve regurgitation at 3 years. Herijgers and colleagues reported resistance of the Contegra BJVC to calcification when implanted in juvenile sheep, albeit for only 5 months [43].

These animal studies were confirmed in human clinical trials with up to 27 months (mean, 1.2 years) of follow-up reported by Breymann and colleagues [44] suggesting that the Contegra BJVC might represent a promising alternative to allograft. A report by Bove and colleagues [45] comparing a modified bicuspid pulmonary allografts and Contegra BJVC supported these findings in 41 patients (mean age 1.9 years) undergoing RVOT reconstruction. The BJVC demonstrated favorable hemodynamics as compared to allografts. Other advantages of the Contegra BJVC include greater shelf availability, natural continuity between valve and conduit, and no requirement for proximal extension.

The principles of Contegra BJVC insertion include: 1) the conduit is rinsed for 5 minutes with continuous manual agitation in four 500-cc baths of normal saline or Ringer's lactate before implantation; 2) the conduit is positioned into the main and left PA to avoid sternal compression; and 3) the outflow end of the conduit is cut so that the conduit valve is positioned as far distally as possible near the PA bifurcation to avoid valve distortion with sternal compression [7]. The inflow end of the conduit is spatulated and sewn with continuous monofilament suture to the edges of the right ventriculotomy without the use of additional prosthetic material.

Patients enrolled in this humanitarian device exemption (HDE) study had their surgical data and preoperative and postoperative catheterization and echocardiographic variables submitted to a core laboratory for analysis and review

by the Contegra primary investigators, who make up the Contegra Scientific Advisory Board. The core laboratory analysis gave the data accuracy and consistency. Several European investigators have published their results, and their data are summarized along with ours in Table 24.2 [28,37,44–52]. Contegra was approved for HDE in the United States in November 2000, and more than 17 000 have been implanted to date.

The mid-term results of RVOT reconstruction using the Contegra BJVC in 153 patients at our institution were retrospectively analyzed [53]. Patient ages ranged from 2 weeks to 18 years (mean, 8.4 ± 7.4 years). The Contegra BJVC size varied in diameter between 12 and 22 mm (mean, 18.5 ± 3.7 mm). Actuarial survival, freedom from dysfunction, and freedom from failure were 95%, 85%, and 89%, respectively, at 3.7 ± 2.4 years' follow-up.

In our series, during 11 years of follow-up, we have not observed shrinkage of the Contegra BJVC using echocardiography. Conduit explantation, perhaps the most stringent measure of performance, was significantly better at 5 and 10 years with BJVC (when compared with allografts) [54]. Our experience is in agreement with the recent work of Boethig and coworkers who demonstrated a freedom from explantation at 5 years for Contegra BJVC at 90% and pulmonary allografts at 70% ($p = .02$) [55].

The Contegra BJVC is a promising alternative for RVOT reconstruction because early hemodynamic performance compares favorably with allografts, it is more readily available in smaller sizes (12–16 mm) than allografts, the location of the valve within the conduit permits proximal infundibular anastomosis without additional prosthetic material, and the cost of the bovine jugular venous valve is approximately one half that of many ACs. In addition, short-term freedom from dysfunction is at better than for most allografts. Since 1999, we have implanted 153 Contegra BJVC at Indiana University and have observed an 8-year freedom from conduit reintervention and explantation of 90% and 94% respectively, which is superior to our experience with allografts in non-Ross RVOT reconstruction (unpublished data). Although longer-term follow-up will determine durability of this conduit, in neonates, infants and young children, it is our prosthesis of choice for RVOT reconstruction (except in Ross AVR patients >5 years of age, where allografts are preferred) [46]. A listing of several reported series of Contegra BJVC conduits is shown in Table 24.2 [37,44–52].

Fiore, Brown, and colleagues compared the mid-term performance of BJVC with pulmonary homografts in children under 2 years of age [54]. At 5 and 10 years, freedom from dysfunction was significantly improved (BJVC, 90%

and 85% versus pulmonary AC, 71% and 24%; $p < .05$); conduit failure trended lower (BJVC, 85% and 67% versus AC, 75% and 45%; $p = .06$), while freedom from explantation was significantly better for BJVC patients (BJVC, 85% and 67% versus AC, 75% and 45%; $p = .06$). Freedom from explantation, perhaps the most stringent measure of conduit durability was significantly better for BJVC patients (BJVC, 85% versus pulmonary AC, 47%; $p = .01$), while freedom from distal conduit and peripheral stenosis were similar in both cohorts.

Percutaneous Pulmonary Valves

In January 2010, the Melody® (Medtronic) stented bovine jugular venous valved RV-PA conduits were released in the United States under HDE to be placed percutaneously via venous access (Plate 24.2, see plate section opposite p. 594). More than 1400 have been used in other countries. Initial results are promising, but follow-up has been short.

Data of the first 99 patients enrolled in the Medtronic Melody study from January 2007 to December 2008 show that 90 of 99 patients enrolled were implanted [56]. Nine patients were excluded because of concern for coronary compression. Catheterization gradients decreased from 35 ± 16 mmHg to 14 ± 7 mmHg ($p < .001$) and all patients had less than trivial PI. Death occurred in 1 patient, and homograft rupture requiring surgery occurred in 1 patient. The RVOT gradient increased from 14 ± 7 mmHg at implant to 20 ± 8 mmHg at 6 months and 22 ± 10 mmHg at 1 year. Freedom from stent fracture was 89%, and freedom from surgical reintervention was 99% at 1 year.

Nonvalved Right Ventricular–Pulmonary Artery Conduits

Non-valved RV-PA conduits deserve mention and are still used in some centers. Early results are satisfactory but many patients develop late RV dilation within 10 years. Dearani and colleagues reported on 126 nonvalved RV-PA conduits and concluded that freedom from conduit failure was no different than for valved conduit [6]. They no longer use nonvalved conduit. We have not used non-valved conduits in more than 10 years.

Stented and Stentless Xenograft Valves in the Right Ventricular–Pulmonary Artery Position

The Contegra BVJC is under HDE category and cannot be inserted in patients over 18 years of age due to patent restrictions. The optimal prosthesis to implant in older children (>18 years) and adults is still an area of controversy. Fiore, Brown, and colleagues [54] retrospectively reviewed the performance of the Mosaic® (Medtronic) porcine, bovine pericardial, and homograft prostheses for pulmonary valve replacement to correct chronic PI. The mean age of patients receiving the prostheses was 22.7 years. All three prostheses significantly reduced chronic PI, but late insufficiency was higher with allografts [57]. Late valve dysfunction (defined as a gradient >40 mmHg or >2+ regurgitation) was highest with homografts (54%), followed by porcine (19%) and pericardial (5.5) valves ($p < .05$). Fiore *et al*. concluded that all three prostheses performed similarly for 3 years. Pulmonary regurgitation developed more rapidly and frequently in homografts, albeit there was longer follow-up in the homograft group (Figure 24.11) [54].

We reviewed 85 patients who underwent pulmonary valve replacement using a stentless (n = 61) or a stented (n = 24) porcine aortic bioprosthesis [58]. All patients except two had prior RVOT reconstruction, and patients' median age was 21 years (range, 2 to 66 years; mean, 24.7 ± 13.0 years). We found that freedom from RVOT reintervention and porcine bioprosthetic explantation was 94% and 99% at 10 years, respectively. Univariate and multivariate analyses identified none of the tested variables as a risk factor for reoperation. Freedom from RV failure and dysfunction were 97% and 96% at 5 years and 96% and 93% at 10 years, respectively. In comparing stented and stentless porcine aortic valves in the RV-PA position, we found no significant difference between the groups in postoperative data, including survival rate, follow-up resting pulmonary gradient, freedom from reintervention and explantation, dysfunction and failure (Table 24.3) [58]. These data were surprising to us because the stentless valve has a one-third larger effective orifice area.

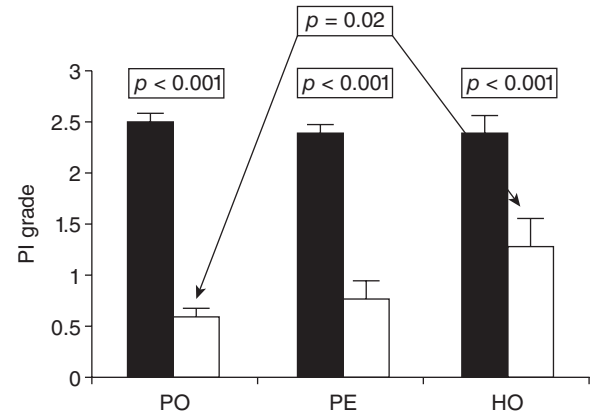

Figure 24.11 The change in pulmonary insufficiency (PI) before pulmonary valve replacement (solid bars) and at latest follow-up (open bars). PI grade: 1, mild; 2, moderate; 3, severe. HO, homograft; PE, pericardial; PO, porcine. (Reproduced with permission from Fiore *et al*. [54].)

Table 24.3 Follow-up data of patients with stented and stentless porcine aortic valves in the RV-PA position. (NYHA, New York Heart Association; PR, pulmonary regurgitation.) (Reproduced with permission from Brown *et al*. [58].)

Variable	Stentless (n = 61)	Stented (n = 24)	*P* value
Mortality (number of patients)	2 (3%)	3 (13%	0.13
Valve explantation (number of patients)	0	1 (4%)	0.28
Reintervention (number of patients)	4 (7%)	1 (4%)	1.00
Moderate PR (number of patients)	4 (7%)	1 (4%)	1.00
Follow-up pulmonary gradient (mmHg)	23.1+11.5	21.1+6.1	0.49
Pulmonary gradients >40 mmHg	5 (8%)	0	0.31
NYHA class III (number of patients)	1 (2%)	1 (4%)	0.49

Hawkins and colleagues reported on 150 patients with a stentless porcine xenograft (Medtronic Freestyle) of >19 mm in diameter between 1998 and 2008 [59]. The patients' mean weight was 50 kg and mean age was 16 years. The RVOT gradient was 13 ± 12 mmHg at 1 year and 25 ± 11 mmHg at 5 years. One hundred forty-five patients had mild or no PI, and five had moderate PI. Freedom from reoperation was 100% at 1 year and 95% at 5 years.

We concluded that the porcine aortic bioprosthesis remains an ideal valve choice for older teenagers (>18 years) and young adults with congenital abnormalities of the RVOT, especially for situations requiring reintervention [58]. We recommend using a stentless valve if a size ≥25 mm stented valve cannot be implanted.

Our current technique for stented valves is to implant them in situ in the RVOT as distally as possible and to roof them over with a small gusset of bovine pericardium if necessary. Our technique for stentless porcine valve (Freestyle) is to resect a short section of the old conduit or native PA and insert the Freestyle valve in situ with end-to-end proximal and distal suture lines to eliminate as much RVOT turbulence as possible.

Mechanical Valves in the Pulmonary Position

Mechanical valves have been used for PVR in a few centers [60,61]. Most centers recommend relatively large doses of Warfarin (International Normalised Ratio 3.5–4.5) and several reports of thromboses have been documented. We have used three mechanical valves in our population of nearly 800 pulmonary valve replacements. The only time we would consider a mechanical valve for PVR would be in an adult patient who has another mechanical heart valve that also requires Warfarin. Table 24.4 shows the reported series of mechanical valves used in the RVOT position [6, 60–67].

Bioengineered Valved Conduits for Right Ventricular Outflow Tract Reconstruction

Bioengineered valved conduits hold promise for RV-PA reconstruction. Biodegradable and biologic scaffolds have been constructed and host cells are said to populate the scaffolds; in some cases the scaffolds later disappear. To date we are not aware of valve-bearing bioengineered conduits in patients with other than short-term durability.

Gottlieb and colleagues demonstrated autologous, engineered tissue, valved conduits that function well at implantation, with subsequent monitoring of dimensions and function in real time by magnetic resonance imaging [68]. In vivo valves underwent structural and functional remodeling without stenosis, but with worsening PI after 6 weeks. Insights into mechanisms of in vivo remodeling are valuable for future iterations of engineered heart valves [68].

Critical to the current approaches to tissue-engineered heart valves is scaffold design, which must simultaneously provide immediate function (valves must function from the time of implant) as well as stress transfer to the new extracellular matrix. From a bioengineering point of view, a hierarchy of approaches will be necessary to connect the organ-tissue relationships with underpinning cellular and subcellular events [69].

When to Operate for Right Ventricular Outflow Tract Dysfunction

Right ventricular outflow tract dysfunction in children and adults is defined as moderate RVOT obstruction (≥40 mmHg) and/or greater than moderate (2+) PI. Patients with less than moderate dysfunction may remain asymptomatic or minimally symptomatic for many years. Detection of RV dysfunction before symptoms occur has become increasingly important because RV recovery may be incomplete if reconstruction is performed late. Preintervention RV volumes were independently associated with RV remodeling. Despite the substantial decrease in patients with very high preoperative RV volumes, normalization could be achieved when preoperative RV end-

diastolic volume (EDV) was <160 mL/m^2 or RV end-systolic volume (ESV) <82 mL/m^2 [70].

The indications for intervention on a dysfunctional RVOT are controversial but patients with signs and symptoms of RV failure and objective evidence of significant RVOT dysfunction should undergo reintervention. Symptoms of RV failure include palpitations, decreased exercise tolerance, and fatigue. Signs include ascites, peripheral edema, atrial and ventricular arrhythmias, decreased RV ejection fraction, tricuspid valve insufficiency, progressive increase in RV EDV and, eventually, a decrease in left ventricular (LV) function.

Echocardiography can accurately quantitate pulmonary stenosis but is considerably less accurate in quantitating regurgitation and/or the degree of RV dilation. The introduction of cardiac magnetic resonance imaging (MRI) has permitted clinicians to quantify PI, which is expressed in cubic centimeters per meter squared and/or as a regurgitation fraction. This modality also permits accurate measurement of RV EDV, which can be compared to LV EDV.

The indications for intervention on a dysfunctional RVOT are evolving but currently include patients with moderate to severe PI and/or stenosis and any of the following problems [24,71,72]:

1. exertional symptoms of New York Heart Association class II or greater;
2. decreased performance capacity on exercise testing;
3. significant RV dilation (>150 mm/m^2 by MRI);
4. a RV/LV volume ratio >1.5 in the presence of symptoms and ≥2 in asymptomatic patients;
5. regurgitation fraction >35% on MRI;
6. significant RV dysfunction;
7. atrial and/or ventricular arrhythmias;
8. QRS duration >180 ms.

Conclusion

Pulmonary valve replacement and RVOT reconstruction with a valved conduit continues to be a "weak link" in our management of congenital heart disease. Nevertheless, progress continues to be made in this area. We recommend a variety of RVOT techniques that depend on the size of the patient and the anatomy of the RVOT. We preserve the pulmonary annulus and leaflets whenever possible. When a transannular RVOT patch is necessary in an infant with tetralogy, or one of the variants, we favor the PTFE monocusp RVOT reconstruction. When a RVOT conduit is required, we favor the Contegra BJVC in infants, children,

and young adults, although patent restrictions currently limit its use in patients ≥18 years of age.

Currently in patients >18 years old who require a pulmonary valve replacement, we use the stentless porcine aortic root (Freestyle) or a stented biologic valve of at least 25 mm in diameter to achieve an adequate effective orifice area. The decellularized pulmonary homograft is our current conduit of choice for replacement of the pulmonary autograft in patients >5 years of age undergoing the Ross AVR. In the younger Ross group (<5 years old), we favor the Contegra conduit.

Regardless of the valve type, we recommend closure of the pericardium with a PTFE pericardial membrane so the RVOT or conduit does not adhere to the underside of the sternum. Our current preference is a low-porosity, 0.1 mm PTFE pericardial membrane. We have considered some other biologic materials but to date have not used them.

Our patients with complex congenital heart disease have benefited greatly by worldwide efforts to improve reconstructive options for the RVOT. Progress has been and will continue to be made in this field because the pulmonary valve is important and is the most common valve requiring replacement in children.

DOUBLE-OUTLET RIGHT VENTRICLE

Introduction

Definition

Double-outlet right ventricle (DORV) represents a complex spectrum of congenital cardiac malformations that morphologically lie between ventricular septal defect (VSD) with overriding aorta and transposition of the great arteries (TGA) with VSD. DORV remains controversial both in terms of its anatomical definition and surgical management and it presents with multiple phenotypes, including a rich spectrum of different anatomical and physiological forms. The frequently associated cardiac malformations that are seen with DORV contribute to its overall complexity. We define DORV as a type of ventriculoarterial connection in which both great vessels arise entirely or predominantly from the right ventricle [1,2]. Hearts with DORV and subpulmonary VSD (Taussig-Bing malformation) are considered a subset of DORV until the pulmonary artery arises more than 90% from the left ventricle; they are then considered a subset of TGA with VSD [3,4]. DORV is usually associated with concordant atrioventricular connections. Rarely, it is associated with discordant [5] or univentricular [6] atrioventricular connections, atrioventricular valve atresia, or atrial isomerism. This chapter focuses on the forms of DORV with two functional ventricles.

Controversies

Whether the definition of DORV should include the presence of *aortic-mitral discontinuity* is controversial. Lev and associates [1] define DORV as that condition in which both arterial trunks emerge almost completely or completely from the right ventricle, and there may or may not be aortic-mitral or pulmonic-mitral continuity. Although exclusion of cases with aortic-mitral and pulmonic-mitral continuity is semantically pure and provides a sharp dividing point between cases of tetralogy of Fallot and DORV with subaortic VSD, this concept does not satisfy the pathologic data. In the transition from tetralogy of Fallot to DORV with subaortic VSD, there is, in the pathological data, a gradual diminution in the extent of normal aortic-mitral continuity until it is completely lost. Also, the pathologist sees a gradual transition from the Taussig-Bing heart without the pulmonary trunk overriding the interventricular septum, to those with an overriding pulmonary trunk, to those with the pulmonary trunk emerging equally from both ventricles, to those with the pulmonary trunk arising more from the left ventricle, and, finally, to those with complete TGA and VSD. During this process there is a gradual development of pulmonic-mitral continuity.

Another related controversy is whether bilateral coni must be present in order to categorize a lesion as DORV. This issue may have arisen from the original description of the Taussig-Bing heart [7,8], which did, indeed, have bilateral and well developed subpulmonary and subaortic muscular coni. That may have encouraged the application of these criteria to the definition of all hearts with DORV. This concept was supported by the radiographic studies of Baron [9] and Hallerman *et al.* [10]; they used the criteria of separation of the aortic and mitral valve leaflets to distinguish radiologically between DORV and tetralogy of Fallot. Howell and his colleagues [11], in an analysis of a selected group of hearts with an unequivocally complete origin of both great arteries from the morphologic right ventricle, stated that only 37.5% exhibited complete

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

muscular and bilateral coni. They concluded that this criterion was a useful morphologic descriptor but was not mandatory for classification as DORV.

History

Peacock [12] and Rokitansky [13] documented cases of DORV in the mid-nineteenth century. In 1952 Braun and colleagues [14] coined the term, *double outlet ventricle*, in their postmortem description of the heart of a 19-year-old male with complete dextroposition of the aorta, subaortic VSD, and pulmonary stenosis. The first correct intraoperative recognition and surgical repair of DORV was at the Mayo Clinic in May of 1957. This 18-month-old male died 2 hours postoperatively of low cardiac output, perhaps owing to inadequate myocardial protection and subaortic stenosis [15]. Witham [16] published a postmortem, morphologic description of four cases of what he termed double-outlet right ventricle 1 month later. Engle *et al*. [17,18] emphasized the surgical importance of preoperative angiocardiography to distinguish DORV (with subaortic VSD and no pulmonary stenosis) from simple VSD and suggested angiographic criteria to differentiate between the two diagnoses. Neufeld and colleagues [19,20,21] published detailed clinicopathological descriptions of two distinct subsets of patients with "origin of both great vessels from the right ventricle," those with [19], and those without [20,21] pulmonary stenosis. He described the similarities of the pathophysiology of DORV with pulmonary stenosis to that of tetralogy of Fallot and underscored the importance of distinguishing between the two diagnoses in planning for surgical repair [19]. In a paper on DORV without pulmonary stenosis, Neufeld *et al*. [20] described the location and pathophysiology of VSDs committed to the aorta, the pulmonary artery and doubly committed VSDs. This insight laid the foundation for a classification of the VSDs associated with DORV. Lev, Bharati, and colleagues [1] built on these observations when they emphasized the importance of the relationship of the VSD to the great arteries: subaortic, subpulmonary, noncommitted and doubly committed. Angelini and Leachman [22], Wilcox *et al*. [23], Piccoli *et al*. [3], and Anderson and colleagues [24] demonstrated the importance of the positional relationships of the great arteries to each other.

While Pernkopf [25] mentioned DORV with subpulmonary VSD in 1926, Helen Taussig and Richard Bing [7] were the first to provide a complete clinical, angiographic, and pathophysiologic discussion of this disorder in 1949. In the postmortem examination of their 5½-year-old patient they described complete transposition of the aorta, slight levoposition of the pulmonary artery over a subpulmonary VSD, and a muscular ridge separating the pulmonary artery from the aorta. They correctly suggested that streaming accounted for the higher oxygen saturation in the pulmonary artery compared with that in both the right ventricle and the aorta. Later reports [26,27] of similar cases classified the Taussig-Bing malformation as a subset of complete TGA with VSD because the physiology of the two disorders was identical. Neufeld *et al.* [20] recognized that the Taussig-Bing heart was an anatomic subset of DORV even though it was more similar to TGA with VSD physiologically. This was confirmed when Van Praagh [8] analyzed the original Taussig-Bing heart and defined the Taussig-Bing malformation as DORV with semilunar valves side-by-side and approximately at the same height, a bilateral conus, and a subpulmonary VSD. Lev *et al.* [1] deemphasized the importance of the presence of bilateral coni and more simply defined the Taussig-Bing heart as DORV with a subpulmonary VSD. Daicoff and Kirklin [28] and Hightower and colleagues [29] performed the first successful surgical repairs of the Taussig-Bing malformation by tunneling the VSD to the pulmonary artery and performing an atrial switch (Mustard procedure). Patrick and McGoon [30] and Kawashima *et al*. [31] performed the first intraventricular tunnel repair of this disorder.

Embryology

The embryogenesis of DORV is controversial [22,32–39]. Anderson and his colleagues [33] studied the morphogenesis of a group of hearts with bulboventricular malformations. This collection included specimens with tetralogy of Fallot, DORV, and TGA with VSD. They contend that the development of this spectrum of hearts with abnormal ventriculoarterial connections is explained by departures from the normal development of portions of the bulboventricular loop. Conal malrotation, changes in the position of the anterior portion of the muscular interventricular septum, and differential conal absorption form the basis of their hypothesis.

Morphology

Sakata *et al.* [40] and Lecompte *et al.* [41] state that the classification and terminology of this complex group of patients with disorders of ventriculoarterial connection is less important than a precise definition of the preoperative anatomic criteria that are useful in determining the best type of surgical repair. Nonetheless, efforts to accurately categorize patients with DORV are necessary to make valid inferences regarding the results of different surgical treatments [3,24] for comparable anatomic subsets.

Atrioventricular and Ventriculoarterial Relationships

Atrial and Ventricular Situs

Approximately 86% of surgical patients with DORV have concordant atrioventricular connections [42]. Atrioven-

tricular discordance is present in 11% [5,42–44]. There may be atrial situs solitus, situs inversus or left/right atrial isomerism [43,45]. Hearts with DORV may have a muscular conus located beneath each of the semilunar valves (bilateral conus), a single conus beneath one of the semilunar valves or, more rarely, no conus at all.

Great Artery Relationships

There are three basic patterns of the relationship of the great arteries to each other in DORV [23]. In most cases the great arteries are normally related to one another – the aortic trunk is situated posteriorly and to the right of the pulmonary trunk, and the two great arteries spiral around each other as they leave the base of the heart. In the second group the aorta is to the right of the pulmonary artery, but these two vessels lie parallel to each other (do not spiral). They are usually side by side, although there can be any degree of anteroposterior variation. The third major group is the least common and consists of parallel trunks with the aorta anterior and to the left of the pulmonary artery (L-malposition). While it was once thought that the relationship of the VSD to the great arteries could be predicted with a reasonable degree of certainty from the relationship of the great arteries to each other [24], this has been disputed by Kirklin and associates [6].

Characteristics of the Ventricular Septal Defect

The VSD, which represents the only outflow tract for the left ventricle, is usually unrestrictive (diameter equal to or larger than the diameter of the aortic annulus). In 10% of the cases [6] the VSD is restrictive [28,46–53]. Very rarely there is no interventricular communication (Figure 25.1F) [46,54–60]. When there is no VSD, mitral valvar and left ventricular hypoplasia usually coexist. A small atrial septal defect (ASD) serves as the only source of a left-to-right shunt. In one isolated case of DORV without an interventricular communication, the anterior leaflet of the mitral valve closed the VSD. Blood shunted left-to-right through a small ASD, and a small opening in the anterior leaflet of the mitral valve allowed blood to flow from the left atrium directly into the right ventricle. In 13% of cases of DORV the VSDs are multiple [6].

Location of the VSD

The actual anatomic location of the VSD in DORV is fairly constant. Most of these defects are conoventricular; they lie

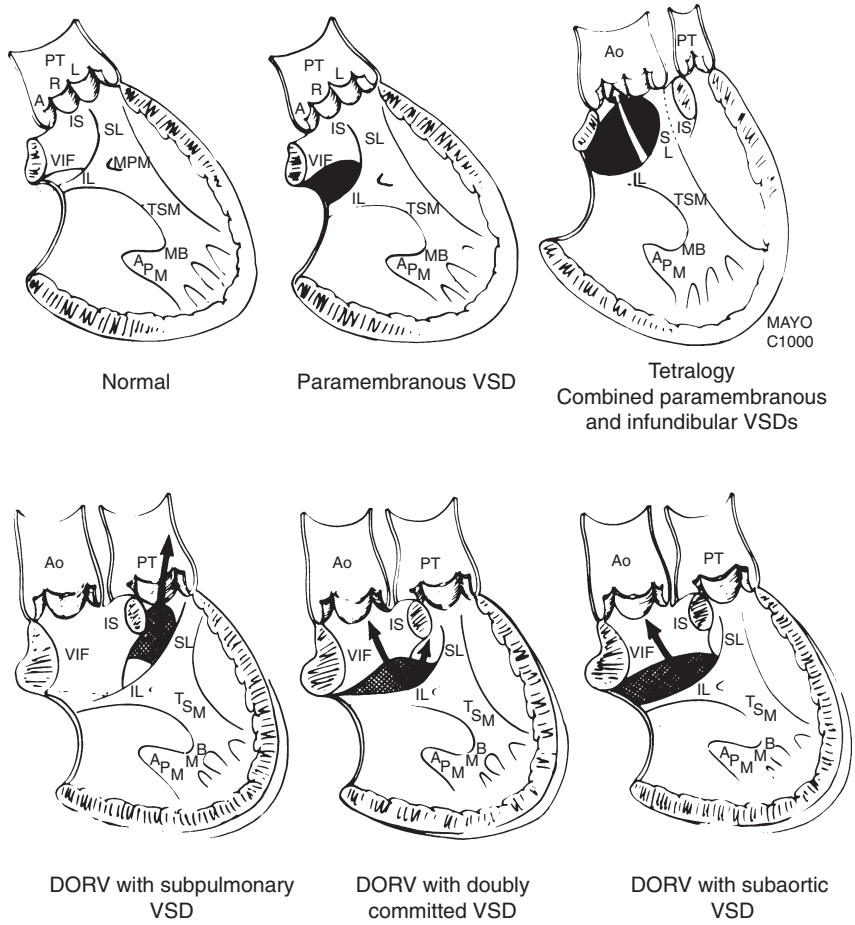

Figure 25.2 Diagrammatic representation of the location of the ventricular septal defect in hearts with an isolated perimembranous ventricular septal defect (VSD), tetralogy of Fallot, double-outlet right ventricle (DORV) with subpulmonary VSD, DORV with doubly committed VSD, and DORV with subaortic VSD. Note the location of the VSD nestled within the limbs of the trabeculoseptomarginalis (TSM). (APM, anterior tricuspid papillary muscle; IL, inferior (posterior) limb of TSM; IS, infundibular (conal) septum; MB, moderator band; PT, pulmonary trunk; SL, superior (anterior) limb of TSM; VIF, ventriculoinfundibular fold.) (Adapted with permission from Edwards [61].)

nestled within the anterior and posterior limbs of the trabeculoseptomarginalis (TSM or septal band) (Figure 25.2) [24,61]. These VSDs are not conoventricular when they are located in the inlet septum, the trabecular portion of the muscular interventricular septum, or when a perimembranous VSD extends inferiorly to occupy the inlet septum [24]. In these rare cases the VSD is typically noncommitted, challenging to repair with an intraventricular tunnel, and can be associated with any relationship of the great arteries [24].

Relationship of the VSD to the Great Arteries

The VSD in DORV is usually described in relational terms as subaortic, subpulmonary, doubly committed or noncommitted [1,19,24,57]. This relationship of the VSD to the great vessels has special surgical, rather than anatomic or embryologic, significance. These terms do not imply that the VSD moves around within the interventricular septum. To the contrary, this important relationship of the VSD to the great arteries depends more on the highly variable relationships of the great arteries to each other and on the orientation and size of the infundibular (conal) septum [24]. In DORV the terms *subaortic* or *subpulmonary* can, but do not necessarily, demand that one of the borders of the VSD is formed by a semilunar valve (juxtaarterial). This distinction between the location of the VSD within the interventricular septum and its relationship to the great arteries is important to complete understanding of this disorder.

Subaortic VSD

Subaortic VSDs (Figure 25.1A,B) [60] are the most common type and occur in approximately 50% of surgical patients with DORV [4,62]. They are located beneath the aortic

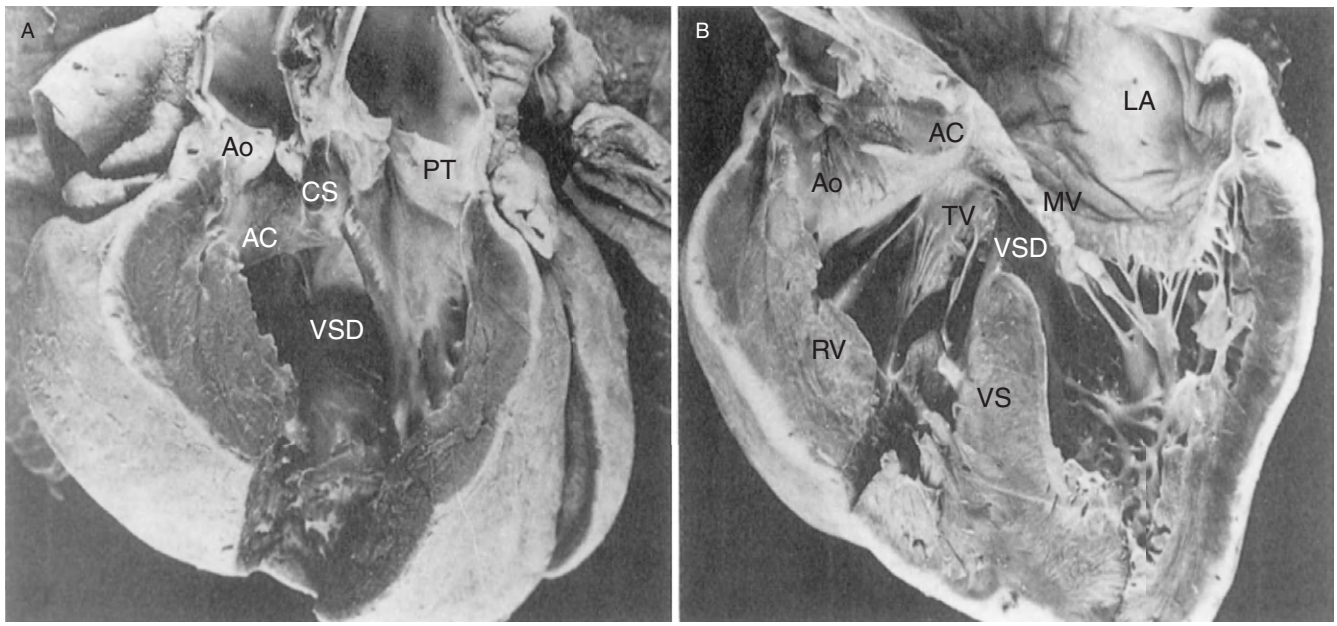

Figure 25.3 Double-outlet right ventricle with subaortic ventricular septal defect (VSD). **A,** A coronal section of the right ventricle through the aortic and pulmonary valves shows the side-by-side relationship of the great vessels. The VSD is related to the aortic valve but is separated from it by the subaortic conus. **B,** A sagittal section across the VSD demonstrates its subaortic commitment. The VSD serves as the only outlet for the left ventricle. The subaortic conus is interposed between the aortic valve and the anterior leaflet of the mitral valve. (AC, subaortic conus; Ao, aorta; CS, conal (infundibular) septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PT, pulmonary trunk; RV, right ventricular free wall; TV, tricuspid valve; VS, interventricular septum.) (Adapted with permission from Neufeld *et al.* [19].)

valve and are separated from the valve by a variable distance depending on the presence and length of the subaortic conus. When a subaortic conus is absent (by definition aortic-mitral continuity is present), the left cusp of the aortic valve or the base of the anterior leaflet of the mitral valve forms the actual posterosuperior margin of the VSD (juxtaaortic) [6]. Typical subaortic VSDs in hearts with a right-sided aorta are located in the superior interventricular septum, posterior to the infundibular septum (Figure 25.3) [19,24]. The VSDs are usually perimembranous; they reach the annulus of the tricuspid valve at its anteroseptal commissure, and there is mitral-tricuspid continuity at the posteroinferior rim of the defect. Occasionally the posterior margin of the VSD is separated from the base of the tricuspid valve by a rim of muscular tissue. This represents fusion of the ventriculoinfundibular fold and the posterior limb of the TSM (Figure 25.4) [11,24,63]. The VSD can extend inferiorly from the perimembranous region to lie partly beneath the base of the septal leaflet of the tricuspid valve [63]. In an autopsy series 77% of patients with DORV and subaortic VSDs had bilateral coni, and 23% had only a subpulmonary conus [6]. Most hearts with aortic-mitral valvar continuity will have subaortic or doubly committed VSDs, and most with pulmonic-mitral valvar continuity will have subpulmonary VSDs [11].

DORV with L-Malposition of the Aorta

When DORV is associated with L-malposition of the aorta [64–68], the VSD is usually subaortic. Although still nestled within the limbs of the TSM, the VSD lies more anteriorly and superiorly within the muscular interventricular septum than it does when the aorta is on the right side (Figure 25.5) [57]. This is similar to the position of the VSD in the Taussig-Bing heart. Typically the superior border of the VSD is the aortic valve (juxtaaortic), and the anterior and posterior limbs of the TSM form its inferior and posterior borders, respectively. The VSD can extend to the annulus of the tricuspid valve posteriorly and be perimembranous. Rarely in DORV with L-malposition of the aorta, the VSD can be subpulmonary [69], noncommitted [70], or doubly committed [71].

Doubly Committed VSD

Doubly committed VSDs (Figure 25.1D) [60] occur in approximately 10% of surgical series of DORV [4,62]. The VSD lies within the divisions of the TSM superiorly in the interventricular septum and immediately beneath the leaflets of the aortic and pulmonary valves (juxtaarterial). The pulmonary and aortic valves generally are contiguous because the infundibular septum is deficient or absent. The semilunar valves form the superior border of this typically large VSD. The TSM, with its anterior and posterior

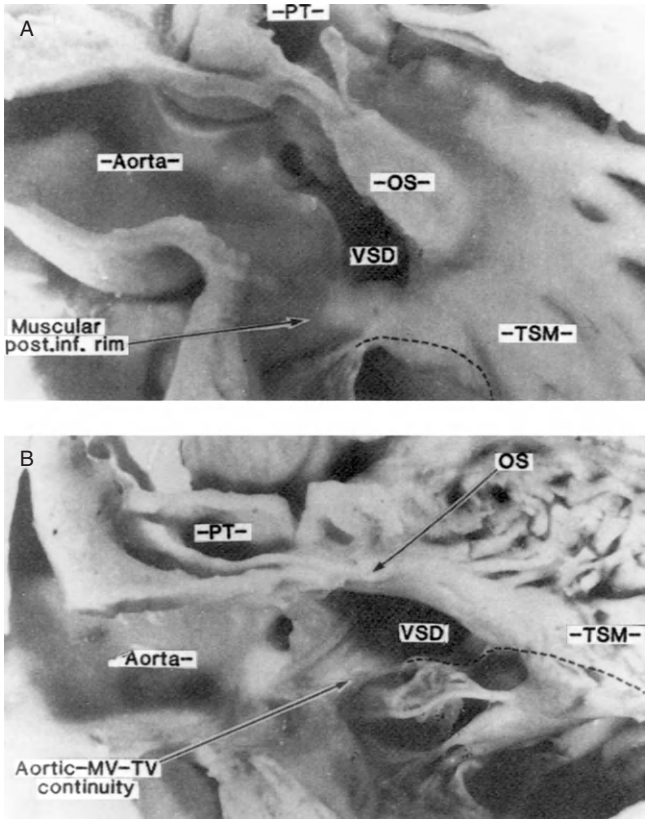

Figure 25.4 Comparison of two hearts with double-outlet right ventricle and subaortic ventricular septal defect (VSD). **A,** The posterior limb of the trabeculoseptomarginalis fuses with the ventriculoinfundibular fold to produce the muscular posterior margin of the VSD that protects the conduction tissue. **B,** In this specimen, there is no fusion of the posterior limb of the trabeculoseptomarginalis and ventriculoinfundibular fold. The VSD reaches the annulus of the tricuspid valve at its anteroseptal commissure where there is aortic–mitral–tricuspid valve continuity. The conduction tissue is vulnerable along the posteroinferior free margin of the VSD. (OS, outlet (infundibular, conal) septum; PT, pulmonary trunk; TSM, trabeculoseptomarginalis.) (Adapted with permission from Anderson *et al.* [24].)

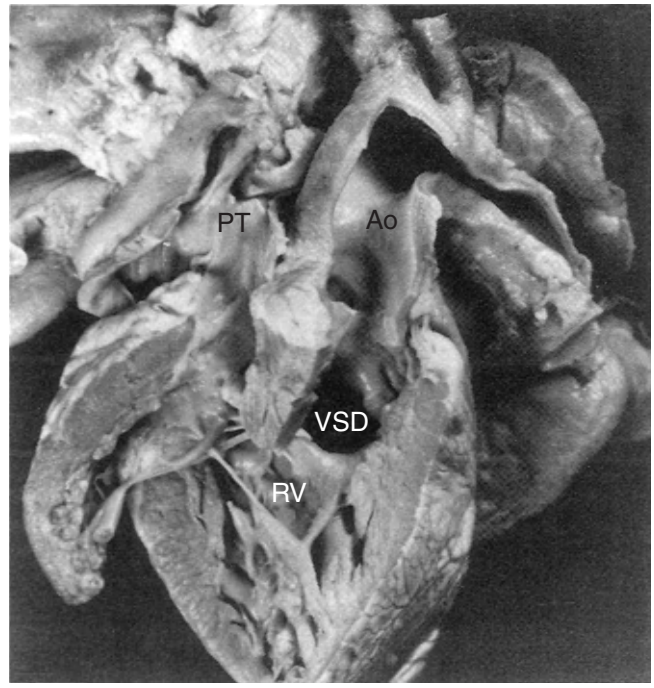

Figure 25.5 Double-outlet right ventricle with L-malposition of the great arteries and subaortic ventricular septal defect (VSD). Coronal section of the right ventricle through the aortic and pulmonary valves. The aorta is to the left and slightly anterior to the pulmonary valve (L-malposition). The VSD lies anteriorly and superiorly just beneath the aortic valve. This is similar to the position of the VSD in the Taussig-Bing malformation. (Ao, aorta; PT, pulmonary trunk; RV, right ventricle.) (Adapted with permission from Sridaromont *et al.* [57].)

divisions, makes up its anterior, inferior and posterior borders. There can be bilaterally deficient coni combined with an absent or deficient infundibular septum [6,72], or a single conus may exist beneath the two semilunar valves [6]. As both great arteries contribute to the superior border of the defect and override the interventricular septum to varying degrees, it is often difficult to determine from which ventricle the great arteries predominantly arise. For this reason Brandt and his colleagues [72] called this variant of DORV *double-outlet both ventricles*.

Subpulmonary VSD (Taussig-Bing)

Subpulmonary VSDs (Figure 25.1C) [60] are present in approximately 30% of patients in surgical series of DORV (Taussig-Bing malformation) [4,62]. These VSDs are usually unrestrictive. They lie anteriorly and superiorly beneath the pulmonary valve in the interventricular septum and are cradled within the limbs of the TSM (Figure 25.6) [73]. This VSD position is similar to that described for DORV with L-malposition of the aorta (Figure 25.5) [57,63]. In the presence of a subpulmonary conus the VSD is separated from the pulmonary valve by a variable distance, and the conus forms the superior boundary of the VSD. If there is pulmonary-mitral continuity (no subpulmonary conus), the pulmonary valve will override the VSD to a variable extent and will form its superior border (juxtapulmonary). The infundibular (conal) septum is sagittally oriented and extends from the interventricular septum to the anterior wall of the right ventricle. So oriented, the infundibular septum does not actually constitute part of the interventricular septum but separates the VSD and subpulmonary region from the subaortic region. This commits the VSD to the pulmonary artery [74]. Hypertrophy of the infundibular septum and the parietal band can cause varying degrees of subaortic obstruction [74,75]. This may account for the relatively common occurrence of coarctation of the aorta

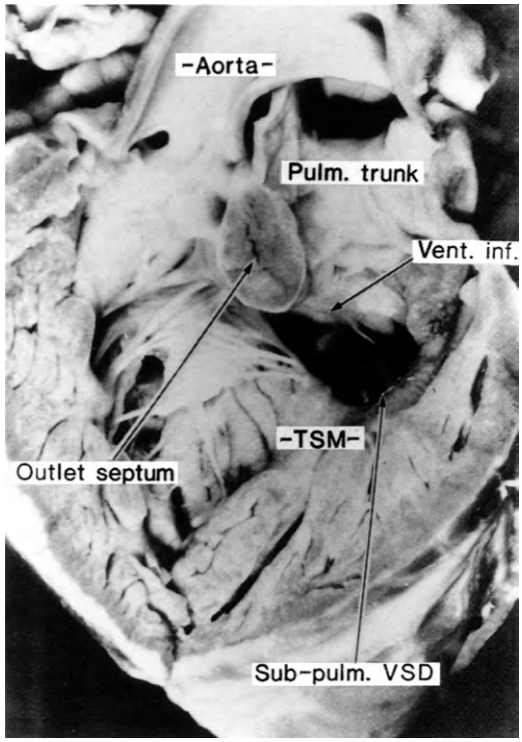

Figure 25.6 Coronal section of the right ventricle through the aortic and pulmonary valves in a heart with double-outlet right ventricle and subpulmonary ventricular septal defect (VSD) (Taussig-Bing malformation). The VSD is closely related to the pulmonary valve and is separated from the aortic valve by the outlet (infundibular, conal) septum. The ventricular septal defect extends to the tricuspid valve annulus posteriorly and, as such, is a perimembranous lesion. Note the sagittal orientation of the outlet (conal, infundibular) septum. (TSM, trabeculoseptomarginalis.) (Adapted with permission from Stellin *et al.* [73].)

(80%) in the Taussig-Bing malformation [74,76]. Bilateral coni or a single, subaortic conus each occur in approximately 50% of hearts with the Taussig-Bing malformation [6]. The pulmonary artery typically arises biventricularly. The aorta is usually to the right and is slightly anterior to or side-by-side with the pulmonary artery. These two great vessels are usually parallel; they do not spiral around each other as in the normal heart.

Noncommitted (Remote) VSD

Noncommitted [1] (remote [56]) VSDs (Figure 25.1E) [60] occur in 10–20% of patients in surgical series [4,62,77]. Lacour Gayet and associates have noted that the superior edge of these defects are located at least the distance of one aortic valve diameter from either arterial valve, both great vessels arise "200%" from the right ventricle and a double conus exists beneath both arterial valves [78,79,80]. These noncommitted VSDs are not nestled within the limbs of the TSM but rather are located within the inlet septum (without perimembranous extension) and/or the trabecular interventricular septum (Figure 25.7) [1,79,81–86]. A restrictive VSD and subaortic conus can frequently cause subaortic obstruction.

Right Ventricular Outflow Tract Obstruction

All of the variations of right ventricular outflow tract obstruction (RVOTO) that are present in hearts with tetralogy of Fallot can be present in hearts with DORV. Right ventricular outflow tract obstruction is most common in hearts with subaortic or doubly committed VSDs. It is extremely uncommon in patients with the Taussig-Bing malformation [74,87–93] and in those with noncommitted defects [1]. While RVOTO is most often infundibular, it can also be purely valvar with or without a small pulmonary valve annulus and hypoplasia of the central pulmonary arteries. Right ventricular outflow tract obstruction rarely can be caused by a diaphragm of muscle inserting between the inflow and outflow portions of the right ventricle. This produces a double-chambered right ventricle [50,94–97]. Other mechanisms of RVOTO: 1) straddling atrioventricular valve [98]; 2) accessory tissue tags; and 3) aneurysms of the membranous interventricular septum [99], occur uncommonly. Double-outlet right ventricle can rarely occur in association with pulmonary atresia.

Subaortic Stenosis

Subaortic stenosis is an uncommon, but clinically important, feature of DORV [56]. It occurs most often in those patients with subpulmonary VSD (35% of the Taussig-Bing hearts in Sondheimers series) [42]. It is especially common in Taussig-Bing hearts with aortic arch obstruction [100]. In this setting the subaortic stenosis is usually owing to a hypoplastic left ventricular outflow tract. Subaortic stenosis can also be caused by atrioventricular valve tissue, by accessory tissue tags, or by hypertrophied muscle bundles [75,101,102]. Aortic valvar stenosis [23,56] or atresia [103] can also be present.

Conduction System

In DORV with concordant atrioventricular connections, the atrioventricular node lies in the usual position in the muscular portion of the atrioventricular septum. The bundle of His penetrates the fibrous right trigone of the central fibrous body and lies along the posteroinferior margin of the VSD in lesions that are juxtatricuspid (perimembranous) whether the defect is subaortic, doubly committed, or subpulmonary. When muscle is interposed between the defect and the tricuspid valve, this muscle protects the bundle, which no longer runs along the posteroinferior free margin of the defect (Figure 25.4) [24].

Coronary Artery Anatomy

In the normal heart there are three aortic cusps. One is oriented posteriorly and is called the *noncoronary cusp*. The

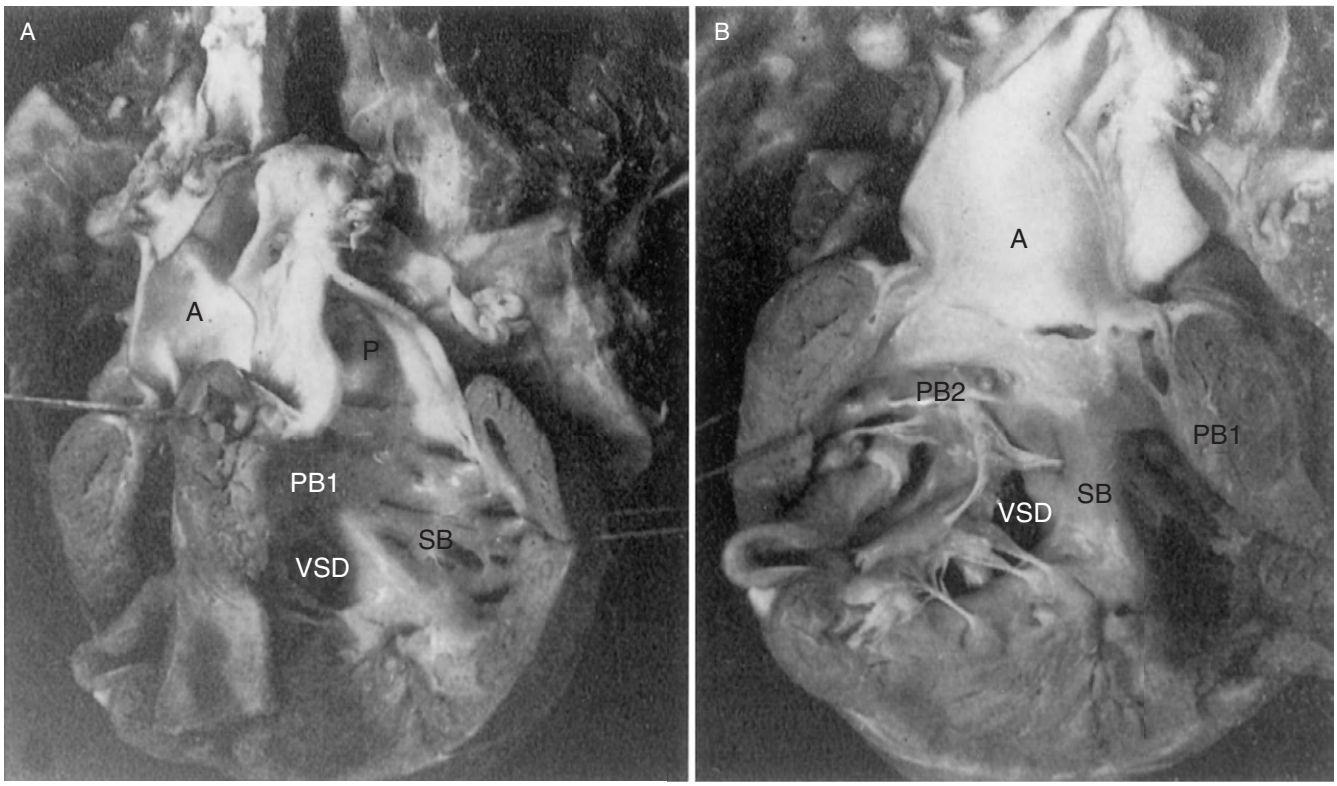

Figure 25.7 Double-outlet right ventricle with noncommitted atrioventricular canal type ventricular septal defect. **A,** Right ventricular view at the outflow tract of the pulmonary trunk. **B,** Right ventricular view at the outflow tract of the aorta. (Adapted with permission from Lev *et al.* [1].)

right anterior sinus gives rise to the right coronary artery (RCA), and the left anterior sinus gives rise to the left coronary artery. In most cases of DORV, the coronary orifices are rotated clockwise [104] as the observer looks from below. Hence, the left coronary artery arises more posteriorly and the RCA arises more anteriorly. With a right-sided and anterior aorta, the coronary artery pattern is similar to that seen in complete TGA. The RCA arises from the right posterior (facing) sinus (sinus 2), and the left coronary artery arises from the left posterior (facing) sinus (sinus 1) [104,105]. Nineteen (30%) of the patients with DORV in the series by Wilcox *et al.* [23] had coronary artery abnormalities. Two (3%) patients had a single coronary artery, one arising from sinus 1 and one from sinus 2. The branching pattern of the coronary arteries is usually normal [106]; however, in the series by Wilcox *et al.* [23] the left anterior descending coronary artery (LAD) arose from the RCA and ran anteriorly beneath the pulmonary valve across the RVOT in 16 (25%) patients. Gomes and colleagues [107,108] at the Mayo Clinic confirmed this finding. In the 3 (5%) hearts with L-malposition of the aorta in the series by Wilcox *et al.* [23], the RCA crossed anteriorly beneath the pulmonary valve on its way to the right atrioventricular groove.

Associated Cardiac Abnormalities

Almost any anomaly of the atrioventricular valves can complicate DORV and, when severe, create formidable obstacles to the performance of an anatomic repair. Examples of such anomalies include atrioventricular valve stenosis and atresia [23,55,56,109,110], straddling [23,111–117], and complete atrioventricular canal defect [118–121]. Coarctation of the aorta and other forms of left ventricular outflow tract obstruction are more common in hearts with the Taussig-Bing malformation [20,41,100,122,123]. Various other cardiac abnormalities including patent ductus arteriosus (PDA), ventricular hypoplasia (especially associated with atrioventricular valve abnormalities), unroofed coronary sinus syndrome, abnormalities of systemic venous return, juxtaposed atrial appendages, situs inversus totalis, dextrocardia, and ASD can occur.

Classification

As described earlier in the section on morphology, DORV has most often been classified anatomically in the literature according to the pure relational anatomy of the VSD to the semilunar valves: subaortic, doubly committed, subpulmo-

nary, and noncommitted (remote). The Society of Thoracic Surgeons' (STS) Congenital Heart Surgery Nomenclature and Database Project Committee, the European Association of Cardiothoracic Surgery (EACTS) and the Association of European Pediatric Cardiologists (AEPC) have adopted a more practical and functional classification of DORV. While this nomenclature system groups these four classical anatomical subtypes into categories that convey a broad sense of the VSD relational anatomy, it also categorizes them according to their clinical presentation and the general approach to their surgical repair [124]. These categories include: 1) DORV, VSD type (subaortic and doubly committed VSDs without RVOTO); 2) DORV, tetralogy of Fallot type (subaortic and doubly committed VSDs with RVOTO); 3) DORV, TGA type (subpulmonary VSDs – Taussig-Bing); and 4) DORV, remote VSD type (uncommitted VSDs with or without RVOTO) [124,125]. A fifth group, DORV+ atrioventricular septal defect (AVSD) (AV canal), has also more recently been added to encompass DORV associated with complete AVSD. This especially complex subset of DORV patients is frequently associated with heterotaxy syndrome. These patients have frequent major associated cardiac lesions including some degree of RVOTO, total anomalous pulmonary venous connection (TAPVC), and partial anomalous systemic venous return (left SVC) along with right-sided atrial isomerism and asplenia. DORV, intact ventricular septum (IVS), though virtually nonexistent, has always been included in this classification for the sake of completeness.

Pathophysiology

Patients with DORV tend to present early in life at a mean age of 2 months (range, 1 day to 4 years) [42]. Without other major cardiac anomalies, the clinical presentation of patients with DORV depends on the relationship of the VSD to the great arteries and the presence or absence of pulmonary stenosis. These basic patterns of presentation for patients with DORV can be profoundly altered by the effect of major associated cardiac lesions [126].

Congestive Heart Failure

Patients with unrestricted subaortic doubly committed or noncommitted VSDs without pulmonary stenosis have unrestricted pulmonary blood flow and present with congestive heart failure. This presentation is indistinguishable from patients with an isolated and large VSD. Although these patients are usually mildly desaturated, they are not clinically cyanotic because the high pulmonary blood flow results in well saturated right ventricular blood owing to mixing with left ventricular blood through the VSD. There is also some preferential streaming of well saturated left ventricular blood into the aorta if the VSD is subaortic or doubly committed. Congestive heart failure can also be caused by left ventricular outflow tract obstruction and an obstructive left atrioventricular valve that produces pulmonary venous obstruction.

Cyanosis

Cyanosis can be produced in patients with DORV either by restriction to pulmonary blood flow, streaming, or a combination of both. In the Taussig-Bing malformation, highly saturated left ventricular blood is preferentially directed into the pulmonary artery by the sagittally oriented infundibular (conal) septum. Since relatively desaturated right ventricular blood tends to flow into the aorta, these Taussig-Bing patients mimic patients with TGA and VSD physiologically and present early in infancy with cyanosis and congestive heart failure. In the presence of significant pulmonary stenosis with any type of VSD, cyanosis can become severe owing to reduced pulmonary blood flow. These infants are similar to patients with tetralogy of Fallot in their presentation.

Diagnosis

Physical Examination, Electrocardiogram (ECG), Chest Radiograph

There are no physical findings or ECG criteria [127] that distinguish DORV from other congenital cardiac malformations with similar clinical presentations. The usual ECG findings are right axis deviation and right ventricular or biventricular hypertrophy. The chest radiograph findings are varied and nonspecific. They depend primarily on the amount of pulmonary blood flow and the presence of associated major cardiac anomalies. In any type of DORV with an unrestrictive VSD and without pulmonary stenosis, the chest radiograph will show evidence of pulmonary overcirculation. Conversely, patients with significant pulmonary stenosis will have relatively clear or oligopenic lung fields. Patients with L-malposition of the aorta can demonstrate a vertical left upper mediastinal aortic shadow on the posterolateral chest radiograph, although this is not a specific finding for DORV.

Echocardiogram

Echocardiography is the cornerstone of the diagnosis of DORV and, because of the subtleties and complexity of the diagnosis, it is often useful for the study to be performed in cooperation with the surgeon. Two-dimensional studies accurately define the diameter, location, number, and commitment of the VSD(s), the origin of both great arteries and their relationship to each other, semilunar-atrioventricular valve continuity or discontinuity, and absence of the normal left ventricular outflow tract. It also allows the accurate

identification of: 1) right and left ventricular volumes; 2) pulmonary stenosis; 3) left ventricular outflow tract obstruction; 4) atrioventricular valve abnormalities such as straddling and/or overriding; 5) abnormal insertions of the tensor apparatus; 6) the distance between the tricuspid and the pulmonary valve annuli; 7) abnormalities of systemic and pulmonary venous return; 8) coronary artery abnormalities; and 9) the presence of complete atrioventricular canal defects [128–131].

Cardiac Catheterization and Cineangiography

Cineangiography with cardiac catheterization (Figure 25.8) [10,57] is not routinely performed unless there are anatomical features that are not adequately elucidated by the echocardiogram. If performed, these studies should be carefully examined for at least eight findings: 1) the size and relationship of the VSD to the great arteries; 2) the presence or absence of multiple VSDs; 3) the relationship of the great arteries to each other; 4) the presence or absence of pulmonary stenosis and the level(s) at which it occurs; 5) the coronary artery anatomy; 6) the presence and level(s) of left ventricular outflow tract obstruction; 7) the relationship of the atria to the ventricles (concordant or discordant); and 8) other associated cardiac anomalies. Because of the accuracy of two-dimensional echocardiography in defining most of the above features, cardiac catheterization is usually not essential for diagnosis and preoperative planning. Rather, it is reserved to define associated cardiac anomalies that are not clearly identified by the echocardiogram (coronary artery anomalies, peripheral pulmonary artery stenoses, etc.), to provide an integrated image of the pulmonary arterial tree, and to identify irreversible pulmonary vascular disease. If cardiac catheterization is not performed in a given case, there should be no suspicion of pulmonary vascular disease or peripheral pulmonary artery stenoses, and the coronary anatomy should be clearly defined by the two-dimensional echocardiogram.

Cardiac catheterization of a patient with DORV, unrestrictive VSD, and no pulmonary or subaortic stenosis will demonstrate equal pressures in both ventricles and both great arteries. Pulmonary blood flow will be high in the presence of normal pulmonary vascular resistance, and both left atrial and left ventricular blood will be highly saturated. Saturations in the right ventricle will be lower owing to the admixture of left ventricular blood with the desaturated systemic venous return. Saturations in the great arteries will depend on the position of the VSD relative to each individual great artery and the streaming produced thereby. Patients with subaortic and doubly committed VSDs will tend to have higher aortic saturations than patients with subpulmonary VSDs. Patients with subpulmonary VSDs will tend to have pulmonary saturations equal to or higher than the systemic saturation [132].

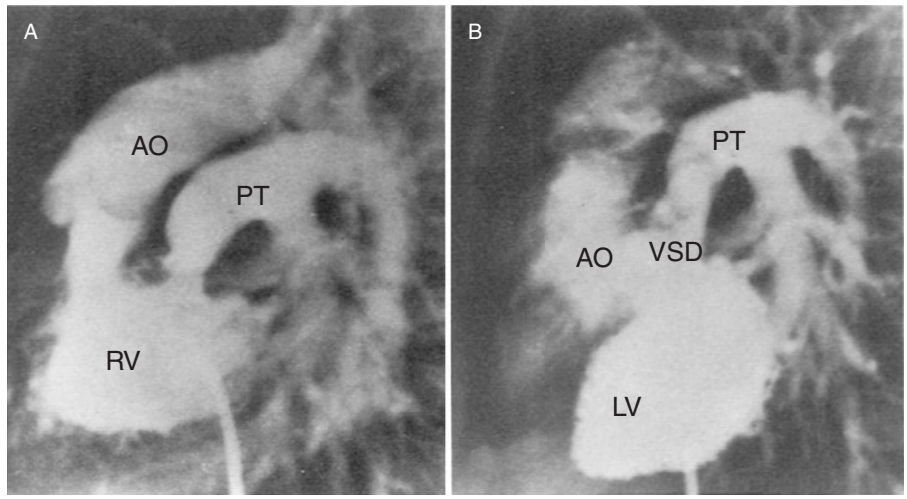

Figure 25.8 A, Lateral view of right ventricular injection in a patient with double-outlet right ventricle (DORV) and subpulmonary ventricular septal defect (VSD) (Taussig-Bing malformation). The aorta is directly anterior to the right pulmonary artery. The aortic conus (anterior to aorta), infundibular (conal) septum (between the two great arteries), and the pulmonary conus (posterior to the pulmonary trunk) are well demonstrated. **B,** Lateral view of a left ventricular injection in a patient with DORV and subpulmonary VSD (Taussig-Bing malformation). The VSD is located beneath the pulmonary artery. (Ao, aorta; LV, left ventricle; MV, mitral valve; PT, pulmonary trunk; RV, right ventricle.) (Adapted with permission from Sridaromont *et al.* [57].)

Magnetic Resonance Imaging

Magnetic resonance imaging can be useful in documenting the adequacy of the ventricular volumes for biventricular repair and in elucidating coexisting cardiac anatomy, such as abnormalities of systemic or pulmonary venous connections and other abnormalities, in some complex cases.

Natural History

The natural history of DORV with a subaortic, doubly committed or noncommitted VSD without pulmonary stenosis is similar to that of a large, isolated VSD except spontaneous closure of the VSD in DORV, a fatal event, is extremely rare [133]. The pulmonary vasculature of patients with DORV, pulmonary stenosis, and a subaortic, doubly committed or noncommitted VSD is relatively protected against the development of pulmonary vascular disease. The natural history of these patients is similar to that of patients with tetralogy of Fallot. The natural history of patients with DORV and subpulmonary VSD is similar to that of patients with TGA and VSD except for the tendency of the Taussig-Bing patients to develop pulmonary vascular disease earlier in life [6]. The natural history of any of these subsets of patients with DORV can be dramatically altered by major associated cardiac lesions such as left ventricular outflow tract obstruction and atrioventricular valve abnormalities with or without ventricular hypoplasia.

Treatment

The goal of the surgical treatment of DORV is complete anatomic repair. This is defined as connection of the left ventricle to the aorta, the right ventricle to the pulmonary artery, and closure of the VSD. In general, the timing of surgical intervention depends on the symptomatic state of the patient and the anatomy of and other cardiac anomalies associated with the DORV itself. The anatomy determines the ultimate, corrective surgical approach, which, in turn, influences the optimal age for definitive repair. The clinical state of the patient before the age at which definitive repair is planned will determine the need for initial palliative procedures. In general, a complete repair is undertaken at as early an age as possible.

Impediments to Complete Anatomic Repair

Anatomic repair of DORV can be contraindicated by the presence of ventricular hypoplasia, serious abnormalities of either atrioventricular valve, the presence of very remote and/or multiple VSDs, and the presence of irreversible pulmonary vascular disease. An atrioventricular valve with a diameter more than two standard deviations smaller than the mean normal value for the patient's body surface area is usually attended by surgically important ventricular hypoplasia. In this situation successful anatomic repair is seldom possible. Severe straddling and/or overriding of either atrioventricular valve can render anatomic repair impossible. The presence of a single VSD far removed from either of the semilunar valves and the presence of multiple VSDs can render anatomical repair more difficult or ill-advised, depending on the anatomical situation. The presence of a borderline size right ventricular volume is a limiting factor for biventricular repair because the construction of the intracardiac right ventricular tunnel will reduce the right ventricular volume even more.

General Aspects of Surgical Repair

The anatomy is assessed through the tricuspid valve and a repair is planned. The repair is performed through the tricuspid valve and/or a vertical right ventriculotomy incision. Sometimes, when the repair is carried out entirely through the tricuspid valve, exposure of the most superior portion of the VSD is enhanced by performing a radial incision along the base of the septal and anterior leaflets of the tricuspid valve and/or by exerting gentle, external, inferior pressure at the aortoventricular junction.

DORV, VSD Type (Subaortic or Doubly Committed VSD Without Pulmonary Stenosis)

Timing of Surgical Repair

This variant represents approximately 25% of all DORV and in 20% the VSD can be restrictive [80,134]. These patients should undergo complete repair in early infancy [135] because the onset of pulmonary vascular disease is at least as rapid as it is in untreated patients with large, isolated VSDs. It has also been shown that young age, per se, is not a risk factor for hospital death [4,136,137].

Technique of Intraventricular Tunnel Repair

An intraventricular tunnel repair, connecting the left ventricle to the aorta, is preferred for patients with DORV, VSD type (Figure 25.9) [60]. Rarely, in patients with refractory congestive heart failure who are thought not to be immediate candidates for complete repair, pulmonary artery banding is required. This procedure is not recommended routinely; total correction should be performed in early infancy as soon as it is felt that the patient is a suitable candidate.

The size of the VSD, as well as its location relative to the aorta, is noted. If the VSD appears to be restrictive (diameter less than that of the aortic valve), it is enlarged by making an incision anterosuperiorly or by resecting a wedge of the interventricular septum in this area (Figure 25.9A) [53,60]. Care is taken not to injure the mitral valve

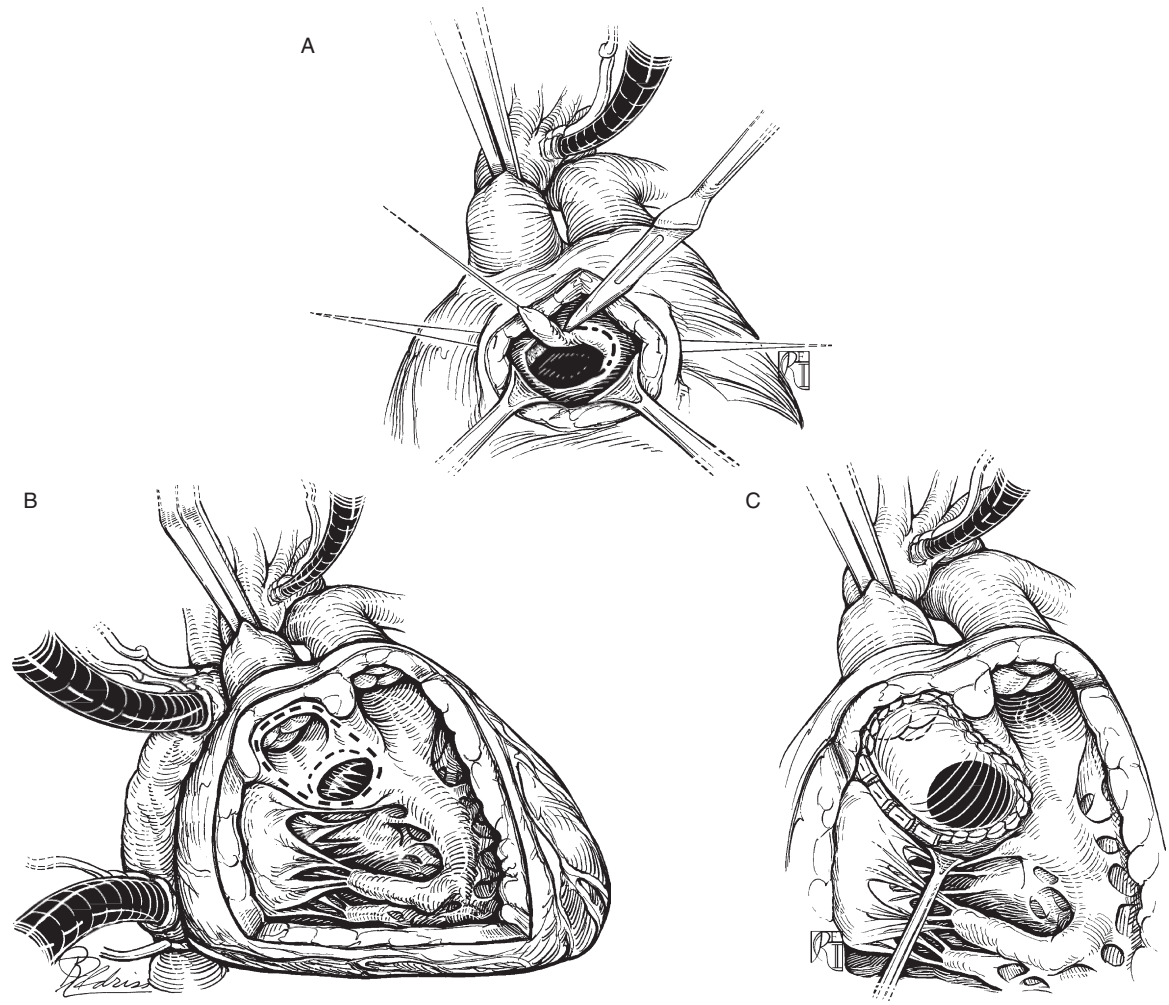

Figure 25.9 Intraventricular tunnel repair of double-outlet right ventricle with subaortic or doubly committed ventricular septal defect (VSD) without pulmonary stenosis. **A,** If the VSD is restrictive, it is enlarged by resection of the interventricular septum in the shaded area. Stippling indicates the portion of the infundibular septum that may require resection to prevent subaortic stenosis. (Inset shows the median sternotomy used for the repair.) **B,** Demonstrates the creation of a tunnel connecting the ventricular septal defect to the aorta (see text for details). **C,** The completed tunneling of the VSD to the aortic valve creating an unobstructed pathway for left ventricular blood to exit the heart.

or its tensor apparatus and to avoid injury to the anterior ventricular wall with its left anterior descending coronary artery and septal perforator [138].

Obstructive right ventricular muscle bundles are resected. Often a portion of the infundibular septum must be resected in order to construct a straight tunnel between the VSD and the aorta. It is usually possible to construct a tunnel from the left ventricle to the aorta without obstructing the pulmonary outflow tract if the minimal distance between the tricuspid valve annulus and the pulmonary valve annulus is equal to or greater than the diameter of the aortic valve annulus. Preoperatively, this distance can generally be estimated accurately with the subxyphoid view of the two-dimensional echocardiogram [40,41].

We create the intracardiac tunnel with an appropriately trimmed flat Gore-Tex patch (W.L. Gore and Associates, Inc, Flagstaff, AZ) secured with running or interrupted sutures. Alternatively, the tunnel can be constructed with a tailored dacron or Gore-Tex tube graft that takes advantage of the inherent graft curvature to create a naturally shaped and unobstructed intraventricular tunnel (Figure 25.9B,C) [60]. The long axis of the patch is oriented perpendicular to a line drawn through the center of the VSD and the center of the aortic orifice. The determination of the actual length of the patch long axis depends on the degree of dextroposition of the aorta. When the entire aorta is dextroposed into the right ventricular cavity, the patch length should be two thirds of the circumference of the

aorta. One third of the circumference of the intraventricular tunnel so created will be composed of autogenous tissue and will, therefore, retain the capacity for growth. The width of the patch should extend from the inferior edge of the VSD to the superior margin of the aortic annulus. The suture line is carried well away from the edge of the VSD along its posteroinferior margin in order to avoid damage to the conduction tissue. Posteriorly, the patch is secured to the base of the septal leaflet of the tricuspid valve. If there is a ledge of muscle separating the posterior edge of the VSD from the tricuspid annulus, the VSD sutures can be placed on the right ventricular side of the free edge of this muscle bundle; the conduction tissue does not run in this muscle along the edge of the defect. That notwithstanding, we generally choose to suture the patch to the base of the septal leaflet of the tricuspid valve and to avoid the posteroinferior margin of the VSD entirely. Sometimes the dimensions of the right ventricular outflow tract must be augmented with an outflow patch because of the production of RVOTO by the intraventricular tunnel.

Complications After Intraventricular Tunnel Repair

Complications after the intraventricular tunnel repair of DORV, VSD type are infrequent. Complete heart block is uncommon, and the functional status of at least 87% of the survivors is New York Heart Association (NYHA) Class I [4]. Over 90% of patients who require only intraventricular tunnel repair for subaortic or doubly committed VSDs are free of reoperation at follow-up. Indications for reoperation should be rare but can include tunnel dehiscence, tunnel obstruction, residual VSD, and discrete, localized subaortic stenosis unrelated to the tunnel itself [4].

Results After Intraventricular Tunnel Repair

In the current era, the risk of death early after repair of DORV, VSD type is low [4,77]. The actuarial 15-year survival, including hospital death, is 96%. In an earlier era, younger age was a risk factor for death after repair. At the present time, the effect of younger age has been neutralized; however, older age has been shown to be a significant risk factor, possibly owing to the presence of increasing pulmonary vascular disease with age [4].

DORV, tetralogy of Fallot Type (Subaortic or Doubly Committed VSD with Pulmonary Stenosis)

Timing of Surgical Repair

This is the most frequent form of DORV and the pulmonary stenosis can range from a relatively mild valvar, subvalvar, and/or supravalvar pulmonary stenosis to frank pulmonary atresia. It may be difficult to differentiate between tetralogy of Fallot and DORV, tetralogy of Fallot type because of the significant anterior malposition of the aorta in both. In the presence of DORV, tetralogy of Fallot type the techniques of repair are similar to those described for repair of tetralogy of Fallot except the VSD is closed with the tunnel technique rather than with a straight patch. Repair is generally advised by 6 months of age if the coronary artery anatomy is normal and if it is felt, with certainty, that an intraventricular repair can be performed. If the preoperative clinical condition of the patient is poor or if there are major associated noncardiac abnormalities, a palliative systemic-to-pulmonary artery shunt may be advisable before performing the definitive repair later in life. An initial systemic to pulmonary artery shunt may also be reasonably considered if the branch pulmonary arteries are severely hypoplastic and/or it is felt that an extracardiac conduit will be required for the final correction. Others advocate early primary repair for essentially all patients with DORV, thereby avoiding the need for palliative procedures with their attendant risks and complications [135].

Strategies of Surgical Repair

We prefer to avoid placement of a transannular patch. When a transannular patch is necessary (Figure 25.10A) [60] owing to pulmonary annular hypoplasia and/or pulmonary valve stenosis, the aggressive use of transatrial and transpulmonary endocardial resection of hypertrophied and obstructive muscle bundles is recommended. This allows the surgeon to limit the distance the transannular incision must be carried into the right ventricular outflow tract and to avoid possible right ventricular dysfunction associated therewith. When exposure of the VSD through the tricuspid valve is unsatisfactory, we do not hesitate to perform a right ventriculotomy. In patients with an anomalous coronary artery crossing the right ventricular outflow tract immediately beneath the pulmonary valve annulus and in patients with a suspected or measured elevation of pulmonary vascular resistance, it is necessary to place a valved, extracardiac conduit when endocardial resection alone will not relieve the RVOTO (Figure 25.10B) [60]. Patients with pure valvar pulmonary stenosis and a normal pulmonary annulus and arterial tree can undergo pulmonary valvotomy or valvectomy. Similar patients with mild-to-moderate pulmonary vascular disease may benefit from the orthotopic placement of a homograft pulmonary valve.

Results of Surgical Repair

The functional status of survivors of repair of DORV, tetralogy of Fallot type is excellent. The time-related actuarial freedom from reoperation after placement of a heterograft valved conduit from the right ventricle to the pulmonary artery is only 50% at 10 years [4]. Although antibiotic-sterilized, cryopreserved homografts are frequently used because of their excellent handling characteristics, it is not known with certainty whether they are more durable. The early and late survival of this group of patients is similar

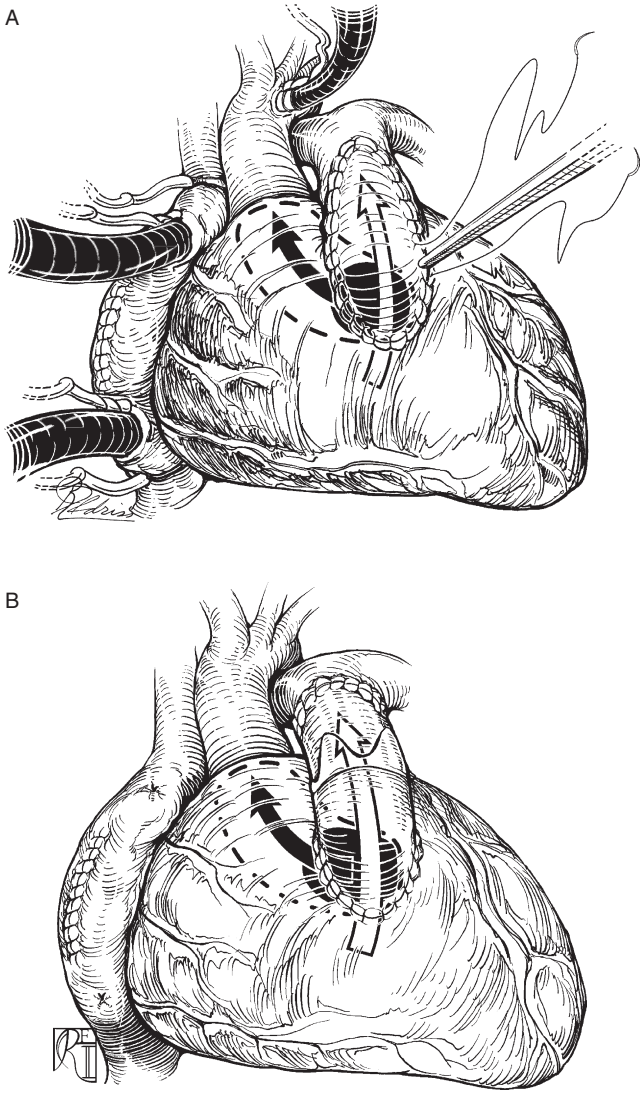

Figure 25.10 Reconstruction of the right ventricular outflow tract during repair of double-outlet right ventricle with subaortic or doubly committed ventricular septal defect. **A,** Patch enlargement of the right ventricular outflow tract with transannular extension into the main pulmonary artery. **B,** The use of a valved, extracardiac conduit to establish continuity between the right ventricle and pulmonary artery.

to that described for patients without pulmonary stenosis if the repair of the pulmonary stenosis did not require the placement of an extracardiac conduit or a transannular patch. In these latter two groups, the instantaneous risks of death in the early and late hazard phases are higher than when simpler forms of relief of RVOTO are used [4].

DORV, TGA Type (Subpulmonary VSD)

DORV, TGA type, as stated earlier, is frequently associated with aortic arch obstruction, subaortic obstruction, side-by-side positioning of the great vessels, and a significant diameter mismatch of the great vessels, with the aortic valve diameter being significantly smaller than that of the pulmonary valve. Surgical repair of this complex subset of patients has evolved over the years: 1) patch tunneling of the VSD to the pulmonary artery combined with an atrial switch procedure (Mustard or Senning) [3,4,29,63,136,139,140]; 2) tunneling of the VSD to the pulmonary artery, aortopulmonary connection (Damus-Kaye-Stansel procedure) and placement of a valved extracardiac conduit from the right ventricle to the distal pulmonary artery [141–143]; 3) direct tunneling of the VSD to the aorta (Kawashima repair) [3,4,27,30,63,74,144–157]; 4) tunneling of the VSD to the pulmonary artery combined with an arterial switch procedure [62,158–160]; and, in select situations, 5) VSD closure to the aorta with placement of a right ventricular-to-pulmonary artery conduit (Rastelli procedure) [161,162], tunneling of the VSD to the aorta with translocation of the pulmonary artery (réparation à l'étage ventriculaire [REV] procedure of Lecompte) [40,41,163–169], or aortic translocation and biventricular outflow tract reconstruction (Nikaidoh procedure) [169–172]. Some of these surgical approaches are of historical importance only because they are no longer used clinically.

Intraventricular Tunnel Repair for the Taussig-Bing Malformation

One approach for the repair of DORV with subpulmonary VSD is a totally intraventricular repair without the need for the arterial switch operation or for the use of an extracardiac conduit. This type of repair has been accomplished using a number of techniques: 1) the posterior, tubular conduit repair of Abe and colleagues [151–153]; 2) the anterior, tubular conduit method of Doty [150]; 3) the anterior, spiral tunnel repair of Patrick and McGoon and colleagues [30,144,154]; and 4) the posterior, straight tunnel technique of Kawashima [31,144,147,156]. Of these four techniques, the Kawashima operation is the only totally intraventricular tunnel technique that is currently used by some surgeons to repair certain forms of the Taussig-Bing malformation.

The Kawashima Operation

When the great arteries are in a more or less side-by-side relationship with the aorta to the right of the pulmonary artery, the Kawashima [31,144,147,155–157] repair connects the left ventricle directly to the aorta with a tunnel that runs posterior to the pulmonary artery between the tricuspid and pulmonary valves (Figure 25.11) [60]. The infundibular (conal) septum must be resected in order to provide an unobstructed path for the tunnel (Figure 25.11B) [60]. The VSD is enlarged only if it is restrictive. Because this tunnel courses between the pulmonary and tricuspid valve annuli,

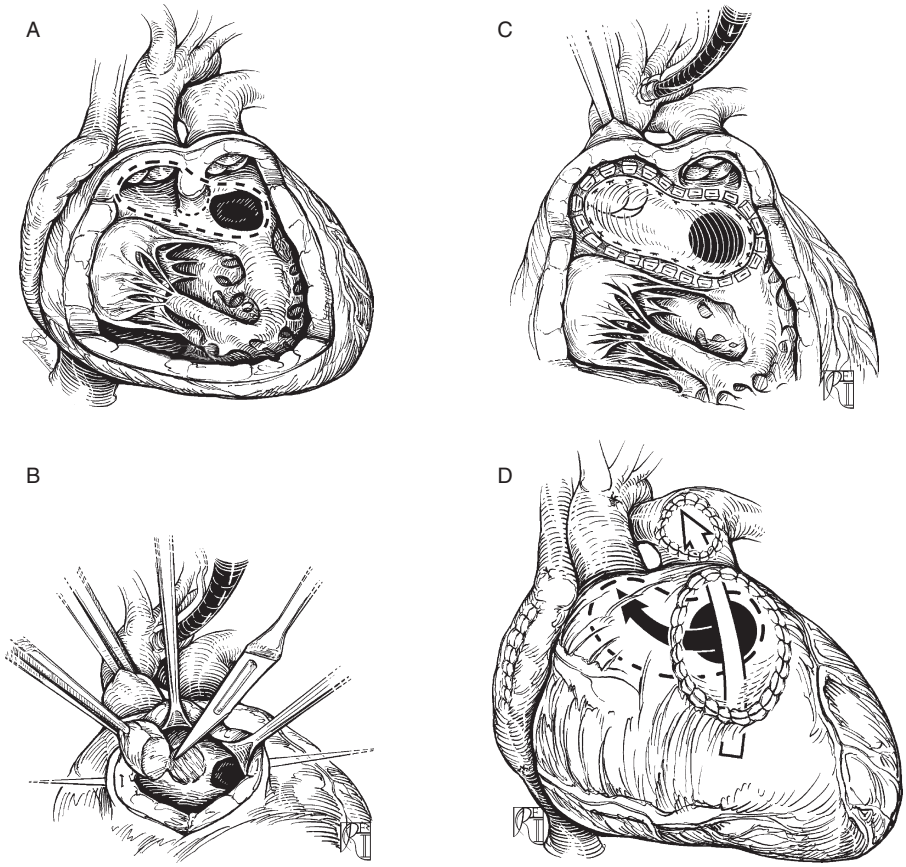

Figure 25.11 The Kawashima operation for double-outlet right ventricle with subpulmonary ventricular septal defect (VSD) (Taussig-Bing malformation). **A,** Inner, small dashed line indicates the portion of the infundibular (conal) septum that may require resection before construction of intraventricular tunnel (outer dashed line). **B,** A generous resection of the infundibular (conal) septum is performed in order to create an unobstructed path between the subpulmonary VSD and the aorta. **C,** The figure depicts the completed intraventricular tunnel repair. Note that there must be sufficient distance between the tricuspid valve and pulmonary valve annuli in order to create the tunnel successfully. **D,** It is sometimes necessary to augment the right ventricular outflow tract in order to relieve subpulmonary stenosis created by the tunnel or to relieve various preexisting pulmonary stenoses.

these two structures must be separated by a sufficient distance to make tunnel creation possible (Figure 25.11C) [60]. In patients with an oblique or anterior-posterior relationship of the great arteries, the tricuspid-pulmonary valve distance may not be great enough to allow the creation of this tunnel, and the arterial switch technique must be employed. The Kawashima repair can be performed either through the tricuspid valve or through a right ventriculotomy. Abnormal attachments of the tricuspid valve tensor apparatus onto the infundibular septum or straddling and/or overriding of the mitral valve may make this repair difficult or impossible.

Results of the Kawashima Operation

The series that report follow-up data on patients undergoing the Kawashima operation [31,74,144,155–157] is small; however, all reported patients were alive and well. One report [155] documents a series of 10 patients out of 41 with the Taussig-Bing malformation who underwent a completely intraventricular repair. The relationship of the great arteries was side-by-side in nine patients and oblique in one patient. Average follow-up was 8 years and 4 months. There were no early or late deaths and reoperation was required in only one patient (residual pulmonary stenosis). Postoperative cardiac catheterization in eight patients showed no clinically significant subaortic stenosis. However, the right and left ventricular volumes were elevated, and the right ventricular ejection fraction was reduced. In summary, the Kawashima operation can be reasonably recommended in patients with a side-by-side relationship of the great arteries and, perhaps, in some with an oblique relationship. If elected, this operation should be

performed as a primary procedure in early infancy. The trend, however, in most institutions has been toward the arterial switch operation even in those patients with side-by-side great vessel orientation.

The Arterial Switch Operation with Tunnel Closure of VSD

The most common approach to the repair of DORV with subpulmonary VSD is the arterial switch procedure combined with tunnel closure of the VSD to the pulmonary artery [157–160,173–177]. The advantage of this technique compared, for example, with the Kawashima operation is its flexibility in that it can be used successfully for the repair of Taussig-Bing hearts with any and all arrangements of the great arteries. The arterial switch operation is optimally performed in the first week of life before the patency of the ductus arteriosus is maintained by a prostaglandin infusion. A preoperative balloon atrial septostomy procedure is usually not required because of adequate mixing at the level of the PDA, the ASD, and the large subpulmonary VSD. In the absence of subaortic obstruction, palliation with aortic arch repair and pulmonary artery banding through a left thoracotomy incision may be considered. This is especially appropriate in cases of Swiss-cheese septum, concern over adequate size of the right ventricle, straddling of the atrioventricular valve or when serious, confounding medical conditions, like severe prematurity, necrotizing enterocolitis or subarachnoid hemorrhage, are present. Otherwise, single-stage repair is preferred [177].

Initial phase (no aortic arch obstruction). Through a standard median sternotomy incision, the thymus is excised and the heart is suspended in a pericardial cradle. The ascending aorta, main pulmonary artery, and PDA are circumferentially dissected, and marking sutures are placed on the pulmonary artery (neoaorta) to mark the site at which coronary artery transfer is to occur. During the initial cooling phase of cardiopulmonary bypass the PDA is snared, the separation of the ascending aorta from the main pulmonary artery is completed, and the right and left pulmonary arteries are dissected circumferentially well beyond their branching points to achieve a tension-free mobilization. The ductus arteriosus is then suture ligated at its pulmonary and aortic ends and is divided. If the Lecompte maneuver is performed, it is facilitated by performing a relatively high aortic transection and a low transection of the main pulmonary artery. The technical details of the arterial switch operation in DORV, subpulmonary VSD (Taussig-Bing malformation) not associated with aortic arch obstruction are illustrated in Figures 25.12–25.14 [60].

Initial phase (aortic arch obstruction). When there is associated aortic arch obstruction with aortic arch hypoplasia and a small ascending aorta (80% of hearts with the Taussig-Bing anomaly) (Figure 25.15), a right radial arterial

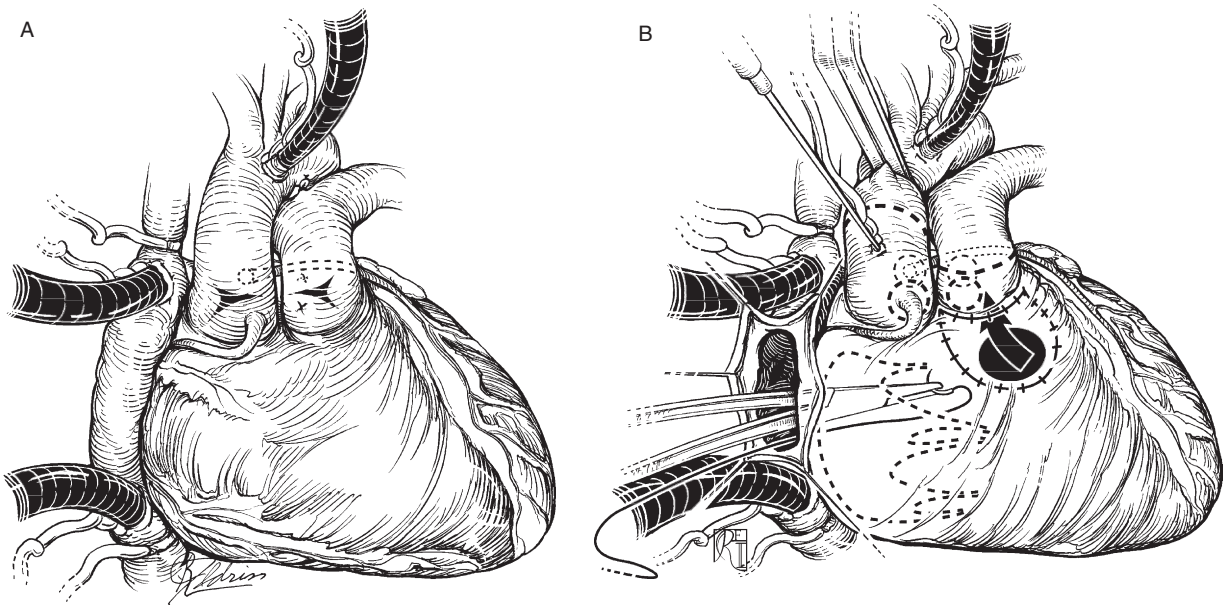

Figure 25.12 The arterial switch operation with tunnel closure of the ventricular septal defect (VSD) in patients with double-outlet right ventricle with subpulmonary VSD (Taussig-Bing malformation) *without* aortic arch obstruction. **A,** External appearance of the heart after cannulation for institution of cardiopulmonary bypass. The sites for coronary artery transfer to the pulmonary trunk (neoaorta) are marked with sutures. The ductus arteriosus has been ligated and divided. **B,** The VSD is closed transatrially or transventricularly. The levels for transection of the great arteries are marked with broken lines. It is assumed, in this illustration, that the Lecompte maneuver will not be used (see text for details of performing the Lecompte maneuver).

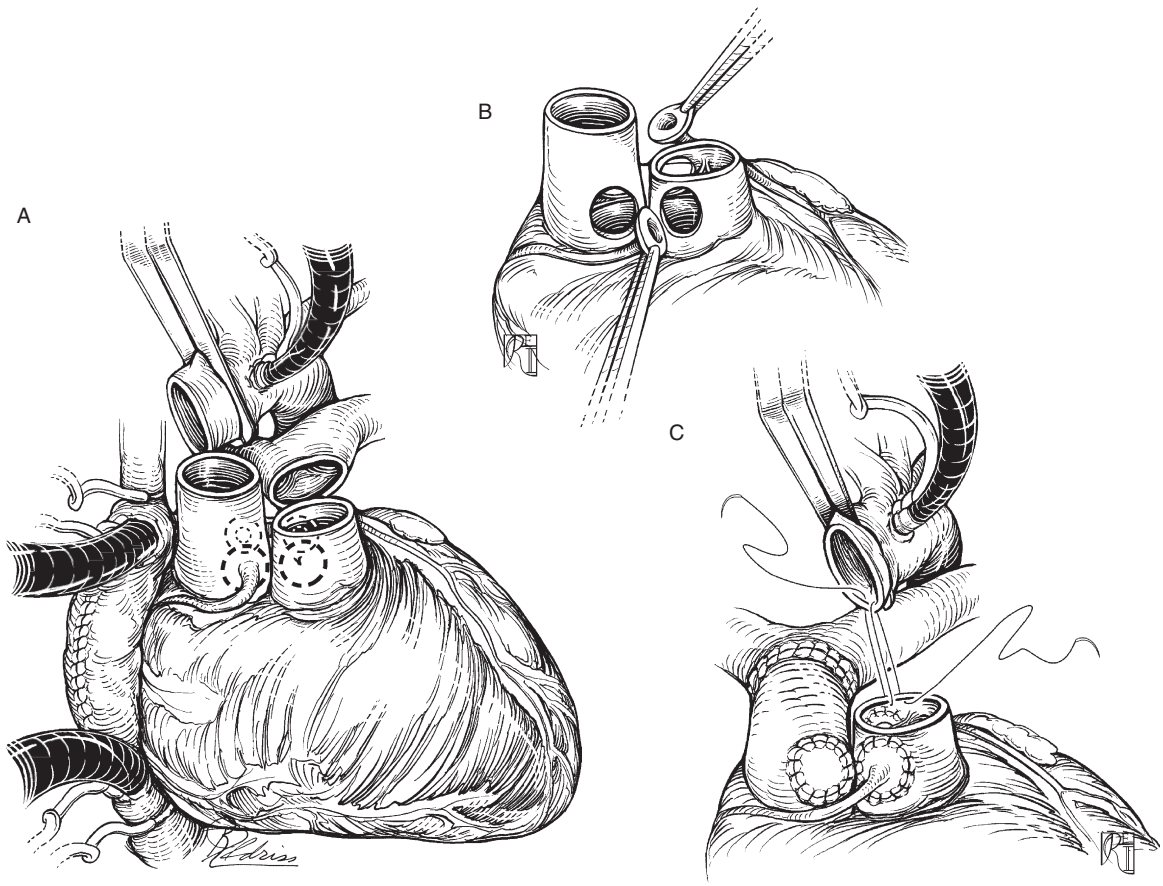

Figure 25.13 The arterial switch operation with tunnel closure of the ventricular septal defect in patients with double-outlet right ventricle with subpulmonary ventricular septal defect (Taussig-Bing malformation) *without* aortic arch obstruction. **A,** The great arteries are transected as if no Lecompte maneuver is to be performed (see text for details). **B,** The coronary artery orifices are excised with a button of native aortic wall. Ovals of the pulmonary artery (neoaortic root) are removed at the previously marked sites in preparation for coronary artery transfer. (Alternatively, these openings in the neoaortic root can be created as *U-shaped defects* or as medially hinged *trap-door* incisions. See Chapter 26, *Transposition of the Great Arteries*.) **C,** The defects in the aortic wall (neopulmonary root) are repaired with autologous pericardium. (Alternatively, this can be accomplished with a pantaloon patch. The mobilized coronary arteries are transferred to the neoaortic root and are sutured thereto without tension or kinking. The distal transected main pulmonary artery bifurcation is sutured to the neopulmonary root.

line and a femoral or umbilical arterial line are inserted preoperatively. The initial dissection is similar to that described above. A technique of dual arterial cannulation with antegrade cerebral perfusion is described in this chapter. An 8F arterial cannula is placed in the main pulmonary artery and is advanced through the PDA into the descending aorta. During the initial cooling phase of cardiopulmonary bypass the PDA is snared around the arterial cannula, the separation of the ascending aorta from the main pulmonary artery is completed, and the right and left pulmonary arteries are dissected circumferentially well beyond their branching points to achieve a tension-free mobilization. The entire transverse arch and brachiocephalic vessels are circumferentially dissected and fully mobilized during the initial cooling phase to 18 °C. During the cooling phase, a 3.5 mm Gore-Tex tube graft is sutured to the innominate artery and is cannulated with a second 8F arterial cannula to mediate antegrade cerebral perfusion and to remove the second arterial cannula from the surgical field. This facilitates exposure and minimizes distortion of the aorta during the reconstruction.

After temporarily occluding the brachiocephalic vessels and during a brief period of deep hypothermic circulatory arrest (DHCA), the PDA is divided and then oversewn at its pulmonary end. The ascending aorta is divided (see details below in Coronary artery translocation). The aortic isthmus is divided at a point just beyond the origin of the left subclavian artery and all coarctation and ductal tissue are excised (Figure 25.16). A vascular clamp is placed across the transected, proximal descending thoracic aorta and antegrade cerebral perfusion is initiated. The proximal descending aorta is fully mobilized deep into the posterior

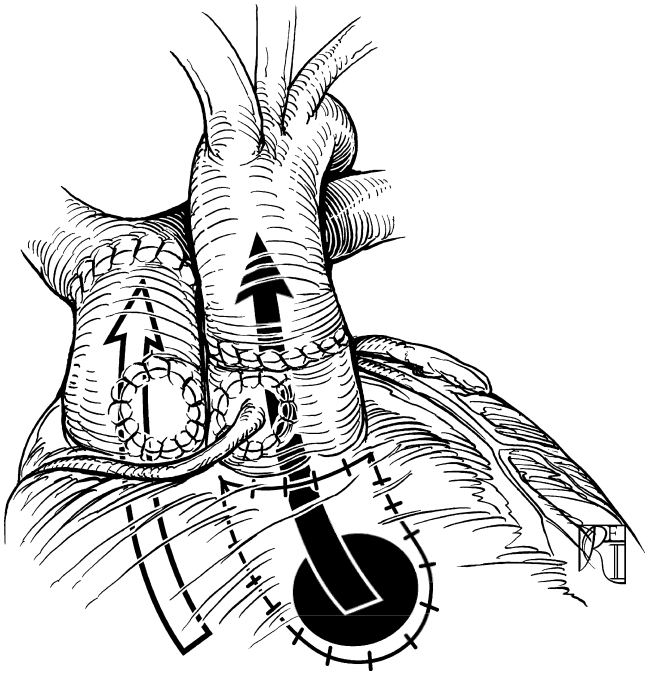

Figure 25.14 The arterial switch operation with tunnel closure of the ventricular septal defect in patients with double-outlet right ventricle with subpulmonary ventricular septal defect (Taussig-Bing malformation) *without* aortic arch obstruction. The neoaortic root is sutured to the distal transected ascending aorta to restore left ventriculoarterial concordance. The neopulmonary root was previously sutured to the distal transected main pulmonary artery bifurcation to restore right ventriculoarterial concordance.

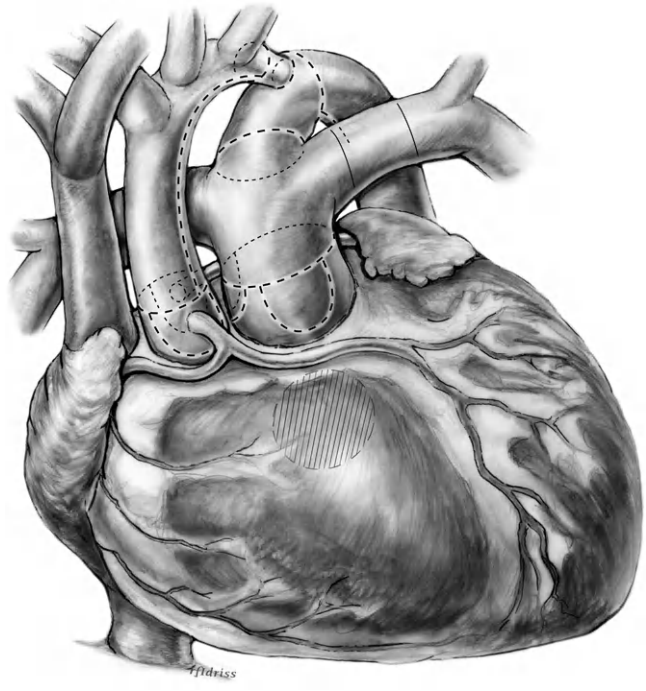

Figure 25.15 The arterial switch operation with tunnel closure of the ventricular septal defect (VSD) in patients with double-outlet right ventricle with subpulmonary VSD (Taussig-Bing malformation) *with* aortic arch obstruction. The great vessels are oriented in a side-by-side configuration. Note the mismatch in the diameter of the ascending aorta and main pulmonary artery. There is severe transverse aortic arch hypoplasia with a coarctation of the aorta. The hypoplastic distal transverse aortic arch inserts, at the point of the coarctation, into the patent ductus arteriosus. The right coronary artery (RCA), arising from the anterior facing sinus, gives rise to the left anterior descending (LAD) coronary artery. The LAD passes leftward and immediately inferior to the native pulmonary valve (neoaortic valve) annulus on its way to the anterior interventricular groove. The coronary artery arising from the posterior facing sinus is the circumflex coronary artery and it passes posterior to the pulmonary artery trunk. The dotted lines represent incisions for the proposed division and ligation of the patent ductus arteriosus, the aortic arch reconstruction and the arterial switch operation. The circular parallel lines represent the location of the subpulmonary VSD.

mediastinum, cauterizing and dividing intercostal vessels along the way, to facilitate mobilization of the descending aorta, and to ensure a tension-free aortic reconstruction. Once the mobilization of the descending thoracic aorta is complete, an incision is made in the inferior aspect of the transverse aortic arch and is extended proximally into the transected point of the ascending aorta. Part of the circumference of the transected proximal descending thoracic aorta is sutured to transected aortic isthmus. A 2 cm counter-incision is made into the inferior aspect of the proximal descending aorta (Figure 25.16). A pulmonary homograft patch is then used to augment the primary aortic anastomosis, the transverse aortic arch, and the distal ascending aorta (Figures 25.16, 25.17). The proximal width of this homograft patch augments the circumference of the transected ascending aorta to match the circumference of the native pulmonary (neoaortic) root. Care should be taken to avoid making the pulmonary homograft patch too wide proximally, thereby creating a bulbous aortic reconstruction that tends to kink or compress surrounding structures (Figure 25.17). The aorta is deaired while placing a cross-clamp above the cardioplegia needle. Antegrade cerebral perfusion through the Gore-Tex tube graft is then transitioned to full-flow by removing the occluders on the brachiocephalic vessels and increasing the flows. The quality of the aortic arch reconstruction can be immediately assessed by comparing the umbilical/femoral pressures with the right radial arterial pressures.

An alternative approach to the technique described above consists of augmenting the entire length of aortic arch with a pulmonary homograft patch without dividing the aortic isthmus. After instituting DHCA, the PDA is divided, and its pulmonary end is oversewn. The proximal descending thoracic aorta is fully mobilized and a vascular

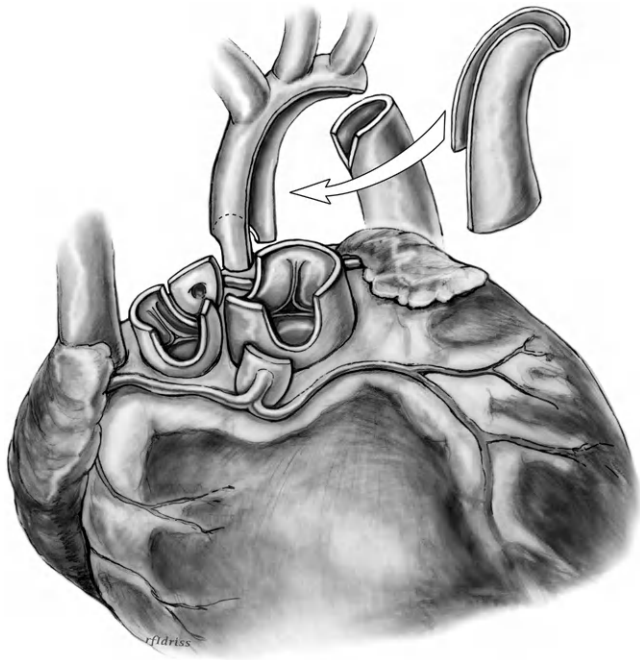

Figure 25.16 The arterial switch operation with tunnel closure of the ventricular septal defect (VSD) in patients with double-outlet right ventricle with subpulmonary VSD (Taussig-Bing malformation) *with* aortic arch obstruction. The patent ductus arteriosus is divided and the pulmonary end is oversewn. The ascending aorta and the aortic isthmus are divided. The descending thoracic aorta is mobilized and all coarctation/ductal tissues are excised. The aortic arch is repaired by partial direct anastomosis with patch (homograft) enlargement as depicted in the figure and as explained in detail in the text. Note the counter-incision in the posterior aspect of the distal, transected ascending aorta to accommodate the high insertion of the circumflex coronary artery.

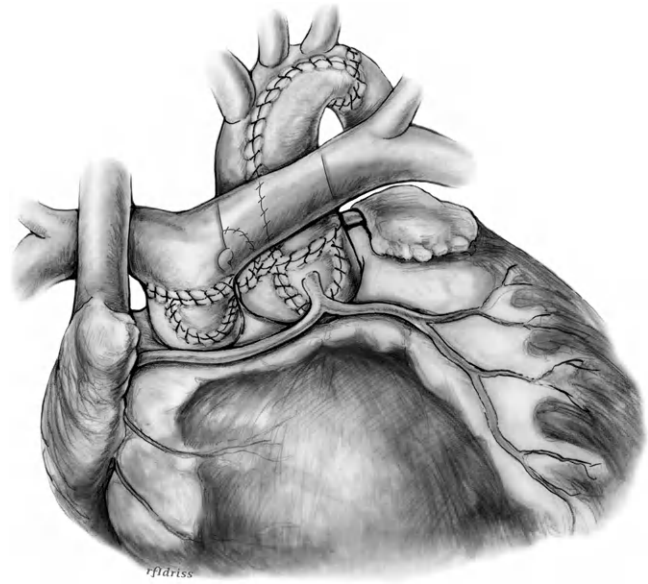

Figure 25.17 The arterial switch operation with tunnel closure of the ventricular septal defect (VSD) in patients with double-outlet right ventricle with subpulmonary VSD (Taussig-Bing malformation) *with* aortic arch obstruction. Note the partial direct anastomosis of the proximal descending thoracic aorta to the transected aortic isthmus and the augmentation of this anastomosis, the transverse aortic arch and the ascending aorta with the homograft patch. This completed aortic arch repair creates an excellent size match between the augmented ascending aorta and the neoaortic root. The circumflex coronary artery translocation is high relative to the right coronary artery translocation (see text for details). The defects in the neopulmonary root are filled with a pantaloon patch of fresh, autologous pericardium. When a Lecompte maneuver is used it is necessary to fashion a leftward shift in the anastomosis of the neopulmonary root to the pulmonary artery bifurcation (see text for details).

clamp is placed well distal to the aortic insertion of the PDA. Antegrade cerebral perfusion through the Gore-Tex tube graft is initiated. The ductal tissue is completely excised and the ascending aorta is transected at a previously marked point above the native aortic valve commissures. An incision is initiated at the medial aspect of the transected ascending aorta and is extended along the inferior aspect of the transverse aortic arch past the coarctation site and into the proximal, descending thoracic aorta to a point well beyond the aortic insertion of the excised PDA. The ascending aorta, transverse arch, and descending aorta are then augmented, in continuity, using a pulmonary homograft patch, as described above. The aorta is deaired, a cross-clamp is placed and standard cardiopulmonary bypass is resumed.

VSD closure. Owing to the malalignment of the conal septum, that is usually entirely located within the right ventricle, two orifices can be defined: the interventricular communication, which is the only outlet of the left ventricle, and the VSD, located between the conal septum and the muscular septum (Figure 25.18). It is the latter that is to be closed in tunneling the left ventricle to the pulmonary artery. The inferior and posterior margins of the VSD can frequently be closed using a transatrial approach through the tricuspid valve. A vertical right ventriculotomy incision is also frequently required to adequately visualize the anterior and, especially, the superior margins of the VSD. This also affords good visualization of the infundibular (conal) septum to facilitate relief of subaortic obstruction. Approaching the VSD through the native pulmonary valve (neoaortic orifice) is associated with the development of aortic valve regurgitation [188]. Closure of part of the VSD through the native aortic (neopulmonary) valve, after harvesting the coronary buttons is a safer approach. Once the VSD is closed, the patency of the newly reconstructed left ventricle outflow is ascertained through the pulmonary (neoaortic) valve.

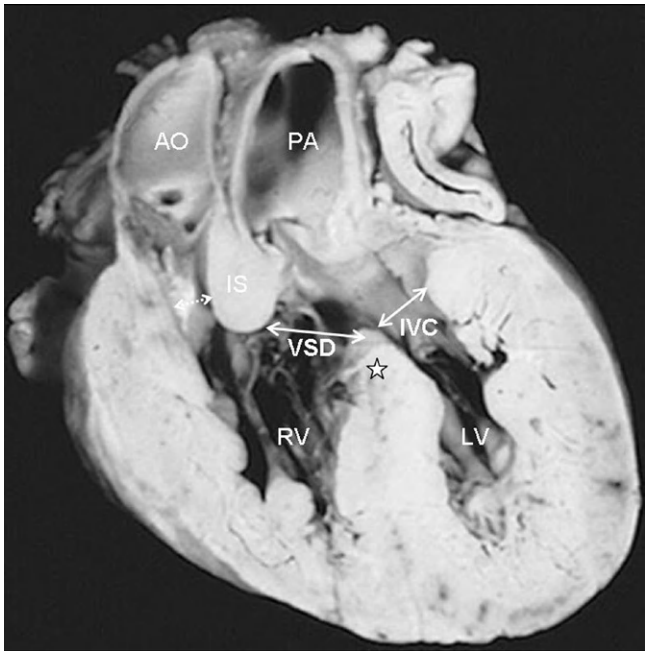

Figure 25.18 A sagittal section through a heart with double-outlet right ventricle with subpulmonary VSD (Taussig-Bing malformation) and subaortic obstruction. The aorta arises entirely from the RV. The PA overrides the crest of the ventricular septum. The anterior malalignment of the infundibular (conal) septum creates subaortic obstruction (dashed arrow). Two orifices are present. The interventricular communication is the only outlet of the left ventricle, and the VSD is the defect that must be closed (see text for details) in addition to performing an arterial switch operation. The RV is normal in size. There is a coexisting aortic arch obstruction that is not seen in this photograph. There are two coronary ostia, one located higher relative to the other. This higher location could indicate an intramural course. The location of the bundle of His is indicated with a star. (IVC, interventricular communication; VSD, ventricular septal defect; AO, aorta; PA, pulmonary artery; IS, infundibular (conal) septum; LV, left ventricle; RV, right ventricle.) (Courtesy of Norman Silverman MD, Stanford University, Stanford, CA, USA.)

Relief of RVOT obstruction. This phase of the operation is critical to avoid one of the most common early and late complications, subpulmonary obstruction. The RVOT is explored through the right ventriculotomy incision and through the native aortic (neopulmonary) valve through which obstructing muscle bundles are thoroughly excised. This phase of the operation is complicated by the presence of a coronary artery coursing across the RVOT and/or by marked hypoplasia of the neoaortic root. With the former, a lower ventriculotomy incision is created well below the level of the crossing coronary artery. Because RVOT hypoplasia is frequent the ventriculotomy incision should be closed with a patch. A small, valved, homograft conduit or a nonvalved Gore-Tex conduit may be required in certain anatomical situations in which the neopulmonary annulus is severely hypoplastic and/or there is a crossing coronary artery.

Coronary artery translocation. The coronary artery translocation can be challenging because of frequent coronary abnormalities. A routine Lecompte maneuver is performed and is facilitated by performing a high aortic transection and a low transection of the main pulmonary artery. Others, however, argue against the routine use of this maneuver and report excellent results [178]. In the final analysis, it is probably safe to exclude the Lecompte maneuver if anterior coronary artery looping (right coronary artery from the left sinus or left anterior descending coronary artery from the right sinus) is not present. When the coronary artery anatomy is "usual" the technique of coronary artery translocation is identical to that of the usual arterial switch operation for TGA. However, in the Taussig-Bing malformation, deviation of the coronary artery anatomy from the "usual" situation is frequent. Therefore, when the RCA button gives rise to the left main coronary arterial trunk or to the circumflex coronary artery, it is placed in a superior position by creating a relatively high defect in the neoaortic root at the previously marked location and by interdigitating as much of the button into the aortic suture line and into a counter incision made in the distal, transected ascending aorta as is necessary to accommodate the remaining circumference of the button. The left coronary artery button is sutured into its corresponding defect created in the neoaortic root and is placed just high enough to avoid kinking of the translocated coronary artery (Figure 25.17).

Reconstructing the pulmonary artery. The defects in the neopulmonary artery root are filled with a generous pantaloon patch of fresh, autologous pericardium (Figure 25.17). While some prefer to do this part of the operation after removing the cross-clamp to reduce the myocardial ischemic time, deferring cross-clamp removal until after this phase of the operation improves precision and reduces the chance of coronary arterial injury. Also, when the RCA originates from the left sinus and loops anteriorly, this pantaloon patch should be placed before the left coronary artery translocation is performed because suturing the pantaloon patch to the left hemi-circumference of the neopulmonary root threatens injury to a left coronary artery button that has already been sutured to the neoaortic root. When a Lecompte maneuver is performed, an incision is made from the right side of the opening in the distal transected main pulmonary artery into the inferior aspect of the right pulmonary artery. The opening in the left side of the distal transected main pulmonary artery is closed with a patch promoting a rightward shift of the anastomosis of the neopulmonary root to the pulmonary bifurcation.

This improves the alignment of the pulmonary reconstruction and reduces the chance of compressing the RCA.

Results of the Arterial Switch Operation

The current hospital mortality of arterial switch for Taussig-Bing malformation ranges from 3–15%, with patients affected by aortic arch obstruction occupying the upper end of this range [157–160,173–178]. Planche and colleagues [174] studied 1200 patients who underwent the ASO, 79 of whom had Taussig-Bing malformation of whom 85% were 30-day survivors (n = 67). With a median follow-up of 4.5 years (range, 6 months to 17 years) the actuarial 10-year survival was 85% with no late deaths after 5 years. There was a 10% rate of reoperation, primarily for RVOTO. Patients with Taussig-Bing malformation and aortic arch obstruction are at particular risk (10–20%) for late subpulmonary stenosis because the hypoplastic native right ventricle outflow becomes the pulmonary outflow tract after the arterial switch operation [178–180]. Other causes of late reoperation are aortic valve regurgitation [181], aortic arch obstruction [177], and coronary obstruction [174].

DORV with Subpulmonary VSD and Pulmonary Stenosis

The arterial switch with VSD closure to the neoaorta, as described above, is contraindicated in patients with DORV, subpulmonary VSD, and pulmonary stenosis because this approach would create stenosis of the neoaortic valve. Three surgical techniques, therefore, have been developed over the last three decades to address this challenging and rare anatomical situation. One approach is the Rastelli procedure that consists of VSD closure to the aorta with placement of a right ventricular-to-pulmonary artery conduit (see Chapter 26, *Transposition of the Great Arteries*). The long-term results of the Rastelli procedure are not optimal, with a 20-year survival of only 52%. This probably relates to the intrinsic long-term liabilities of the anteriorly located right ventricular-to-pulmonary artery conduit, itself [161,162]. Lecompte introduced REV procedure in 1982 as an alternative to and an improvement of the Rastelli procedure by reconstructing the pulmonary outflow tract without having to use a right ventricular-to-pulmonary artery conduit [41,163–167]. His original operation has been modified by others to include harvesting the intact pulmonary root, rather than simply transecting the main pulmonary artery, to promote improved competency of the neopulmonary root [168,169]. Finally, Nikaidoh proposed a complex, aortic translocation and biventricular outflow tract reconstruction that creates more anatomically aligned left and right ventricular outflow tracts than either the Rastelli or the REV procedures [170]. His original procedure has been modified by other authors [169,171,172].

Techniques of the REV Procedure

(See Chapter 26, *Transposition of the Great Arteries*.) The initial stages of the REV procedure are the same as those used for the arterial switch procedure. The pulmonary arteries are dissected as far peripherally as possible. The aorta is completely freed from the pulmonary artery and from its pericardial attachments. After arresting the heart, the inferior portion of a vertical right ventriculotomy is performed, and this incision is carried superiorly, under direct vision, as close to the aortic valve as possible. The decision to perform the Lecompte maneuver should be made at the beginning of the operation. When the aortic and pulmonary arteries are side-by-side or when the aorta is slightly anterior to the pulmonary artery, it may not be necessary to perform this maneuver and, therefore, it is not necessary to transect the aorta. When the decision to perform the Lecompte maneuver has been made, the aorta is transected several millimeters above the aortic valve commissures. The intact pulmonary root is dissected and detached from its right ventricular attachments, using low-energy electrocautery, being careful to avoid injury to any adjacent coronary arteries. The infundibular (conal) septum, located between the two semilunar valves, is aggressively resected if its presence interferes with the construction of a tunnel from the VSD to the aorta. When the aorta is posterior and to the right of the pulmonary artery, the infundibular septum does not always interfere with the construction of the tunnel and may form its anterior wall. When the great arteries are in an anterior-posterior relationship, the infundibular septum typically is interposed between the VSD and the aorta and requires resection. Lecompte recommends inserting a dilator through the pulmonary artery into the left ventricle. This maneuver exposes the infundibular septum and protects the mitral valve apparatus during the infundibular resection. The infundibular septum is resected by making two vertical incisions parallel to the axis of the aorta. A third incision is made just beneath the aortic valve, joining each of the previous two incisions. Great care is taken to avoid injury to the aortic valve leaflets. When there are abnormal attachments of the tensor apparatus of the tricuspid valve to the infundibular septum, the latter can be reflected anteriorly, rather than resected, leaving these attachments intact. The VSD is then tunneled to the aorta, and the infundibular septal flap, with the attached tricuspid chordal attachments, is secured to the right ventricular surface of the patch. The main pulmonary artery and its confluence are translocated anterior to the previously transected aorta and the aorta is reconstructed (if the Lecompte maneuver was performed). If there is subpulmonary stenosis in the face of a nonobstructed pulmonary valve and main pulmonary artery, the posterior segment of the pulmonary annulus is anastomosed to the superior margin of the right ventriculotomy incision and the RVOT is reconstructed with a

simple patch. If, on the other hand, the pulmonary valve and main pulmonary artery are obstructed, the posterior segment of the anteriorly opened pulmonary annulus is anastomosed to the superior margin of the right ventriculotomy incision. The RVOT can be reconstructed with a single-valved bovine jugular vein patch or an extemporaneous monocusp Gore-Tex or pericardial valve [41], placing the valve at the level of the native pulmonary valve leaflets, to help maintain a competent neopulmonary valve.

Technique of the Nikaidoh Procedure

The inspiration for the Nikaidoh procedure [170] was derived from the aortoventriculoplasty of the Konno [182] procedure and the aortic translocation procedure described by Bex and his colleagues [183] for the treatment of TGA with intact ventricular septum. As originally described, the Nikaidoh procedure consists of harvesting the aortic root from the right ventricle (with attached coronary arteries), relieving the LVOTO by dividing the outlet septum and excising the pulmonary valve, reconstructing the left ventricular outflow tract by closing the VSD and posteriorly translocating the aortic root, and reconstructing the right ventricular outflow tract with a pericardial patch [170]. More recently, however, important modifications have been reported by Hu *et al*. [169,171] and Morell and colleagues (Figure 25.19) [169,172]. The ascending aorta is divided just above its sinotubular junction. One or both coronary arteries are detached and mobilized in selected cases by Hu *et al*. [169,171] and both are routinely detached and mobilized by Morell and colleagues [172]. The aortic root is excised from the ventricle. The pulmonary root, itself, along with its semilunar valve, is also excised (when it is no more than moderately stenotic) [169,171]. When the pulmonary root is more severely stenotic this modification can not be used and the pulmonary valve is simply excised in situ, the main pulmonary artery having been divided at its sinotubular junction [172]. The pulmonary annulus and underlying conal septum are divided to relieve the subvalvar pulmonary stenosis. A patch is used to close the VSD. The detached aortic root is translocated posteriorly to the position of the original pulmonary trunk and the coronary arteries are reimplanted. After performing the Lecompte maneuver, aortic continuity is reestablished. When the stenosis of the pulmonary root is no more than moderate, the detached pulmonary root, with its semilunar valve, is then translocated anteriorly and its posterior hemi-circumference is sutured to the RVOT. The anterior wall of the pulmonary root is incised and a single-valved bovine jugular vein patch or an extemporaneous monocusp Gore-Tex or pericardial valve is used to enlarge the RVOT, thereby still maintaining growth potential and pulmonary valve competence [169,171]. When the pulmonary root is more severely stenotic, pulmonary insufficiency can be minimized by reconstructing the RVOT with a pulmonary homograft [172]. The advantage of these modifications reported by Hu *et al*. [169,171] and Morrel and colleagues [172] is that they afford greater mobility of the aortic root for its posterior translocation because it is not tethered by one or both attached coronary arteries that may limit its mobility. This may reduce the possibility of producing coronary insufficiency during the posterior aortic translocation [172]. These modifications may also allow the Nikaidoh procedure to be used in the situation in which there is unusual and difficult coronary artery anatomy. Finally, as opposed to the original technique reported by Nikaidoh [170], these modifications reduce pulmonary insufficiency and, in the case of the Hu modification [169,171], allow for the possibility RVOT growth.

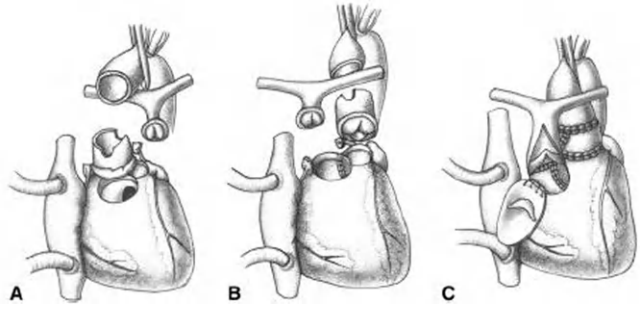

Figure 25.19 Double root translocation technique. **A,** Aortic and pulmonary root manipulation. Both the aortic and the pulmonary root are mobilized and excised. The ascending aorta is transected and the coronary arteries are detatched from the aortic sinus. **B,** Lecompte maneuver is performed in most cases. **C,** Restoration of left ventricle-aorta and right ventricle-pulmonary artery continuity. A single-valved bovine jugular vein patch was used to repair right ventricular outflow tract and enlarge the stenotic main pulmonary artery. (Reproduced with permission from Hu *et al.* [169].)

Results of the Rastelli, REV, and Nikaidoh Procedures

In general, larger series of the Rastelli, REV, and Nikaidoh procedures are not simply limited to patients with DORV, subpulmonary VSD, and pulmonary stenosis. Therefore, the results of the application of these three techniques to this particular anatomical substrate are not known with precision. In the Rastelli series from Boston Children's Hospital [161], the overall mortality was 7%, the freedom from reintervention for right-sided obstruction was 21% at 15 years, and there was a 10% incidence of LVOTO. The overall freedom from death or transplantation at 20 years was 52%. The Mayo clinic reported a similar experience [162] with a 59% survival at 20 years. For the REV procedure, the hospital mortality was 18% in an older series of 50 patients with anomalies of ventriculoarterial connection and VSD [166]. As usual, this series was not limited only to patients with DORV. The postoperative functional status

of this heterogeneous group of patients was excellent, and the left ventricular shortening fraction was normal at a mean follow-up time of 20 months. Assessment of right ventricular size and function was difficult to interpret owing to the lack of standard normal values for these variables in the presence of pulmonary insufficiency; however, the right ventricular size and contractility were considered normal in 83% of the 29 patients whose follow-up interval exceeded 1 year [166]. Despite its surgical complexity, reported results for the Nikaidoh procedure have been excellent with a 0% [169], 5% [184], and 8.3% [172] hospital mortality. In the largest reported series of Nikaidoh, himself, the median survival was 13.6 years (longest 23.0 years) in 19 patients [184]. Seven right ventricular outflow tract reoperations were required in five patients. No reoperations have been required on the LVOT or aortic valve.

When considering familiarity, applicability, and technical ease, the Rastelli procedure appears to be the "gold standard" for patients with DORV, subpulmonary VSD, and pulmonary stenosis. However, the Rastelli procedure stands alone when compared to the REV and Nikaidoh procedures, in producing an "ectopic" RVOT prone to sternal compression. Hu and his colleagues have also shown that both the Rastelli and the REV procedures share the same liability of producing a less anatomical and less laminar LVOT [169]. Though the Nikaidoh procedure is not guilty of producing either an "ectopic" and "vulnerable" RVOT or a long and tortuous LVOT, it is, by far, the most technically complex of the three procedures by virtue of its root translocation(s) and its potential for ischemic complications. Certainly, one could make a convincing argument for performing the Nikaidoh procedure in patients with inadequate anatomy for performing either a Rastelli or REV operation. Such relative contraindications might include coronary artery anomalies that interfere with a vertical right ventriculotomy incision, the presence of an inlet VSD, straddling atrioventricular valve or right ventricular hypoplasia. The argument for the Nikaidoh procedure is strengthened by the fact that it produces a more anatomical LVOT and RVOT than the Rastelli or REV procedures. Despite its theoretical advantages, caution should be exercised in strongly recommending the Nikaidoh procedure for DORV, subpulmonary VSD, and pulmonary stenosis since, of the cases reported in the literature, it has probably been used in fewer than seven patients worldwide [169, 184,185] with this anatomical substrate. Thus the ideal procedure for DORV/subpulmonary VSD/pulmonary stenosis, whether the Rastelli, REV or Nikaidoh procedures, remains elusive and requires further analysis.

DORV, Remote VSD Type

The goals of the two-ventricle repair of DORV with remote VSD with or without RVOTO is to construct an optimal intracardiac tunnel between the VSD and either one of the two arterial valves. The ideal tunnel should be as short as possible to avoid a long, noncontractile area on the surface of the interventricular septum. The tunnel should also be nonobstructive and avoid interfering with the tricuspid valve apparatus. Two-ventricle repair is best performed in early infancy rather than the neonatal period. Initial palliation with a systemic-to-pulmonary artery shunt or a pulmonary artery band may, therefore, be required.

Two-Ventricle Repair of DORV, Remote VSD Type (Without RVOTO)

There are two two-ventricle repair techniques to consider in patients with DORV, remote VSD without RVOTO: 1) intraventricular tunnel repair to the aorta; and 2) arterial switch with intraventricular tunnel to the pulmonary artery. The ability to perform the intraventricular tunnel repair to the aorta depends on the presence of an adequate distance between the tricuspid valve and the pulmonary valve as well as the ability to negotiate around the tricuspid subvalvar apparatus [78,79]. Tunnel repair to the aorta may require resection of the parietal band, reimplantation of the conal tricuspid papillary muscle on the tunnel patch, VSD enlargement superiorly/anteriorly, and resection of the subaortic conus [78,79,82]. If, for anatomical reasons, the VSD cannot be thus tunneled to the aorta, an arterial switch with tunneling of the VSD to the pulmonary artery may be preferable (Figures 25.20 and 25.21) [78,79]. This approach frequently results in the creation of a shorter tunnel and may result in less interference with the subvalvar apparatus of the tricuspid valve. The Lecompte maneuver is optional depending on the great vessel relationships. Surgical series of DORV with remote VSD are generally small [4,62,79,81–83] but the results have been improving over time with hospital mortality rates as low as 6.6% [77–79,82]. Longer-term results are needed to compare mortality, reintervention, exercise tolerance, and quality of life to other surgical approaches such as single-ventricle palliation.

Two-Ventricle Repair of DORV, Remote VSD Type (with RVOTO)

The RVOTO can be valvar, subvalvar or pulmonary atresia. If there is an isolated, muscular, subvalvar RVOT obstruction, then an intraventricular tunnel repair or an arterial switch with VSD closure (as described above) may be supplemented with a right ventricular infundibular patch augmentation to successfully repair the defect. When the RVOT obstruction is valvar and the VSD can be tunneled to the aorta, the pulmonary outflow tract is closed and a Rastelli-type or, preferably, an REV-type procedure is performed [166–169,186,187]. Hu and colleagues have recently reported no hospital deaths or reinterventions after a 22-month mean follow-up of six patients with DORV, remote VSD, and RVOTO treated with their modification

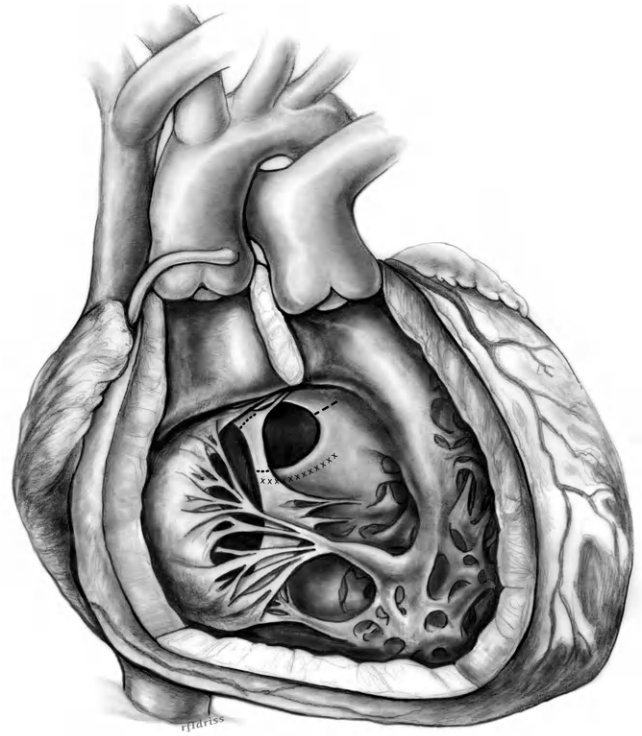

Figure 25.20 Intraventricular tunnel repair of double-outlet right ventricle, remote ventricular septal defect (VSD) type. The presence of tensor apparatus of the tricuspid valve makes the construction of a tunnel from the VSD to the aorta impossible. The VSD is enlarged superiorly when restrictive (anterosuperior dashed line). The VSD is tunneled to the pulmonary artery. Notice that the distance from the VSD to the infundibular ostium is relatively short. The intracardiac tunneling of the VSD to the pulmonary artery is followed by an arterial switch operation. The tricuspid valve and infundibular septum are spared.

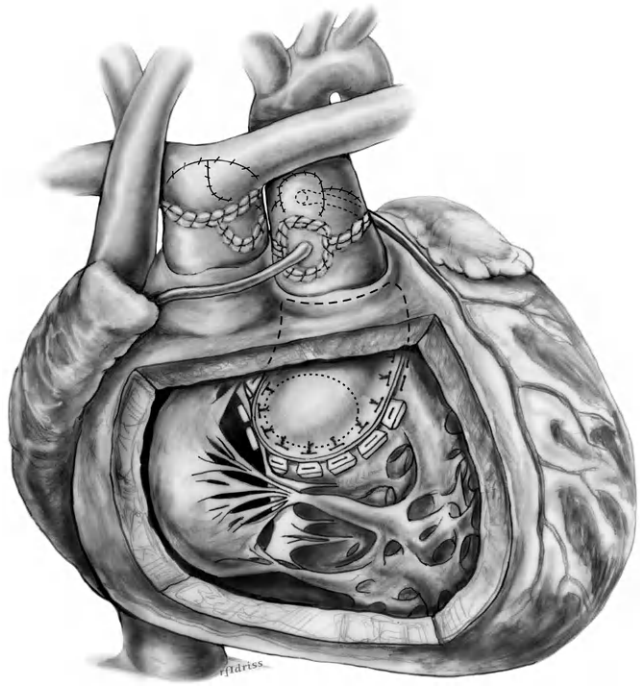

Figure 25.21 Intraventricular tunnel repair of double-outlet right ventricle, remote ventricular septal defect type. The left ventricle is tunneled to the pulmonary artery (neoaorta), which is depicted after completion of an arterial switch operation with a Lecompte maneuver.

of the Nikaidoh procedure adapted to address the anatomy of DORV, remote VSD [185]. This approach has yet to be substantiated by long-term results.

Single Ventricle Repair of DORV, Remote VSD Type (with or Without RVOTO)

Single ventricle palliation must be performed when neither of the two-ventricle repairs described above is feasible. This is especially true when there is significant ventricular hypoplasia, severe atrioventricular valve straddling or overriding and/or Swiss-cheese VSD. Significant cyanosis or pulmonary overcirculation is initially palliated with a systemic-to-pulmonary artery shunt or pulmonary artery band, respectively, until 6 months of age when a bidirectional cavopulmonary connection is performed. Palliation is completed with a total cavopulmonary connection procedure at 1.5–2 years of age. If tunnel closure of the VSD produces a critical reduction of the right ventricular volume, a one and one-half ventricle repair can substitute for a Fontan procedure although some authors [188] have suggested that a total cavopulmonary connection is a superior surgical remedy. Late restriction of the VSD can occur after Fontan palliation in patients with DORV and remote VSD [189,190], leading to left ventricular exclusion and hypertension. Enlargement of a restrictive or borderline VSD at the time of Fontan palliation is, therefore, recommended [79,85,134,190,191].

DORV with AVSD

Two-Ventricle Repair of DORV with AVSD

This especially complex subset of DORV patients is frequently associated with the heterotaxy syndrome, most frequently a right isomerism with asplenia and abnormal systemic venous connections. These patients usually present with RVOTO (pulmonary stenosis to atresia), TAPVC, and frequent intestinal malrotation requiring a Ladd procedure. Compared with AVSD associated with tetralogy of Fallot, where Down syndrome is frequently associated, the patients with DORV-AVSD generally have a normal genotype [192]. The AVSD anatomy is typically Rastelli type C and the VSD is similar to the one found in

tetralogy of Fallot-AVSD, with a large superior component extending close to the aortic valve annulus [23,84]. The distance from the superior edge of the subaortic component of the VSD to the aortic annulus varies but, in many instances, this distance is less than the diameter of the aortic annulus [131]; thus the term "noncommitted VSD" remains controversial to describe this subset of DORV.

Complete repair is performed after 6 months of age; therefore, in the presence of severe cyanosis a palliative systemic-to-pulmonary artery shunt is performed. Emergent repair of obstructed TAPVC is undertaken simultaneously with the performance of the systemic-to-pulmonary artery shunt. At the time of complete repair, incising the anterior bridging leaflet of the common atrioventricular valve enhances exposure of the aortic valve. Tunnel closure of the VSD is accomplished through a right atriotomy and ventriculotomy using a patch with a large anterior–superior extension. Postoperative pulmonary valve competence is desirable necessitating the placement of a right ventricular-to-pulmonary artery conduit when the intraventricular tunnel obstructs the RVOT. If the intraventricular tunnel causes a significant reduction in the right ventricular volume, a one and one-half ventricle repair can be performed.

Despite the technical complexity of performing a two-ventricle repair in DORV-AVSD, some groups advocate a two-ventricle repair based on superb early and intermediate-term results performing a complete repair in the majority of patients who present with DORV-AVSD [85,120,192].

Complex DORV with Straddling Atrioventricular Valves

Some authors [193] have documented better survival after Fontan palliation in patients with various complex forms of DORV including patients with straddling atrioventricular valves. Others [117] have successfully performed biventricular repairs in this high-risk group of patients.

Late Sudden Death in Survivors of Repair of DORV

It is interesting to note that Shen and his colleagues [194] found an 18% incidence of late sudden death when they analyzed 89 survivors of repair of DORV. Cox proportional hazards multivariate analysis demonstrated that older age at the time of operation, perioperative or postoperative ventricular tachyarrhythmias, and third-degree atrioventricular block were significant risk factors for late sudden death. This high incidence of late sudden death has not been reported in more recent surgical series of DORV.

DOUBLE-OUTLET LEFT VENTRICLE

Introduction

Double-outlet left ventricle (DOLV) is a rare congenital cardiac malformation of ventriculoarterial connection in which both great arteries arise wholly or in large part from the morphologic left ventricle [195–197].

History

In 1967, Sakakibara *et al*. [198] reported the first successful intraventricular repair of DOLV in a patient with two adequately sized ventricles. The wide morphologic variations of this disorder were established in subsequent case reports [72,194,199–201]. Kerr *et al*. [200] and Pacifico and colleagues [195] described the complete repair of DOLV with pulmonary stenosis using a valved extracardiac conduit to establish continuity between the right ventricle and the pulmonary artery. Sharratt *et al.* [202], in 1976, first reported the use of the Fontan procedure to correct DOLV with right ventricular hypoplasia.

Embryology

At one time it was thought that DOLV was an embryologic impossibility [37,203]. Goor and colleagues [203], however, demonstrated that a process of differential conal absorption draws the aorta over the cavity of the left ventricle. If this absorptive process continues, both coni are absorbed above the primitive ventricle. As a result, the pulmonary artery and aorta are drawn over the morphologic left ventricle to produce DOLV [203].

Morphology

General

Because of the great morphologic variability of DOLV, it is necessary to examine the segmental anatomy of each patient to understand the defect and to determine the optimal surgical approach [196]. Although DOLV occurs most commonly in the presence of atrial situs solitus with atrioventricular concordance, it has been described with situs inversus and/or atrioventricular discordance. The position of the aorta relative to the pulmonary artery can be to the right and posterior (normal), to the right and side-by-side, to the right and anterior (D-malposition) and to the left (L-malposition) [72,195,196,204].

Ventricular Septal Defect

Rarely, the interventricular septum is intact [196,199]. As with DORV, the VSDs of hearts with DOLV are

conoventricular lesions that can be classified according to their relationship to the great arteries. In the series by Bharati *et al.* [196] of 45 cases 71% of the VSDs were subaortic, 18% were subpulmonic, 9% were doubly committed, and 2% were noncommitted. The subaortic VSD of DOLV can extend to the tricuspid annulus or be separated from it by a band of muscle, similar to hearts with DORV. When the VSD is juxtaaortic, the aorta can override the interventricular septum to a variable degree, and the lesion must be differentiated from TGA and VSD. When the VSD is doubly committed it is, by definition, juxtaarterial. In this case because both great arteries form the superior border of the defect and override the interventricular septum to a variable degree, it is often difficult to determine whether the heart lesion is DOLV or DORV. Brandt *et al.* [72] has called this *variant double-outlet both ventricles*.

Subaortic and Subpulmonary Coni

There is usually aortic-mitral continuity because of the absence of a subaortic conus. A subpulmonary conus is frequently present; however, when the subpulmonary conus is absent there is pulmonary-tricuspid continuity. Rarely, bilateral coni are present.

Associated Cardiac Lesions

Pulmonary stenosis affects the majority of patients with DOLV and can occur at the valvar and subvalvar levels. In the series by Bharati *et al.* [196], 38% of patients with DOLV had tricuspid valve and right ventricular hypoplasia. Tricuspid atresia [196,205], Ebstein anomaly [72], and mitral atresia [205] have also been associated with this disorder.

The Conduction System

The atrioventricular node and bundle of His are normally positioned in DOLV. When the VSD is juxtatricuspid, the bundle runs along its inferoposterior free edge and is at risk for injury during repair. When there is a band of muscle between the defect and the tricuspid valve annulus, the conduction tissue does not run along the free edge of the VSD. This relationship of the VSD to the conduction tissue is identical to that of DORV.

Pathophysiology

The clinical presentation of patients with DOLV is largely determined by the presence or absence of pulmonary stenosis. Since pulmonary stenosis is present in 85% of patients with DOLV, most patients present with varying degrees of cyanosis. Cyanosis can also be produced by the streaming of desaturated right ventricular blood into the aorta through a subaortic VSD. When pulmonary stenosis is not present, the patient may present with congestive heart failure and, later in life, develop fixed pulmonary hypertension owing to pulmonary vascular disease.

Diagnosis

Biplane cineangiography with left and right ventricular injections profiling the septum will demonstrate the origin of both great vessels from the left ventricle, the position and number of VSDs, the presence and location of pulmonary stenosis, and the size and adequacy of the tricuspid valve and right ventricle (Figure 25.22) [72].

Natural History

When pulmonary stenosis coexists with DOLV, the natural history is similar to that of tetralogy of Fallot. In the absence of pulmonary stenosis, the natural history is similar to that of an isolated, large VSD except the VSD in DOLV does not have a tendency to close over time.

Treatment

General

The principles of cardiopulmonary bypass, myocardial protection, and avoidance of the conduction tissue are the same for hearts with DOLV as described for those with DORV. In general, a complete repair should be undertaken in early infancy if this can be accomplished. When an extracardiac conduit is to be employed, repair can be delayed until a later age when a larger conduit can be placed; however, there is no consensus regarding this point. As a general rule the use of palliative procedures, systemic to pulmonary artery shunts and pulmonary artery bands, should be minimized. Sparse follow-up data relating to the results of surgical repair in the current era are available for this rare entity.

DOLV with Pulmonary Stenosis

Complete Intraventricular Repair

When the pulmonary annulus is not obstructive and when the subpulmonary obstruction is localized, a completely intraventricular repair may be possible [198,206]. The subpulmonary obstruction is resected through the tricuspid valve, the pulmonary valve, and/or a right ventriculotomy. The VSD is tunneled to the pulmonary artery through a right ventriculotomy.

Pulmonary Artery Translocation

Usually, a completely intraventricular repair is not possible because the subpulmonary obstruction is long and

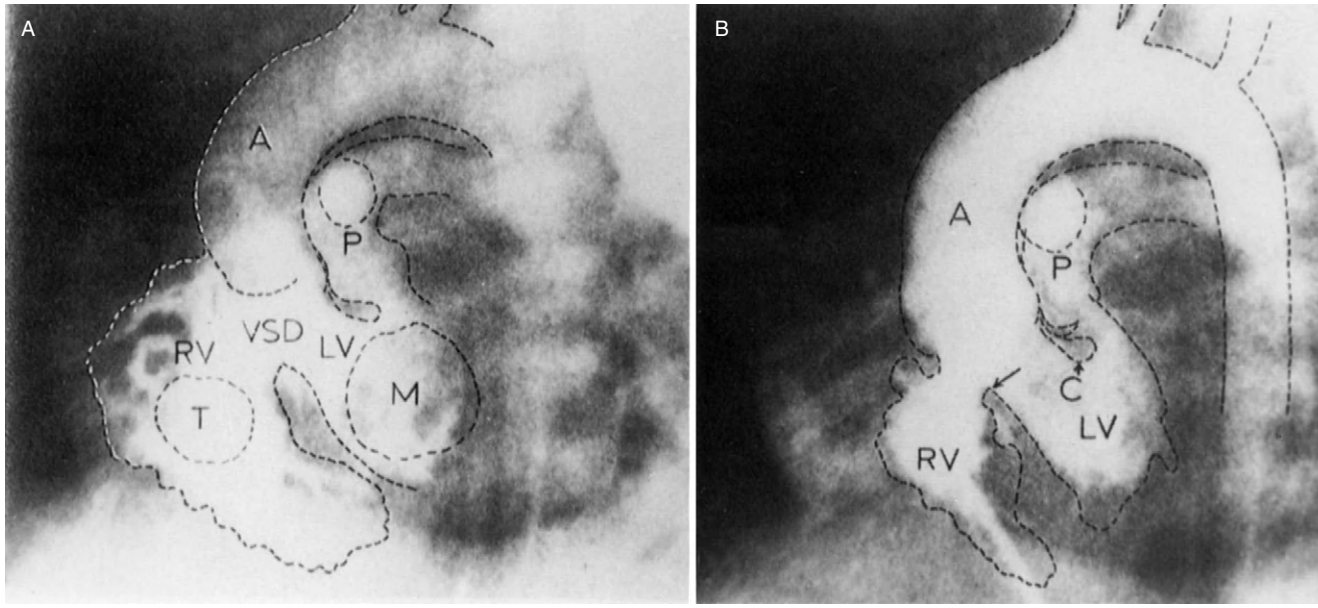

Figure 25.22 Cineangiogram of a patient with double-outlet left ventricle (DOLV). **A,** The right ventricular injection with left anterior oblique view demonstrates flow of contrast medium from the right ventricle, through the VSD into the left ventricle. The opacified aorta and pulmonary artery clearly arise from the left ventricle. **B,** The systolic frame of the same right ventricular injection demonstrates the subaortic VSD. The larger arrow demonstrates the inferior margin of the VSD and clearly shows that the entire aorta, except for the rightward anterior sinus, arises from the left ventricle. (A, aorta; LV, left ventricle; M, mitral valve; P, pulmonary artery; RV, right ventricle; T, tricuspid valve; VSD, ventricular septal defect.) (Adapted with permission from Brandt *et al*. [72].)

narrow. It is not possible to place a transannular patch because the left anterior descending coronary artery runs immediately inferior to the pulmonary valve ring. In this situation, when the pulmonary valve annulus and pulmonary valve are normal or near normal, a repair can be accomplished using pulmonary artery translocation (Figure 25.23) [60,206–208]. The right ventricle is opened with a vertical right ventriculotomy. The subpulmonary stenosis is closed through the VSD (Figure 25.23A) [60], and the VSD is closed with a simple patch (Figure 25.23B) [60]. The pulmonary artery trunk, with its intact valve, is removed from the base of the left ventricle, being careful to avoid injury to the adjacent left coronary artery branches (Figure 25.23B) [60]. The pulmonary outflow tract is then closed from the outside of the left ventricle. The intact pulmonary trunk is translocated anteriorly, and its posterior circumference is sutured to the superior aspect of the vertical right ventriculotomy (Figure 25.23C) [60]. The remainder of the right ventricle-to-pulmonary artery connection is completed with autologous pericardium (Figure 25.23D) [60]. This procedure has been reported in a 4-month-old patient [207]. There was a moderate right ventricular outflow tract gradient 14 days postoperatively, and there are no long-term follow-up data published to date.

REV Procedure

When, as is most common, a long and narrow subpulmonary obstruction is associated with a small and obstructive pulmonary annulus, the REV procedure may be used for repair (see Chapter 26, *Transposition of the Great Arteries*) [41,163–167]. While this does not involve translocation of the native pulmonary valve, it does provide an unobstructed repair without the need for an extracardiac conduit. The resultant pulmonary insufficiency should be well tolerated.

Rastelli Procedure

Alternatively, repair can be undertaken with a valved extracardiac conduit. Through a right ventriculotomy, the subpulmonary stenosis is viewed through the VSD and closed with pledgeted, horizontal mattress sutures. The VSD is patched and a valved, homograft extracardiac conduit is sutured to the pulmonary artery distally and then to the right ventriculotomy proximally.

DOLV Without Pulmonary Stenosis

In some cases an entirely intraventricular repair can be performed, as described above [182]. When this is not possible, repair with a valved extracardiac conduit is

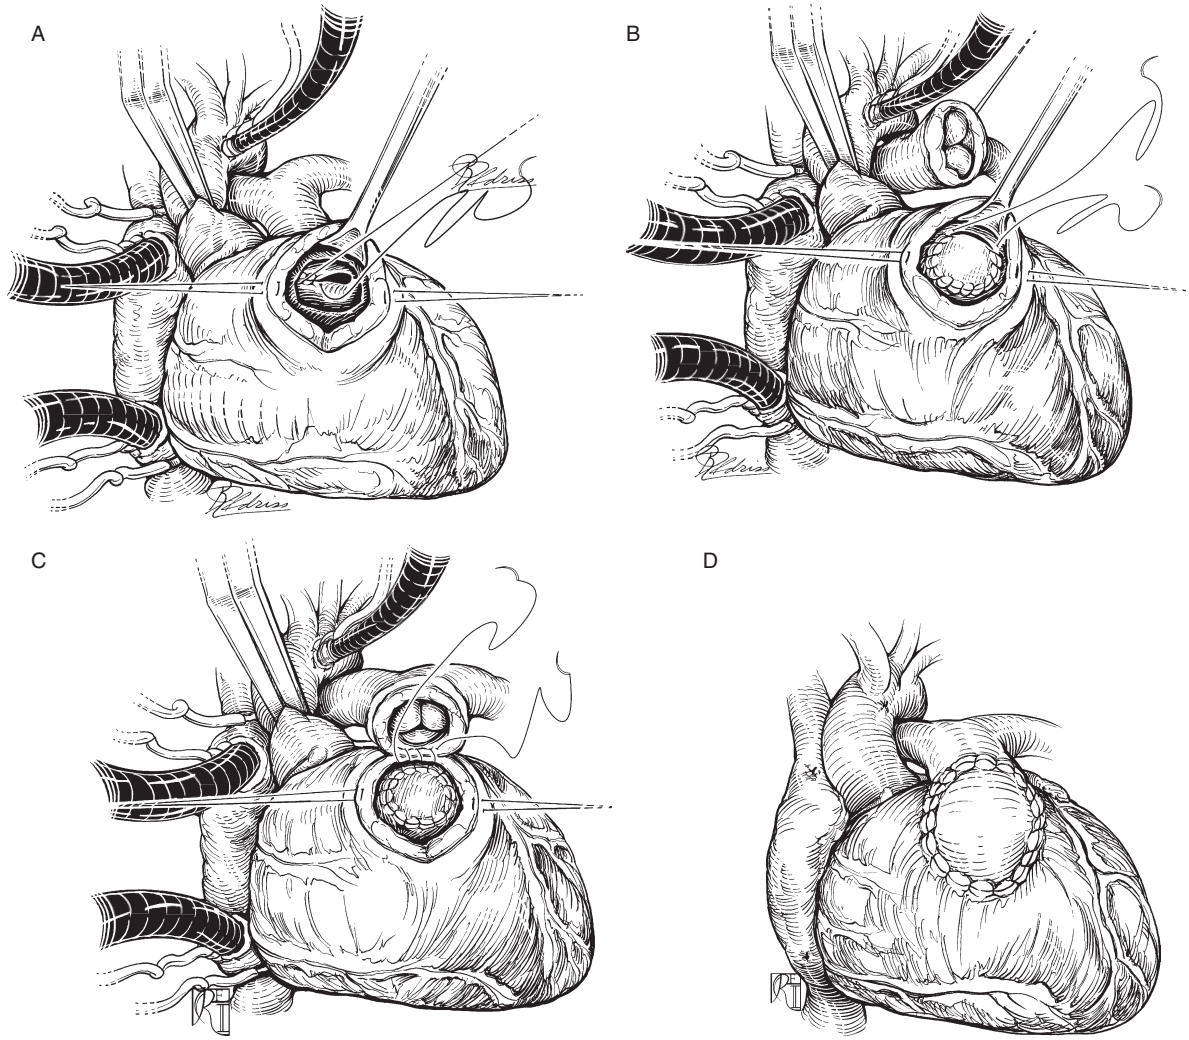

Figure 25.23 Pulmonary artery translocation for repair of double-outlet left ventricle (DOLV). **A,** The repair is performed through a vertical right ventriculotomy. The subpulmonary area is closed through the ventricular septal defect. **B,** The pulmonary artery trunk, with its intact valve, is removed from the base of the left ventricle. Care is taken to avoid injury to the adjacent coronary arteries. The ventricular septal defect is patched. **C,** The pulmonary trunk is translocated anteriorly, and its posterior circumference is sutured to the superior aspect of the right ventriculotomy. **D,** The connection of the right ventricle to the pulmonary artery is completed with an autologous pericardial patch.

recommended. It may be possible, under certain circumstances, to close the VSD so that the right ventricle ejects into the aorta. Ventriculoarterial concordance is restored with an arterial switch procedure. While the REV procedure theoretically could be employed in this situation, it is not recommended in patients without preoperative pulmonary stenosis. The postoperative pulmonary insufficiency is generally not well tolerated in such patients.

DOLV with Tricuspid and Right Ventricular Hypoplasia

When a two-ventricle repair cannot be performed, a bidirectional cavopulmonary anastomosis is performed at 6 months of age. This is followed by a total cavopulmonary connection at 1–2 years of age. Depending on the presence or absence of pulmonary stenosis, a systemic to pulmonary artery shunt or a pulmonary artery banding may have to be performed in early infancy as a brief prelude to the eventual two-staged Fontan procedures.

CHAPTER 26

Transposition of the Great Arteries

Constantine Mavroudis[1] and Carl L. Backer[2]

[1]Florida Hospital for Children, Orlando, FL, USA
[2]Ann & Robert H. Lurie Children's Hospital of Chicago, formerly Children's Memorial Hospital, Chicago, IL, USA

Transposition of the great arteries (TGA) is a congenital defect of the heart in which the anatomic relationship of the great arteries is reversed. Unlike in normal positioning, the aorta arises anterior to the pulmonary artery and from the right ventricle, while the pulmonary artery lies posterior to the aorta and arises from the left ventricle. In this chapter we will discuss patients with transposed great vessels who have undergone D-looping with two ventricles. Anatomic variations, which include tricuspid or mitral atresia, heterotaxy syndromes, and single ventricle, will be discussed in Chapter 28, *The Functionally Univentricular Heart and Fontan's Operation*. L-Loop transposition of the great arteries is discussed in Chapter 27, *Congenitally Corrected Transposition of the Great Arteries*.

Patients with TGA are subdivided into those with intact ventricular septum (50%), ventricular septal defect (VSD) (25%), and VSD with pulmonary stenosis (25%). Other frequently found cardiac anomalies include patent ductus arteriosus, coarctation of the aorta, and interrupted aortic arch. Transposition of the great vessels is the most common cyanotic heart defect in infancy and accounts for 9.9% of all cases of congenital heart disease [1].

Embryologic and Anatomic Considerations

After the description of TGA by Baillie in 1797 [2], numerous theories have been postulated concerning the morphogenesis of this abnormal relationship between the great arteries and the ventricles. These include 1) the straight truncoconal septum hypothesis, incriminating an abnormal septation of the aorta and pulmonary artery [3–9]; 2) the abnormal fibrous skeleton hypothesis in which pulmonary-mitral fibrous continuity instead of the normal aortic-mitral fibrous continuity occurs [10,11]; 3) the abnormal embryonic hemodynamics hypothesis, caused by obstructive and alternative flow characteristics [12–18]; and 4) the inverted truncal swellings theory, citing the inverted development of the regions below the semilunar valves [19–21]. The latter interpretation resembles Van Praagh's analysis [22,23] in which he postulates that the subaortic conus persists and develops during the normal D-looping, while the subpulmonary conus undergoes absorption and eventual fibrous continuity with the mitral valve. As a result the aortic valve is anterior to the pulmonary valve, allowing both semilunar valves to align and connect respectively with the distal great vessels, without undergoing the usual twisting and untwisting that is hypothesized about normal hearts. The results of these events *in utero* lead to TGA.

Anatomic variations are encountered often. Although mesocardia and dextrocardia have been described [24], the heart is left-sided with atrial situs solitus in 95% of patients. The incidence of systemic venous anomalies is no greater than in other congenital heart defects. Left or right juxtaposition of the atrial appendages can be encountered and may signal other anomalies [25]. Most atrial communications are via a patent foramen ovale; a true ostium secundum defect is present in 10–20% of cases. A right-sided aortic arch is present in 4% of patients with TGA and intact ventricular septum and in 16% of those with VSD [26].

In patients with TGA and intact ventricular septum, functional obstruction of the left ventricular outflow tract may be present owing to septal bulging toward the mitral valve, which is caused by the differential in ventricular pressures. These defects, however, are resolved by anatomic correction. Rarely will a patient with TGA and intact ventricular septum have anatomic subvalvar stenosis [27–29].

Of patients with TGA, up to 50% will have a VSD, many of which close spontaneously. Theoretically VSDs can be

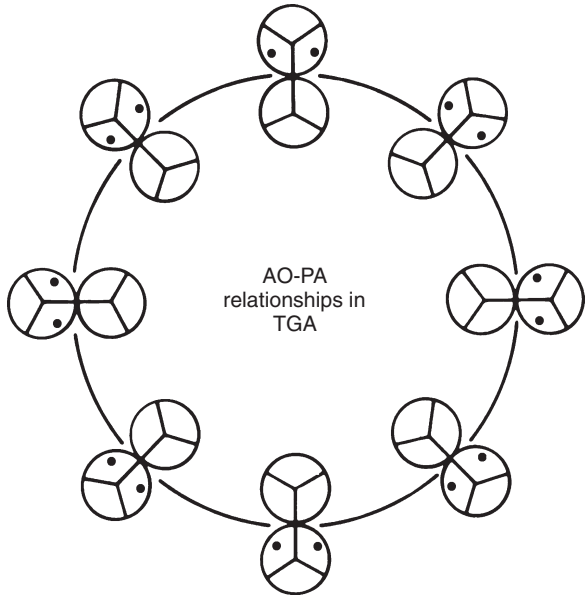

Figure 26.1 Schematic diagram shows the wide range of spatial relationships between the great arteries in patients with "complete" transposition of the great arteries (TGA). (AO, aorta; PA, pulmonary artery.)

located anywhere in the ventricular septum, although most have been found in the infundibular and perimembranous locations [30,31]. Additional cardiac anomalies are more prevalent in patients with TGA and VSD. These include all levels of pulmonary stenosis, pulmonary atresia, overriding or straddling atrioventricular valves, coarctation of the aorta, and interruption of the aortic arch. Right ventricular outflow obstruction is exceedingly rare [32].

The spatial relationship between the great vessels is variable (Figure 26.1) [33,34], but most often the aorta is at the right and anterior to the pulmonary artery. Whatever the variation, in virtually every case the sinuses of Valsalva and coronary artery ostia face the corresponding pulmonary artery sinuses of Valsalva, favorable for a coronary transfer and arterial switch [33,35–39]; only a small number pose problems for an arterial switch (see section Special Coronary Problems).

Functional abnormalities of the mitral and tricuspid valves are infrequent [40–42] in patients who have an intact ventricular septum. In patients with VSD, tricuspid abnormalities resulting in straddling or overriding can occur. A straddling tricuspid valve has chordal attachments in the left ventricle, whereas an overriding tricuspid valve allows flow into the left ventricle without straddling chordae. Whether the tricuspid valve is straddling or overriding, the associated right ventricular hypoplasia carries with it major therapeutic implications regarding the choice of eventual repair [43,44].

Physiology

Transposition of the great arteries is characterized by two separate parallel circulations, in which the systemic venous blood passes through the right ventricle to the aorta while the pulmonary venous blood passes through the left ventricle, resulting in cyanosis [24,45,46]. Some mixing between the circulations is mandatory to sustain life and is dependent largely on the type of TGA.

Patients with TGA and intact ventricular septum survive because of aortopulmonary flow through a patent ductus arteriosus, often enhanced by prostaglandin E1 [47,48], and a left-to-right atrial shunt through a dilated patent foramen ovale caused by high left atrial pressure and an incompetent flap of the foramen ovale. This mixing, however, allows for only marginal tissue oxygenation, which is not improved with higher concentrations of inspired oxygen. Atrial balloon septostomy or surgical creation of an atrial septal defect improves systemic oxygen saturation and sets conditions for longer-term survival.

Patients with TGA and VSD have higher oxygen saturations by virtue of the anatomic defects, which allow more pulmonary flow and greater mixing at both the atrial and ventricular levels. There is, however, a spectrum of ventricular defects, from the small to the very large. Small defects allow minimal mixing and cyanosis indistinguishable from TGA and intact ventricular septum. Large defects also allow increased pulmonary flow and mixing, resulting in a pink patient who is subject to pulmonary overcirculation and the dangers of acquired pulmonary vascular hypertension.

Pulmonary outflow tract obstruction will alter the degree of cyanosis, more or less with the severity of the obstruction. In patients with intact ventricular septum, valvar stenosis is rare. The usual location of obstruction is subvalvar, owing to septal deviation caused by right ventricular distension. This problem is solved by an arterial switch, which eliminates the systemic right ventricular forces on the septum [49,50]. More often, subvalvar stenosis is associated with VSD. These patients usually have a more balanced physiology, resulting in mild cyanosis, and they tend to show symptoms of TGA later than other patients. When pulmonary stenosis becomes clinically significant, a systemic-to-pulmonary artery shunt is performed initially and followed by anatomic repair with a right ventricle-to-pulmonary artery conduit (Rastelli operation [51]), or the Lecompte or *réparation à l'étage ventriculaire* (REV) procedure [52,53], which allows anatomic repair without use of a conduit. Pulmonary vascular disease can occur in patients with TGA regardless of the presence of a VSD. Moreover, patients with TGA and VSD tend to develop pulmonary vascular disease earlier than patients who have VSD without TGA [54,55]. The reasons for these findings are speculative and may relate to differences in

oxygen saturation, carbon dioxide content, and pulmonary arterial pH [46].

Clinical Presentation

Recent reports have demonstrated that antenatal diagnosis of TGA (fetal echocardiography) correlates with increased perioperative stability and improved surgical outcomes [56–59]. Unfortunately, prenatal detection rates depend on the institutional experience and can vary from 20% to 72% [56,59–63]. As a result, most infants with TGA will present with cyanosis, varying degrees of acidosis, and hemodynamic instability depending on the degree and type of associated anomalies [24,46]. Cyanosis is prevalent during the first days of life in patients with TGA and intact ventricular septum, whereas cyanosis may be less or not noticed in those with VSDs.

Infants with TGA may be at a higher risk for cerebral ischemic compromise resulting from chronically decreased oxygen delivery to the brain in fetal life [59]. Transposition of the great arteries causes oxygenated blood to preferentially flow into the lower body and not to the brain as occurs in the normal fetus. Park and associates [64] used proton magnetic resonance spectroscopy to show that cerebral metabolism was altered specifically in the parietal white matter, which suggested that a maturation delay rather than acute postnatal insult was responsible [59].

Cardiac examination reveals a mildly overactive precordium. Cardiac murmurs, when audible, are usually soft and occur during systole. The second heart sound is characteristically loud and single. The femoral pulses are normal or bounding when there is a large patent ductus arteriosus [24]. The liver may be enlarged, especially when there is a large systemic-to-pulmonary shunt, and the child may have tachypnea, intercostal and subcostal retractions, and inability to nurse successfully.

The electrocardiograph findings are usually within normal limits at birth, with progression to right ventricular hypertrophy with advancing age. The chest roentgenograph findings are also normal at birth except in those patients with large VSDs, who will have cardiomegaly, increased pulmonary vascularity, and evidence of congestive heart failure. In older infants, moderate cardiomegaly is often present with an "egg-on-its-side" appearance [24]. There may also be asymmetry of pulmonary blood flow, resulting in right-sided plethora owing to preferential right pulmonary artery flow.

The diagnosis of TGA generally can be made by echocardiography. A posterior great artery, dividing into right and left pulmonary arteries and arising from the left ventricle, along with an anterior aorta arising from the right ventricle, confirms the diagnosis (Figures 26.2 and 26.3) [34]. Doppler techniques can determine intercavitary shunting, which can occur from a ductus arteriosus, patent foramen

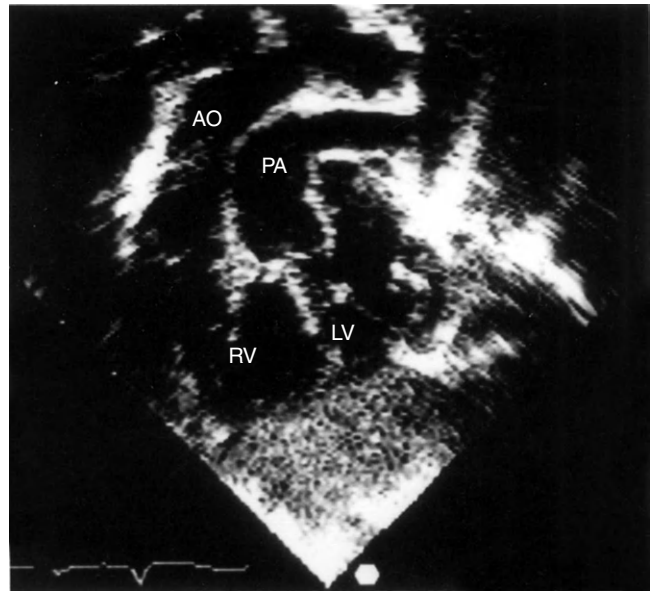

Figure 26.2 Subcostal sagittal view of an infant with transposition of the great arteries and intact ventricular septum. This view is obtained by positioning the transducer in the subcostal region, with the plane of sound tilted posteriorly to anteriorly to the level of the great vessels. (AO, aorta; PA, pulmonary artery; LV, left ventricle; RV, right ventricle.)

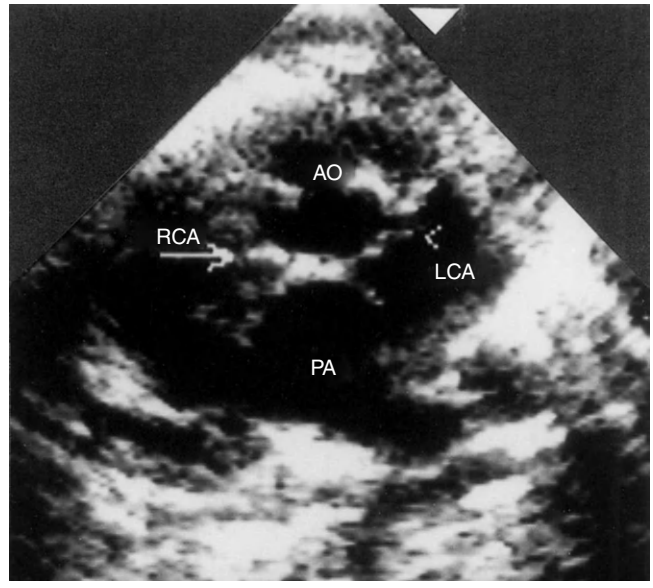

Figure 26.3 Parasternal short-axis view of a patient with transposition of the great arteries, intact ventricular septum, and normal coronary artery anatomy. The aorta is anterior, and the left main and right coronary arteries are visualized originating from the left and right coronary cusps, respectively. The pulmonary artery is posterior, and bifurcation of the left and right pulmonary arteries is demonstrated. This view is obtained with the transducer positioned in the left parasternal intercostal space, with the plane of sound directed from the left ventricular apex toward the head. (AO, aorta; RCA, right coronary artery; LCA, left coronary artery; PA, pulmonary artery.)

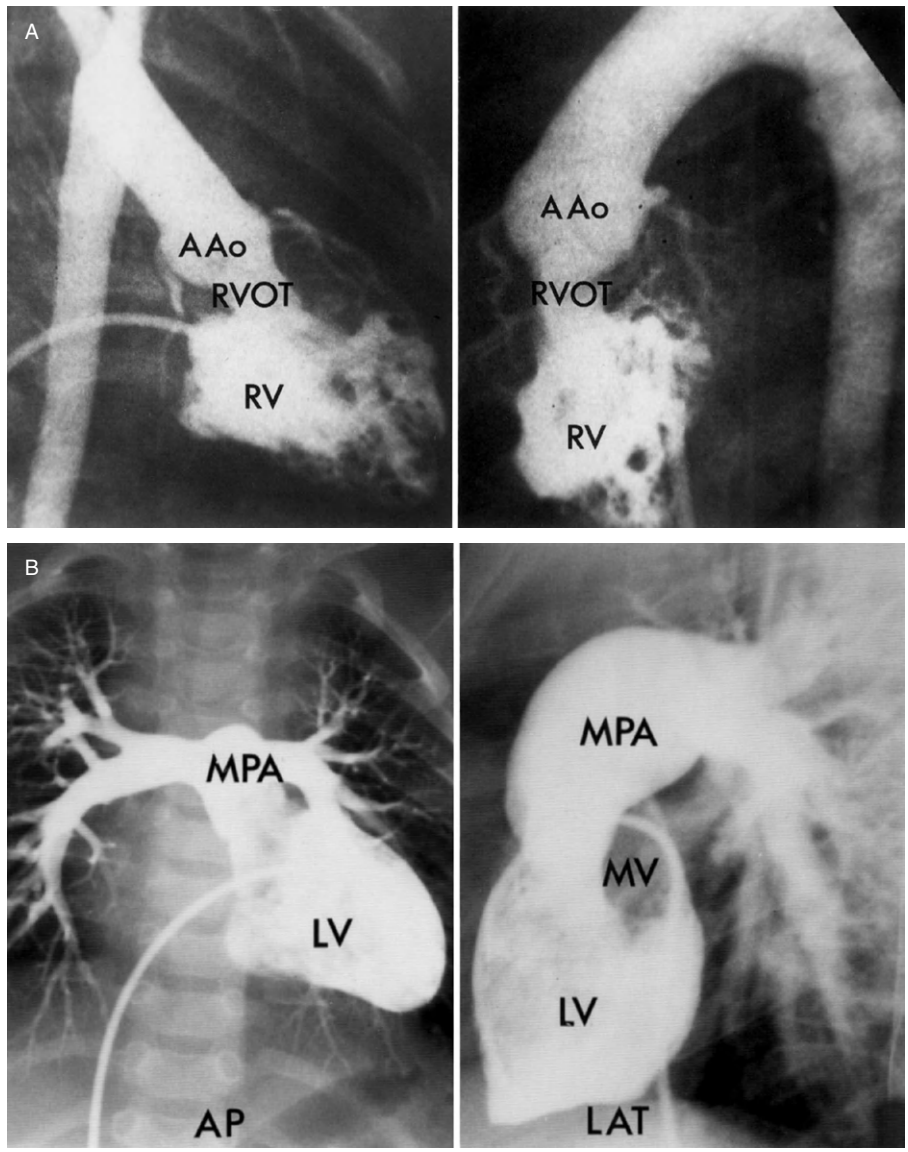

Figure 26.4 A, Right anterior oblique and left anterior oblique views of a trabeculated right ventriculogram in a patient with transposition of the great arteries and intact ventricular septum. **B,** Anterior (AP) and lateral (LAT) views of a smooth, nontrabeculated left ventriculogram in a patient with transposition of the great arteries and intact ventricular septum. (AAo, ascending aorta; LV, left ventricle; MPA, main pulmonary artery; MV, mitral valve; RV, right ventricle; RVOT, right ventricular outflow tract.)

ovale, or VSD [65]. Multiple views can determine the size and location of a VSD with reference to the infundibular septum, the nature of the atrial septal communication, the anatomy of the atrioventricular valves, the site and degree of pulmonary stenosis, and, in most cases, the course and anatomic variation of the coronary arteries [66].

Cardiac catheterization usually is reserved for those few patients in whom clinical instability demands Rashkind balloon atrial septostomy [67] or when more physiologic and anatomic data are required concerning the coronary arteries, the VSD, the degree of left ventricular outflow obstruction, or other anatomic variations such as interrupted aortic arch, coarctation, and the like (Figures 26.4 and 26.5) [34]. More often than not, however, these issues can be resolved with magnetic resonance imaging/magnetic resonance angiograpy (MRI/MRA) or computed tomography (CT) scans [68].

Medical Management of the Neonate

Medical management of neonates with TGA focuses on the stabilization and correction of physiologic aberrations

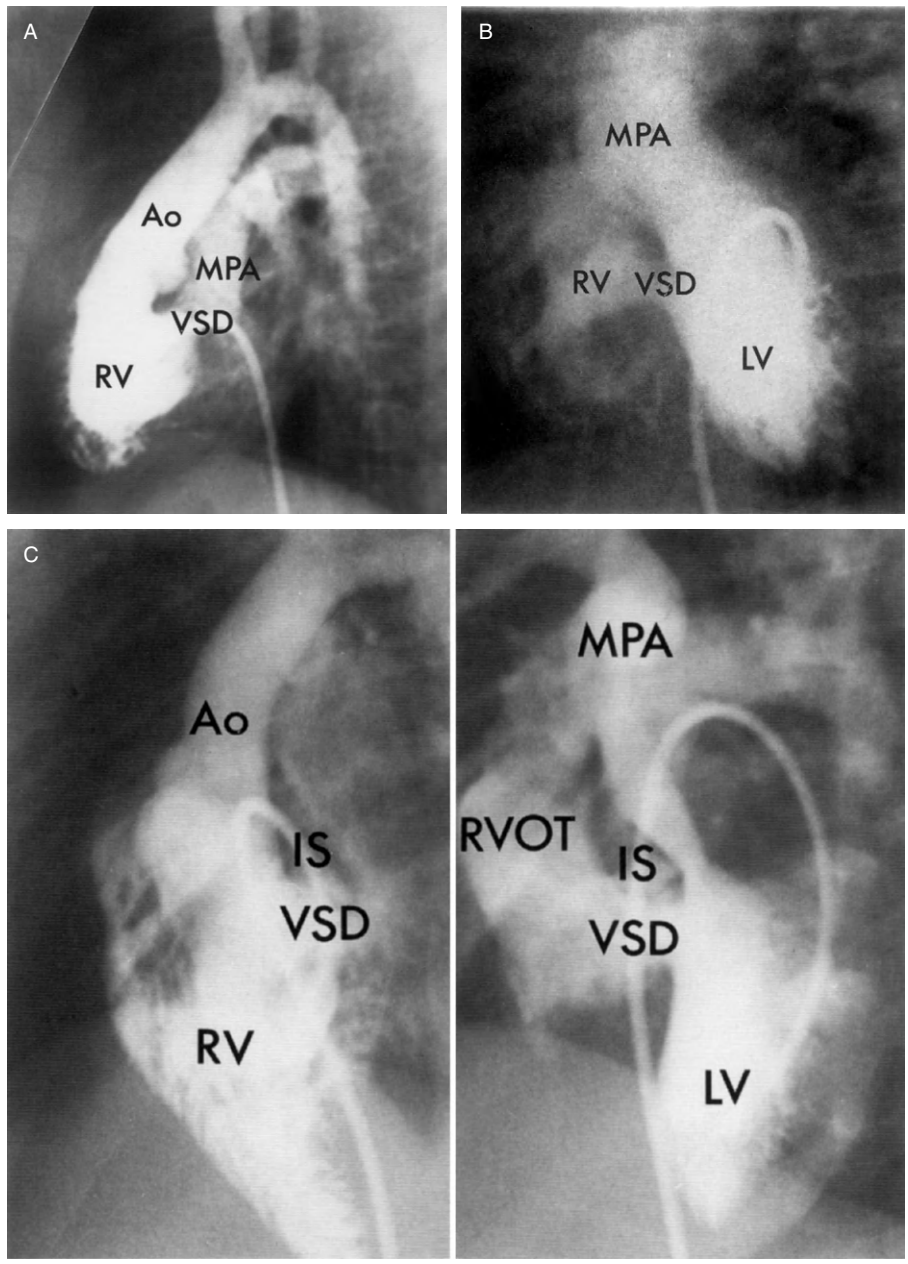

Figure 26.5 A, Cine cardioangiogram of a patient with transposition of the great arteries, nonmalalignment ventricular septal defect, and no pulmonary stenosis. **B,** Cine cardioangiogram of a patient with transposition of the great arteries, noncommitted, nonmalalignment ventricular septal defect, and no pulmonary stenosis. **C,** Cine cardioangiograms of a patient with transposition of the great arteries, ventricular septal defect, and subpulmonic stenosis caused by a posteriorly deviated infundibular septum. (Ao, aorta; IS, infundibular septum; LV, left ventricle; RV, right ventricle; MPA, main pulmonary artery; RVOT, right ventricular outflow tract.)

caused by cyanosis and poor perfusion. Correction of acid-base balance, maintenance of normothermia, prevention of hypoglycemia, and other routine supportive measures are undertaken. Prostaglandin E1 is administered to increase pulmonary blood flow and is usually followed by atrial balloon septostomy [67] to improve mixing. Whether balloon septostomy is used or not depends on the stability of the patient and the operative decision concerning arterial switch. A recent multicenter study of the incidence and causes of preoperative death in isolated TGA revealed that 20 of 199 neonates (9.9%) with TGA died before surgery [69]. The authors concluded that the high preoperative mortality rate was mainly because of absent or small atrial shunt and furthermore that prenatal diagnosis of TGA

with institution of prostaglandin E1 and balloon atrial septostomy immediately after birth could avoid a fatal outcome [69].

Surgical Management

The surgical management of TGA is determined by the associated lesions. Historically, numerous operations were introduced and employed until new therapeutic modalities limited their use.

The Blalock-Hanlon atrial septectomy was introduced in 1950 [70]. The operation, although associated with a high mortality rate, was successful in increasing atrial mixing at a time when balloon catheters and cardiopulmonary bypass were yet to be introduced. This procedure has been replaced largely by balloon septostomy, or open septectomy when necessary.

Pulmonary artery banding first was introduced for palliation in patients with VSD. The trend toward earlier corrective surgery and primary VSD closure has limited this operation to 1) patients with TGA and intact ventricular septum who, for one reason or another, did not undergo neonatal arterial switch and require left ventricular training; and 2) patients with TGA and right ventricular failure after an atrial baffle operation who might benefit from staged conversion to an arterial switch (see Arterial Switch). Internal pulmonary artery band placement has been used instead of classic banding to reduce the risk of pulmonary valve damage, pulmonary artery distortion, and pulmonary artery dilatation, with possible related coronary compression [71].

The Mustard [72] and Senning [73] atrial baffle procedures were created to reroute systemic venous return and pulmonary venous return to the ventricles that were associated with the appropriate great vessels. The pericardial baffle in the Mustard operation (Figure 26.6) [74] and the right atrial flap in the Senning operation (Figure 26.7) [34] direct systemic venous return to the left ventricle, pulmonary arteries, and the lungs for oxygenation. Oxygenated blood returns to the pulmonary atrium, right ventricle, aorta, and the systemic circulation. This obviously results in a physiologic correction but not an anatomic correction,

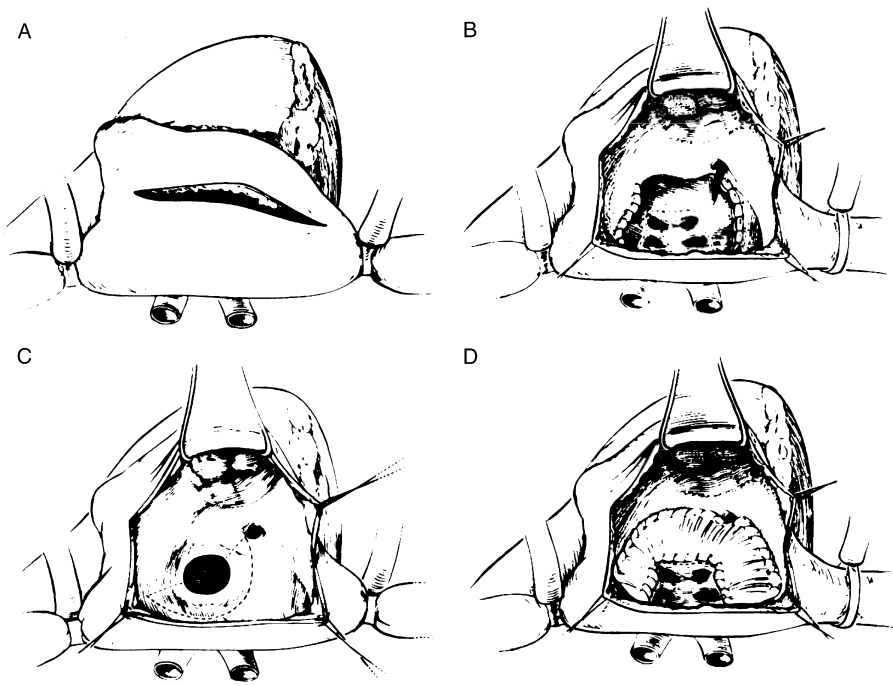

Figure 26.6 The Mustard operation. **A,** The right atrium is opened with a longitudinal incision well away from the sinoatrial node. **B,** The atrial septum is incised from the midpoint on a superior border of the atrial septal defect to the middle of the superior vena cava orifice. All the septum lateral to this incision is excised, avoiding the orifices of the right pulmonary veins. The ridge of the septum medially is preserved. **C,** The coronary sinus is cut back into the left atrium and all raw margins of atrial septum are oversewn. The *dotted line* indicates where the baffle will be sutured. **D,** Starting at the anterior lip of the left pulmonary vein orifices, the baffle is sutured in place, thus diverting the caval venous return to the mitral valve and the pulmonary venous return to the tricuspid valve. (Reproduced with permission from Trusler *et al.* [74].)

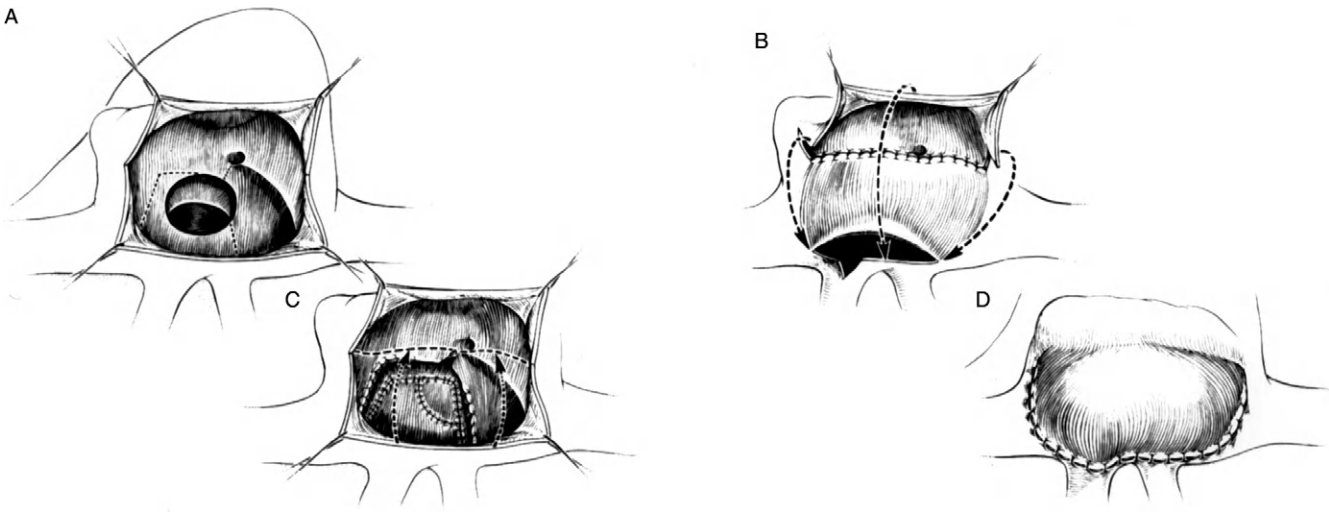

Figure 26.7 The Senning operation. **A,** The atrial septum is cut near the tricuspid valve, creating a flap attached posteriorly between the caval veins. **B,** The flap of atrial septum is sutured to the anterior lip of the orifices of the left pulmonary veins, effectively separating the pulmonary and systemic venous channels. **C,** The posterior edge of the right atrial incision is sutured to the remnant of atrial septum, diverting the systemic venous channel to the mitral valve. **D,** The anterior edge of the right atrial incision, lengthened by short incisions at each corner, is sutured around the cava above and below and to the lateral edge of the left atrial incision, completing the pulmonary channel and diversion of pulmonary venous blood to the tricuspid valve area.

because the systemic circulation is based on the right ventricle. The clinical results with these procedures were reproducible and associated with a low operative mortality rate (<5%). Long-term problems of superior vena caval obstruction, baffle leak, atrial and ventricular arrhythmias, tricuspid valve insufficiency, and right ventricular failure raised concerns with this approach [75,76]. The arterial switch operation has largely replaced the atrial baffle operations, with excellent mid- and long-term clinical results (see Arterial Switch).

Arterial Switch Operation for Transposition of the Great Arteries with Intact Ventricular Septum

The arterial switch operation has developed into the procedure of choice for TGA and associated great vessel malposition anomalies because of improved techniques of coronary transfer, myocardial protection, and neogreat vessel reconstruction [37,77–112]. These advances have resulted in improved survival statistics that compare favorably with the atrial baffle procedures [78,113–117]. The arterial switch operation results in left ventricle-to-aorta continuity and has not been associated with atrial arrhythmias, baffle stenoses, tricuspid insufficiency, right ventricular failure, and sudden death, all of which have been noted in patients who had atrial baffle repairs. Complications after an arterial switch have thus far been infrequent. Coronary insufficiency is the most common cause of early death [118], and right ventricular outflow tract (RVOT) obstruction, supravalvar and subvalvar, is the most common long-term complication leading to reoperation [97,118–123]. A multicenter study [123] reported a risk-adjusted base incidence of 0.5% per year of reintervention for right-sided outflow obstruction. Akiba and associates [124] postulate that even subtle size mismatch between the proximal aorta and pulmonary trunk may initiate adaptive infundibular hypertrophy. Potential problems of semilunar valvar regurgitation and supravalvar neoaortic stenosis have been infrequent [123]. Recent studies [125] have identified patients with coronary artery obstruction that has been treated by proximal coronary arterioplasty and internal thoracic artery-to-coronary artery bypass. It seems, however, that these problems will prove to be infrequent in the long term (Figure 26.8) [34,126].

The principles of the arterial switch operation for TGA with intact ventricular septum (simple transposition) are similar for the more complex anatomic anomalies such as TGA with VSD, the Taussig-Bing type of double-outlet right ventricle with subpulmonic VSD, and staged conversion of the Mustard operation to arterial switch. For the latter more complex cases the arterial switch is combined with VSD closure, subvalvar muscular resection, or atrial baffle conversion.

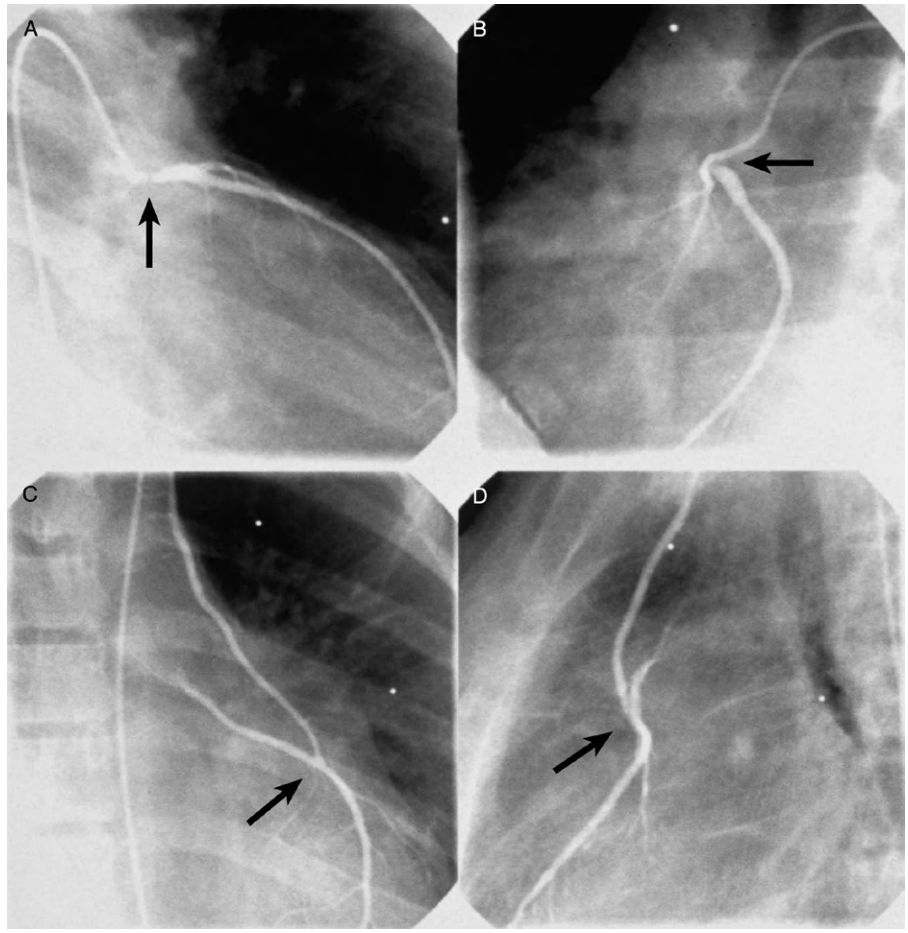

Figure 26.8 Cine cardioangiograms showing left main coronary artery stenosis 10 years after arterial switch. Arrows in **A** and **B** point to the areas of significant stenosis. **C, D,** Patent left internal thoracic artery to the middle left anterior descending coronary artery. Not shown is the proximal left main arterioplasty that was performed in concert with the coronary artery bypass graft.

An arterial switch for TGA can be divided into six stages, which include 1) pericardial harvest, evaluation, and dissection; 2) cannulation and cardiopulmonary bypass; 3) myocardial protection; 4) neoaortic reconstruction with coronary transfer; 5) neopulmonary artery reconstruction; and 6) separation from cardiopulmonary bypass and postoperative support.

Pericardial Harvest, Evaluation, and Dissection

After median sternotomy, pericardial harvest is performed for future neopulmonary artery reconstruction. Great care is taken to avoid injury to the phrenic nerves in the same manner as described for the Mustard operation [72,126]. The smooth visceral side should serve as the inner surface of the neopulmonary artery reconstruction. Some authors have recommended glutaraldehyde treatment [79,97] to stiffen and shrink the pericardium, thereby enhancing technical manipulation and preventing further pericardial shrinkage. We have avoided pericardial glutaraldehyde treatment because of anecdotal experience in a referred patient with significant and early supravalvar neopulmonary artery stenosis caused by pericardial shrinkage, which was confirmed at exploration. Presently we rely on a large redundant pantaloon pericardial patch with liberal tailoring, which has yielded a very low reoperation rate for neopulmonary artery stenosis.

The relationship of coronary artery distribution and origin to great vessel anatomy represents the most crucial planning stage of the arterial switch. Recognition of coronary anatomic patterns and ventricular flow distribution allows the surgeon to visualize the coronary transfer to the pulmonary artery-facing sinuses for the neoaortic reconstruction. During the developmental stages of neonatal arterial switch, some surgeons speculated that some

coronary artery patterns could not be switched because of poor results having to do with coronary insufficiency. Others [84,85,104,110–112] have noted that the great majority of patients are candidates for arterial switch as long as favorable coronary transfer is performed, thereby avoiding the hazards of kinking and obstruction. This issue is still being debated because of wide variations in coronary anatomy [36,127–130], operative conditions relating to anatomic configurations, and the widely divergent experience of surgeons. Increasing experience with this operation, however, has resulted in improved results for patients with all types of coronary anatomy patterns [108,131–133]. This will obviously decrease the incidence of the bail-out atrial baffle procedure, which has a high complication rate under these circumstances [81,99].

Extensive and meticulous great vessel dissection aided by needle tip electrocautery is performed routinely before initiation of cardiopulmonary bypass, with great emphasis on freeing hilar attachments from the respective pulmonary arteries [37,80,84,86–88,90,91,93–95,99–101,110–112]. Failure to perform this part of the operation effectively may result in excessive tension, bleeding, and supravalvar neopulmonary artery stenosis after the maneuver of Lecompte [91].

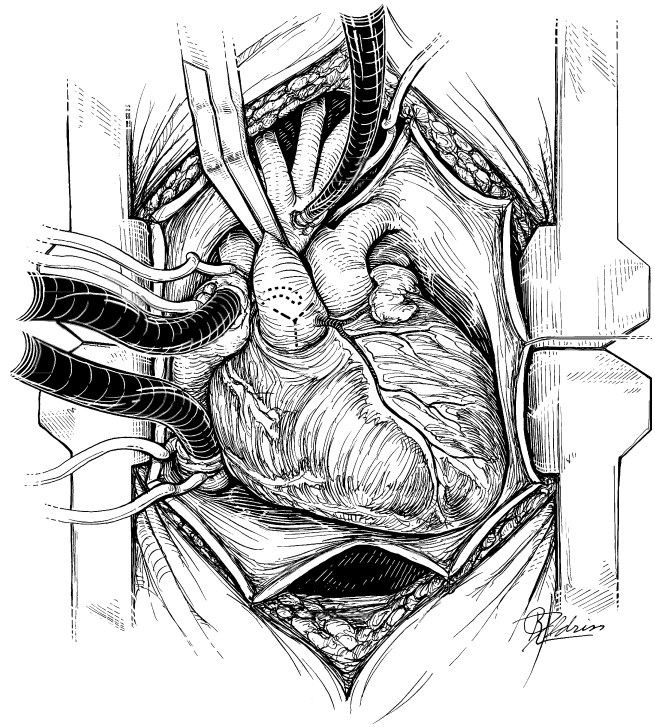

Figure 26.9 Aortobicaval cardiopulmonary bypass in a patient with transposition of the great arteries and intact ventricular septum. The aorta is cross-clamped in anticipation of antegrade cardioplegia and great vessel transaction.

Cannulation and Cardiopulmonary Bypass

Neonatal cannulation techniques for arterial switch are generally straightforward, varying slightly if deep hypothermia and circulatory arrest are employed. We place an 8-F arterial cannula (DLP, Inc., Grand Rapids, MI) near the innominate artery origin to maximize the available length of ascending aorta for neoaortic reconstruction and for the maneuver of Lecompte. Bicaval cannulation (Figure 26.9) [34] facilitates exposure to the atrial septal defect (patent foramen ovale or balloon septostomy tear) or VSD during continuous cardiopulmonary bypass without subjecting the patient to the hazards of circulatory arrest. In addition, the surgeon and perfusionist are spared the inconvenience of air in the venous line, which may occur with single venous atrial cannulation during the neopulmonary artery reconstruction. On the other hand, disadvantages of bicaval cannulation include small size and right atrial fragility, cannula-induced coronary artery tension, and atrial arrhythmias.

Single right atrial cannulation (Figure 26.10) [34] is simple and quick, and it provides effective venous drainage for cardiopulmonary bypass. The surgeon may elect to use deep hypothermia and circulatory arrest or various methods of continuous cardiopulmonary bypass during the stages of the arterial switch operation. Circulatory arrest during the atrial septal defect closure and neoaortic reconstruction frees the operative field of the left ventricular vent, two venous cannulas, and vena cava slings. Many authors [80,87,110–112] have reported excellent results with this technique. On the other hand, we feel that long periods of circulatory arrest (greater than 30 minutes) should be avoided if other reasonable means are available. Many studies [134–139] have emphasized that the safe period of deep hypothermia and circulatory arrest may be shorter than originally thought. Other recent experimental data have shown the superiority of hypothermia and low-flow states to deep hypothermia and circulatory arrest [140,141].

The Boston Circulatory Arrest Study Group [142–146], in a series of studies, has addressed the influence of hypothermic circulatory arrest versus low-flow cardiopulmonary bypass on the neurodevelopmental [142–145] and nonneurologic status [146] of neonates and infants who underwent surgical repair of TGA. Patients who had low-flow bypass had significantly greater weight gain and positive fluid balance while in the hospital after arterial switch; however this did not translate into a significant impact on duration of mechanical ventilation, intensive care unit stay, or hospital stay [146]. Duration of circulatory arrest was not associated with developmental outcome [143]. However, in a prospective study of infants undergoing arterial switch operation for TGA with or without VSD, circulatory arrest was associated with a higher risk of clinical seizures and overall greater central nervous system disturbance than a

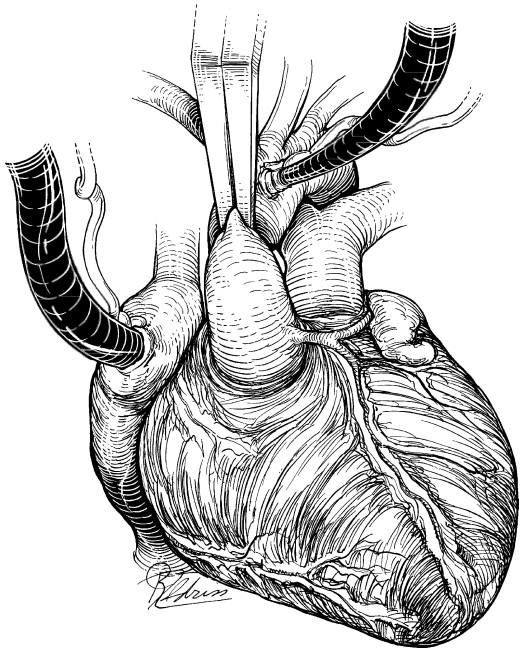

Figure 26.10 Aortouniatrial cardiopulmonary bypass in a patient with transposition of the great arteries with intact ventricular septum. The aorta is cross-clamped in anticipation of blood cardioplegia and great vessel transection. Special attention must be paid to the single atrial catheter position to avoid air introduction.

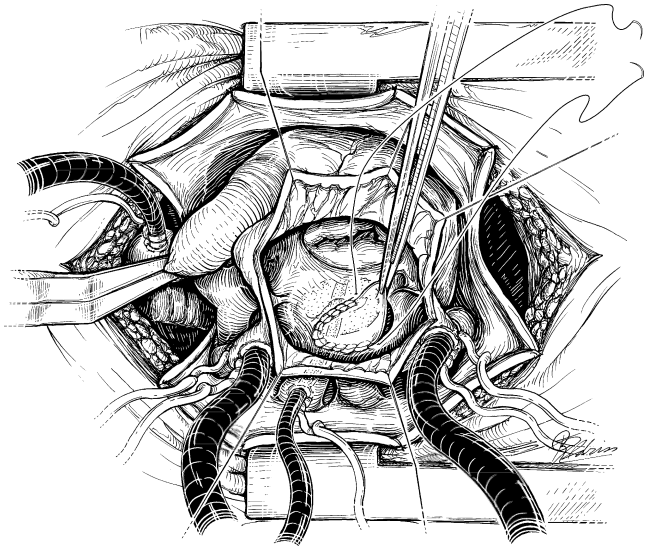

Figure 26.11 The atrial septal defect is repaired using bicaval cardiopulmonary bypass and cardioplegic arrest. Shown here is atrial septal reconstruction using a pericardial patch. Atriorrhaphy is then performed.

strategy of low-flow cardiopulmonary bypass [144]. Assessment at intermediate-term follow-up at 4 years of age and after arterial switch operation showed that the low-flow or circulatory arrest strategy choice and the duration of circulatory arrest did not significantly impact IQ scores or overall neurologic status, but use of circulatory arrest was associated with poorer motor coordination and planning [142]. Interestingly, the performance of the full cohort was below expected in IQ, expressive language, visual-motor integration, motor function, and oromotor control. Further longitudinal studies may help to identify critical factors for successful outcomes in neonates and infants who undergo repair of TGA.

Single venous cannulation does not necessarily require deep hypothermia and circulatory arrest for arterial switch. Low-flow states (0.2–0.4 L/min/m^2) with systemic hypothermia (22 °C) and sucker bypass can be employed for atrial septal defect closure. After atriorrhaphy, single venous drainage can be reinstituted for the remainder of the operation. Three disadvantages of this technique include 1) unwanted air may enter the venous line during the neopulmonary artery reconstruction; 2) undrained atrial blood may enter the right ventricle and cause local myocardial warming during cardioplegic arrest; and 3) undrained blood may enter the operative field and obscure landmarks and suture lines. We always have used continuous flow techniques with a bias toward bicaval venous cannulation for this operation. The initial extra time required to establish bicaval cannulation allows the surgeon uninterrupted time to perform the neogreat vessel reconstructions free from the inconveniences and potential hazardous episodes of venous line air, myocardial warming, and their attendant problems.

Conduct of Cardiopulmonary Bypass

Cardiopulmonary bypass is established with a standard blood prime, membrane oxygenator, and nonpulsatile perfusion. Flows are calculated at 2.0–2.5 L/min/m^2 with systemic hypothermia (22 °C). Left ventricular drainage is by a 10-F catheter placed via the right superior pulmonary vein. Bicaval cannulation allows right atriotomy for atrial or VSD closure without sucker bypass and prevents venous line air during the reconstruction phase (Figure 26.11) [34]. Low-flow (0.2–0.4 L/min/m^2) is used for short periods during neoaortic reconstruction to decrease venous return as necessary and increased gradually to 2.0 L/min/m^2 after myocardial reperfusion. Halfway through the neopulmonary artery reconstruction, the flow is increased further to 2.5 L/min/m^2 and the patient is rewarmed to 37 °C for separation from cardiopulmonary bypass.

Myocardial Protection

The evolution of neonatal myocardial protection techniques is based on sound experimental data [100,147–150].

We use antegrade single-dose blood cardioplegia, which in our practice is composed of cardiopulmonary bypass perfusate with 20 mEq/L of potassium chloride, 3 g/L of mannitol, 200 µg/L of nitroglycerin, and 12.5 g/L of albumin. In the event of unforeseen long cross-clamp time, retrograde coronary sinus cardioplegia infusion may be preferable to direct catheter coronary injection [151]. We also bathe the heart with iced saline slush during cardioplegic arrest to augment the benefits of blood cardioplegia [152].

Neoaortic Reconstruction and Coronary Artery Transfer

After aortic cross-clamping and cardioplegia are achieved, great vessel transection, the maneuver of Lecompte, and neoaortic reconstruction are performed. Adjustments for great vessel transection may be necessary based on the lengths of the vessels and their anatomic relationship.

Coronary artery excision from the respective sinuses of Valsalva is performed adjacent to the aortic commissures resulting in a large patch surrounding the coronary ostium, which will facilitate transfer and suture reconstruction (Figure 26.12) [34]. Fine-needle electrocautery and scissors are used to complete the dissection. The utmost care is exercised to avoid coronary injury during this part of the operation. Occasionally a small conal branch may require ligation to create more length for the coronary transfer. We have found, however, that careful and extensive dissection almost always obviates the need for ligation. The maneuver of Lecompte is then performed, translocating the pulmonary artery anterior to the aorta, along with repositioning of the aortic cross-clamp (Figure 26.13) [34]. Some surgeons have advocated side-by-side anatomic great vessel reconstruction [37], but most use the Lecompte maneuver, which minimizes neopulmonary artery tension.

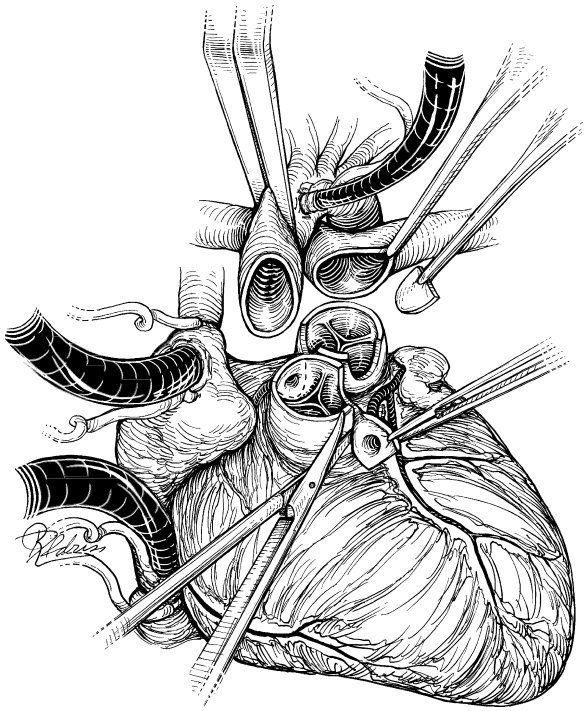

Figure 26.12 Fine scissor excision of the left coronary artery button from its sinus of Valsalva is shown. A liberal amount of aortic wall with the coronary artery is taken to facilitate the transfer to the neoaorta. Care is taken to avoid injury to coronary arteries.

The pulmonary artery–facing sinuses of Valsalva into which the coronary arteries are to be transferred have been prepared by punch excision [37,87,88,91,100,104], partial wall excision [93], and linear incision [79,84,85]. Some [79,153] advocate proximal pulmonary artery-to-distal aortic anastomosis before coronary transfer. This is followed by coronary patch alignment with the blood-filled neoaorta. The aortic clamp is then reapplied for the coronary patch transfer for a presumably more accurate reconstruction. We prefer to perform linear incisions, V-incisions, or U-shaped excisions into the facing sinuses, which allow for liberal excursion of the coronary patches thereby minimizing coronary kinking or obstruction. The coronary patches are placed in a "best lie" position for optimal flow after the reconstruction. The anastomotic lines are performed with running 8-0 monofilament suture (Figure 26.14) [34].

Special Coronary Problems

Anomalies of the coronary circulation in patients with TGA are common and varied [128,133,135,154–158]. In most cases there are two coronary ostia from the aortic sinuses of Valsalva, which favorably face the adjacent pulmonary artery sinuses of Valsalva (Figure 26.15) [159]. Special attention must be paid to coronary arteries arising from the nonfacing sinus (very rare), the single coronary artery, and the intramural coronary artery [39], which can traverse a commissure before emerging from the aortic wall. The rare circumstance of an artery arising from the nonfacing cusp is nontransferable unless prosthetic material or an internal mammary artery graft is used. Under these circumstances an atrial baffle operation may be preferable. The single coronary artery, however, is transferable by a number of techniques [102,130,155,160,161] depending on the anatomic relationships. Yacoub and Radley-Smith (Figure 26.16) [130] and Planche and associates (Figure 26.17) [102] have described methods to transfer the single coronary by the "trap door" technique employing aortic wall flaps for a favorable anastomosis. Sometimes the single coronary patch can be rotated in a "best lie" configuration, which can be managed by the aforementioned suture technique.

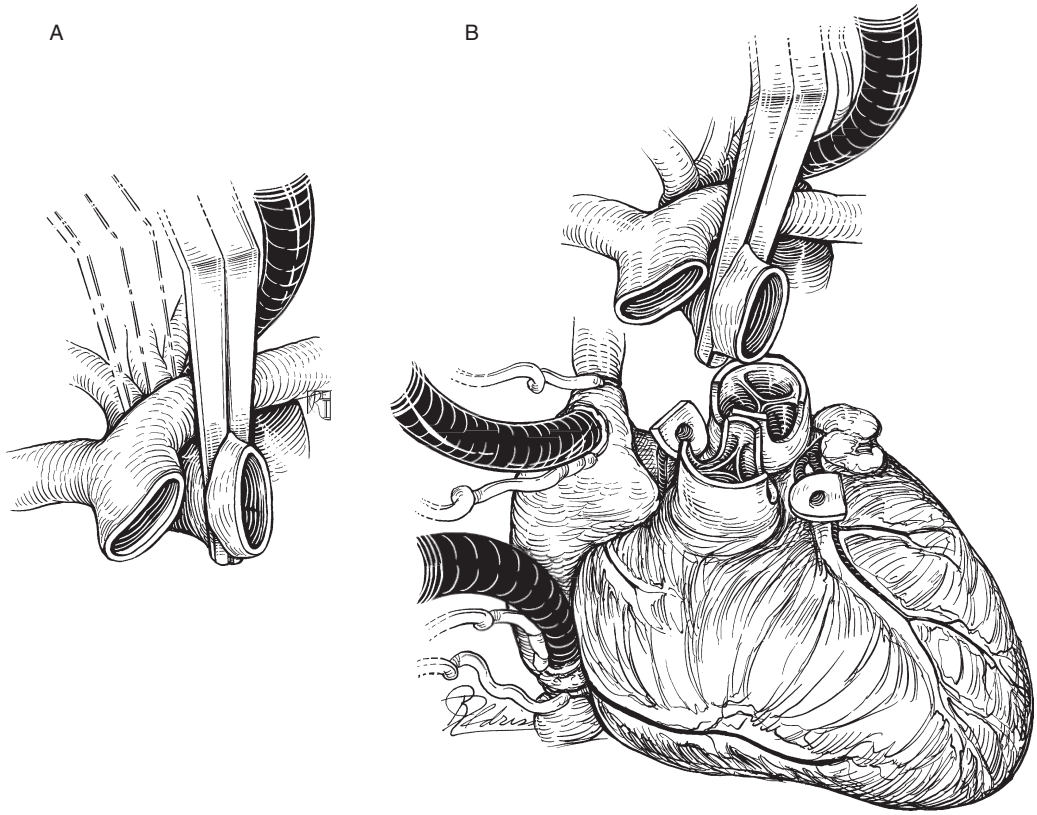

Figure 26.13 A, The maneuver of Lecompte (positioning the pulmonary artery anterior to the aorta) is shown, with aortic cross-clamp repositioning to retract the pulmonary artery during the neoaortic reconstruction. The phantom clamp represents the initial position on the aorta just before the administration of blood cardioplegia. The real clamp represents the new position on the aorta in order to retract the pulmonary artery after the maneuver of Lecompte. **B,** After the maneuver of Lecompte, the coronary artery buttons are mobilized in anticipation of anastomosis to the facing sinuses of the old pulmonary artery. After the reconstruction this will be called the *neoaorta*.

Whatever the circumstances the surgeon must be familiar with all these techniques in order to select the proper reconstruction for optimal coronary flow.

The intramural coronary artery [36,162,163] requires special attention and represents the greatest risk to the patient. The main principles for transfer are to recognize the anatomy before patch excision to avoid coronary transection, to accurately identify the intramural aortic wall entry and exit points, and to sacrifice valvar and commissural tissue in favor of the coronary artery anastomosis since the neopulmonary valve can be resuspended and reconstructed with pericardium to minimize the well tolerated possibility of neopulmonary valvar insufficiency. Oftentimes the orifice of the intramural branch coronary artery will require unroofing to prevent coronary hypoperfusion and resultant myocardial infarction [164,165]. New technical modifications have been introduced including the use of pericardial hoods [166], arterial switch with *in situ* coronary relocation [167], and arterial switch without coronary relocation [168] to meet the challenges of coronary artery anatomy in transposition.

Neopulmonary Artery Reconstruction

The goal of the neopulmonary artery reconstruction is to avoid the development of supravalvar stenosis. This is achieved by pericardial patch augmentation of the dissected sinuses of Valsalva of the old aorta, prevention of pulmonary artery distortion by extensive dissection to both pulmonary hili, and having direct continuity of native distal pulmonary artery and proximal neopulmonary artery for at least a portion of the anastomosis for eventual growth. Many methods have been described. Pacifico and colleagues [100] employed the posterior incision method, which depends on the distal pulmonary artery tissue to fill out the dissected sinuses of Valsalva without resorting to pericardium or graft material. Others [37,81,93,94] have advocated redundant double pericardial patches. We use the single pantaloon pericardial patch technique

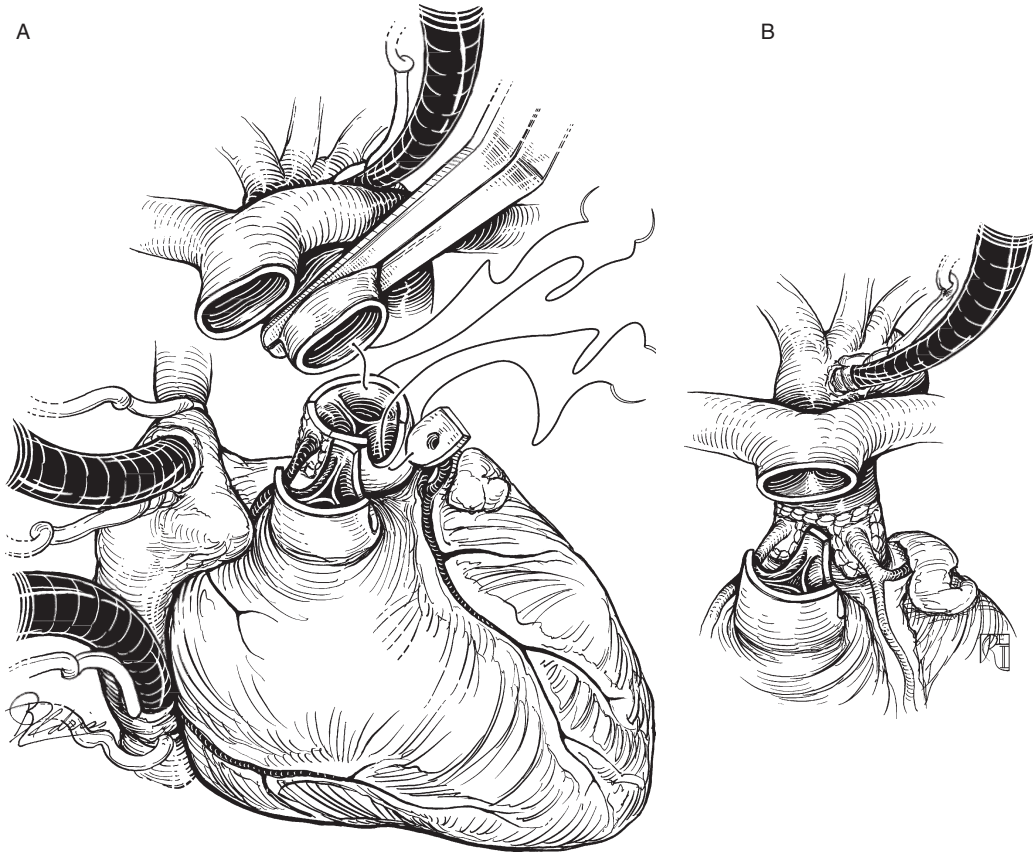

Figure 26.14 A, After the coronary patches are mobilized, they are sutured to the facing sinuses of Valsalva at the old pulmonary artery (neoaorta). **B,** Neoaortic reconstruction is completed with the end-to-end anastomosis between the proximal neoaorta and the ascending aorta. Coronary artery reperfusion is established after the cross-clamp is removed.

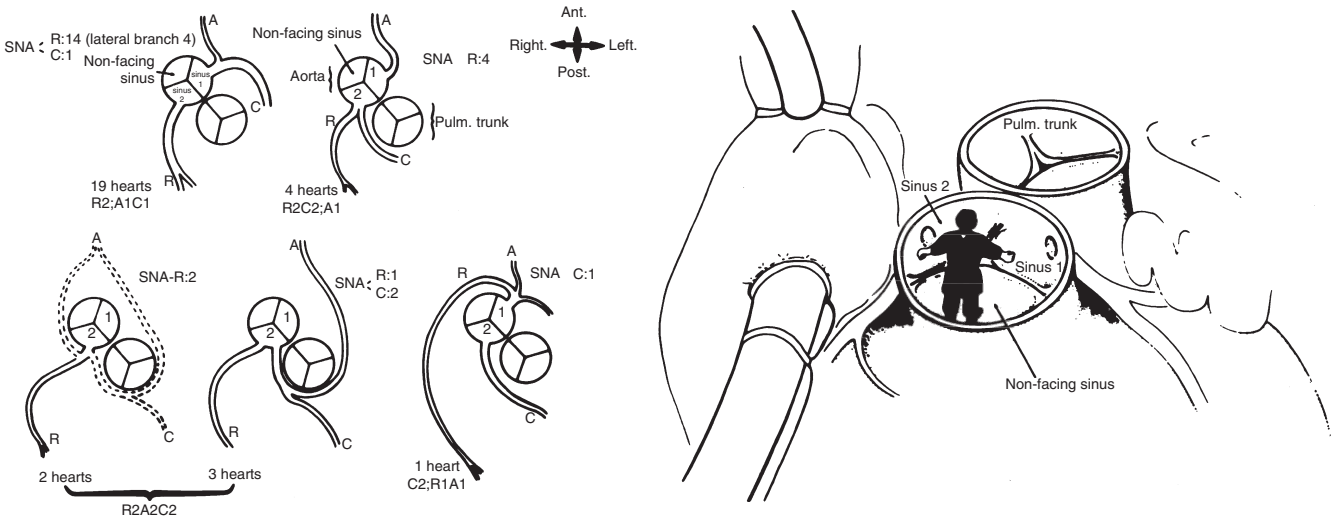

Figure 26.15 These two drawings show the convention for naming the aortic sinuses by Gittenberger-de Groot and colleagues. On the right, the two sinuses of the aorta face two sinuses of the pulmonary trunk and the third sinus is nonfacing. The figure in the diagram is standing in the nonfacing sinus and looking toward the pulmonary trunk. The coronary sinus to the right is sinus 1 and that to the left is sinus 2. On the left, the four patterns of coronary artery origin, including the origins of the sinus node artery (SNA) in each pattern, are noted. In all, the sinus node artery arose from the right coronary artery (R) in 25 hearts and from the circumflex artery (C) in three hearts. The coronary artery patterns are described using a simple system that takes into account the origins of the right coronary artery, the circumflex artery, and the anterior descending coronary artery (A) from either sinus 1 or sinus 2. The designation R2;A1C1, for example, describes the origin of the right coronary artery from sinus 2 and the latter two arteries from sinus 1. (Reproduced with permission from Rossi *et al.* [159].)

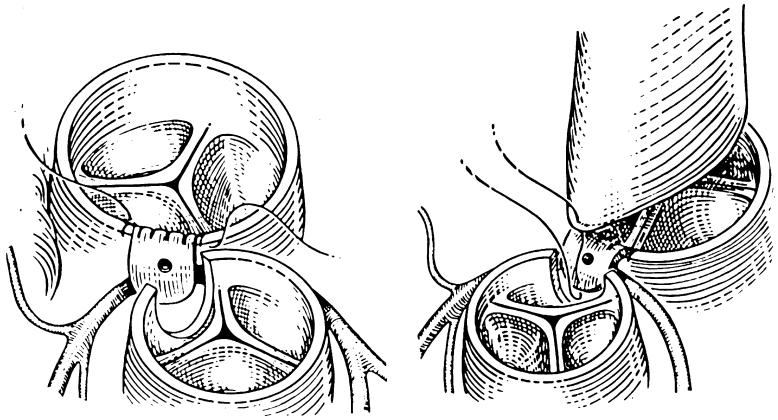

Figure 26.16 Yacoub's method of single coronary artery transfer. The coronary patch is turned 180 degrees and sutured upsidedown to the neoaorta. The distal aorta and the proximal aorta are then anastomosed to facilitate flow and avoid coronary obstruction. (Reproduced with permission from Yacoub *et al.* [130].)

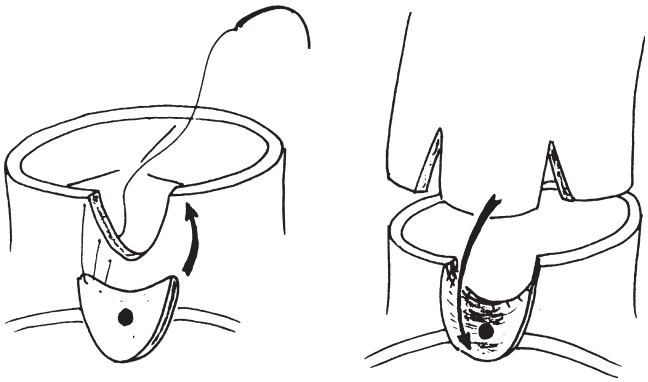

Figure 25.17 Planché's method of single coronary artery transfer. After the 180-degree coronary patch turn, a "trap door" is constructed at the distal aorta to form the neoaortic reconstruction without coronary kinking. (Reproduced with permission from Planché *et al.* [102].)

(Figure 26.18) [34,79,84,85]. A generous redundant pericardial patch is recommended without glutaraldehyde pretreatment. This method also allows the option of added posterior length, which may facilitate the repair and avoid coronary artery compression. The anterior portions of the distal pulmonary artery and the neopulmonary artery are always primarily anastomosed to allow for proportional growth.

Reconstruction of the neopulmonary artery for patients with Taussig-Bing anomaly or TGA with VSD and coarctation represents a significant challenge because of the associated small aorta, which is to become the neopulmonary artery. Hirata *et al*. [169] recently reviewed their experience with 51 patients and found that neonatal single-stage repair for TGA/coarctation achieves excellent survival without transannular patch at first operation. Although some of those patients had pressure gradients across the neo-RVOT, these lesions were amenable to reintervention in a small number of patients and with minimal morbidity. Sinzobahamvya and associates [170] advocate subaortic (subpulmonary artery) resection to treat this problem.

Separation from Cardiopulmonary Bypass and Postoperative Care

Separation from cardiopulmonary bypass is preceded by a careful evaluation of anastomotic suture lines and coronary perfusion. Coronary insufficiency can be suspected by qualitative regional wall dysfunction, high dose pressor requirements, and persistent ischemic electrocardiographic changes. In some cases filling of the heart during separation from cardiopulmonary bypass may result in coronary stretching, kinking, or occlusion. Other causes of coronary obstruction are neopulmonary artery compression, coronary malrotation, and intimal dissection. Corrective measures can be employed after reinstitution of cardiopulmonary bypass, including coronary pericardial patch augmentation [94], pulmonary artery suspension to treat coronary artery compression, and internal mammary artery grafting to the affected coronary artery [171]. Rarely extracorporeal membrane oxygenation (ECMO) may be necessary to support the stunned myocardium until recovery [172]. In general this form of circulatory support is most successful if the affected patient has had a period of circulatory stability before decompensation. It is important to correct the original problems that led to hemodynamic instability if a successful outcome is to be achieved.

The great majority of patients are separated from cardiopulmonary bypass with dobutamine (5μg/kg/min), dopamine (5μg/kg/min), and milrinone (.5μg/kg/min). Under these circumstances the patient's blood pressure can be expected to range between 65 and 85mmHg systolic with a wide pulse pressure and excellent peripheral perfusion. Drug doses may vary to achieve optimal levels of cardiac output, afterload reduction, and organ perfusion.

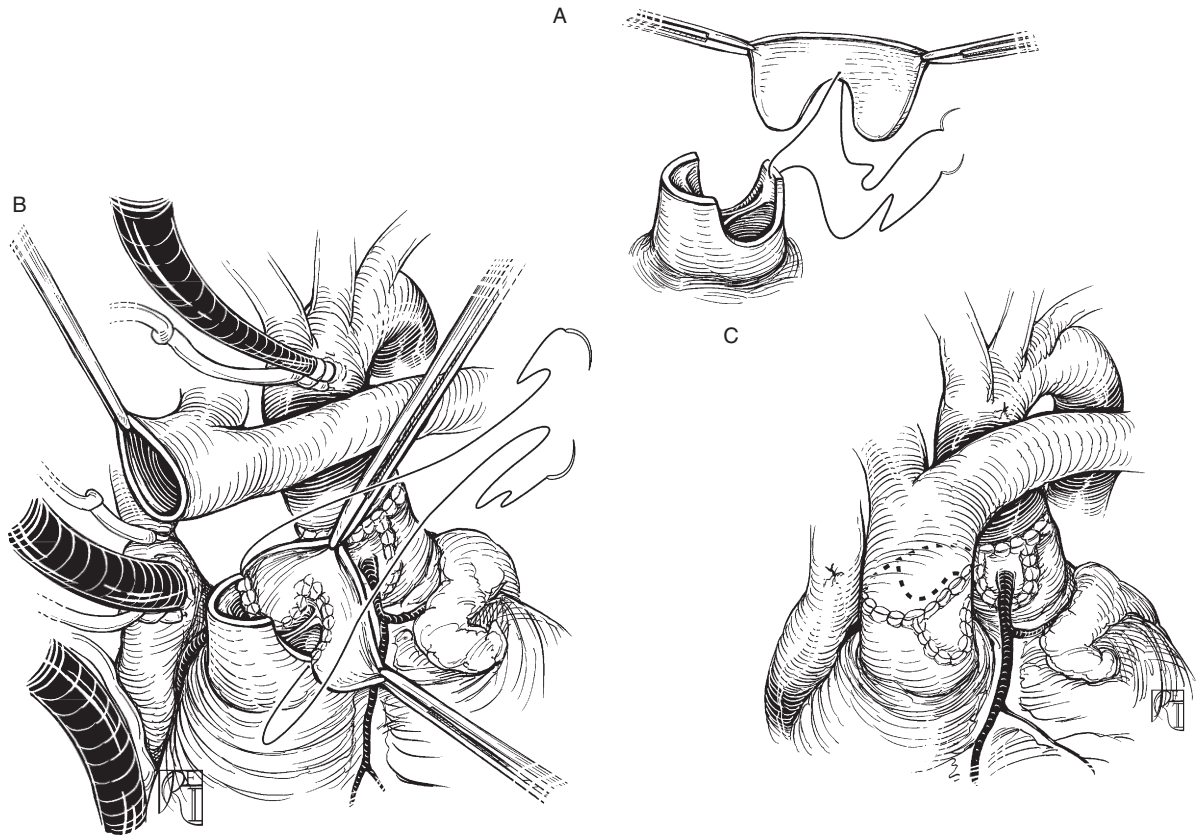

Figure 26.18 A, The "pantaloon" pericardial patch is shown being oriented to the old aorta (neopulmonary artery). **B,** During the rewarming stage the pantaloon pericardial patch can be sutured to the sinuses of Valsalva, thereby filling out the neopulmonary artery. **C,** The completed anastomosis is shown after separation from cardiopulmonary bypass.

Once hemodynamic stability has been ascertained, we employ a 10-minute period of modified ultrafiltration [173,174], which can be expected to yield 200–400 mL of transudate. This procedure was initially thought to remove myocardial depressant factors and harmful cytokines from the circulation, thereby enhancing myocardial performance. The more likely mechanism is that modified ultrafiltration has the effect of increasing the hematocrit and concentrating the pressor agents so that the effective doses in circulation tend to be higher. This allows for an elective decrease in pressor agents to achieve optimal hemodynamics. After sternal closure and transfer to the pediatric intensive care unit, repeated physical examination noting fontanelle fullness, liver edge level, strength of peripheral pulses, capillary filling time, and hourly urinary output will guide postoperative care. Ventilatory support is adjusted to maintain adequate oxygenation and mild respiratory alkalosis. The weaning process can then be started on the day following surgery or sooner if the program has instituted an early extubation policy.

Results and Analysis

The mid- and long-term survival rates of patients who had arterial switch for TGA are encouraging [103,106,108]. In the latest communication from the Congenital Heart Surgeons Society, 513 infants underwent an arterial switch repair [97]. The 1-month, 1-year, and 5-year survival rates were 84%, 82%, and 82%, respectively. Identified risk factors for death include origin of the left main coronary artery or only the left anterior descending or circumflex artery from the right posterior sinus (even stronger when an intramural course was present), multiple VSDs, longer global myocardial ischemic time, and total circulatory arrest time. Certain institutions were risk factors for death; with increasing experience, results improved in some centers while in others they worsened. These results were sustained in a follow-up study from the same cohort of patients [175].

Numerous other reports from large institutions have confirmed these results [79,102–104,106,108,176–185]. Sup-

ravalvar pulmonary stenosis was more likely in the early experience with arterial switch but became less prevalent after conversion to the autologous pantaloon-shaped pericardial patch to fill out the dissected sinuses of Valsalva of the neopulmonary artery [85]. Myocardial ischemia owing to coronary insufficiency is still the most common cause of perioperative death but has been decreasing with improved myocardial preservation and techniques for coronary transfer. Normal sinus rhythm is present in the vast majority of patients (>95%) and neoaortic regurgitation, when present (5–10%), is mild and nonprogressive.

The arterial switch operation for neonates with TGA and intact ventricular septum can be performed with a <5% operative mortality at most centers. The repair results in both anatomic and physiologic correction and appears to offer great expectations for excellent long-term results. Postoperative complications associated with the atrial baffle operations, which include atrial arrhythmias, ventricular dysfunction, and baffle obstructions, have been virtually eliminated. Moreover the incidence of anastomotic strictures, neoaortic insufficiency, and supravalvar pulmonary stenosis with the arterial switch operation has been quite low. Consequently the arterial switch operation for neonates with TGA and intact ventricular septum is the procedure of choice.

Arterial Switch and Ventricular Septal Defect Closure for Transposition of the Great Arteries and Ventricular Septal Defect

Arterial switch for TGA and intact ventricular septum required a learning curve for surgeons to achieve the survival statistics of the atrial baffle procedures [112]. Not so with arterial switch for TGA and VSD. The mortality rate for the atrial baffle procedures combined with VSD closure was so high (>21%) [109,186] that the initial reports by Jatene *et al.* (16% mortality) [37] and Pacifico and colleagues (0% mortality) [100] quickly established arterial switch and VSD closure as the procedure of choice and provided a more optimistic future for these patients who have become virtually free from the complications of arrhythmias, right ventricular failure, and late death.

With increasing experience, patient selection and timing of the operation have evolved. Initially arterial switch and VSD closure were delayed until 2–18 months of age while patients were treated medically or surgically (pulmonary artery band) for excessive pulmonary blood flow. Recently the trend has shifted toward earlier intervention. Bove [187] reported 12 infants (mean age, 19 days) with TGA and large VSD undergoing arterial switch and VSD closure with one early death and no late deaths. It appears that the limiting factor for early repair is patient size. The surgeon may elect to perform pulmonary artery banding with subsequent anatomic repair at a later date in low-birthweight neonates.

Over the last 25 years the clinical results for arterial switch and VSD closure have been excellent [188]. Increasing experience and familiarity with the operation has resulted in earlier intervention without pulmonary artery banding. Likewise, there was a change from staged repair in those patients with coarctation or interrupted aortic arch to transmediastinal one-stage repair using extended end-to-end aortic anastomoses in addition to arterial switch and VSD closure.

Current Approach

The operative procedure for TGA and VSD is similar to that previously described with the obvious additional need for VSD closure. Aortobicaval cannulation is established to maximize exposure for right atrial, transpulmonary, or transaortic access to the VSD. We recommend that VSD closure be performed before the arterial switch. This is important as the neoaortic reconstruction cannot be disrupted by the retraction maneuvers required for intracardiac exposure of the VSD. Experimental studies [189,190] have supported the practice of cardioplegic arrest or reperfusion and subsequent cardioplegic arrest when used under these clinical conditions. Alternatively, multiple administrations of retrograde cardioplegia can be performed.

Our usual approach to VSD closure is transatrial (Figure 26.19) [34], but can also be through the pulmonary artery

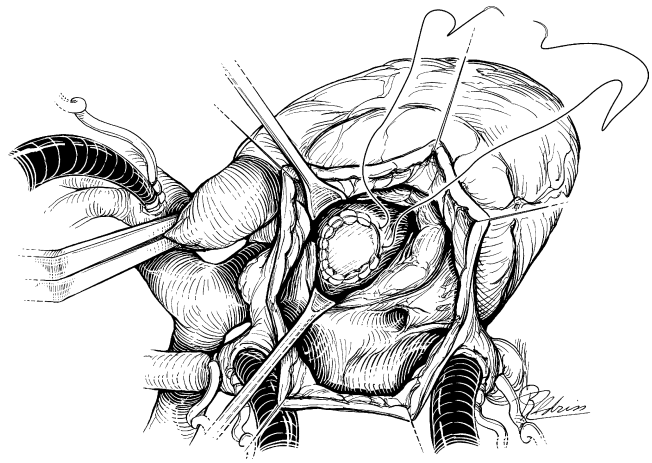

Figure 26.19 After arterial and bicaval venous cannulation, the ventricular septal defect is approached and closed through the right atrium under blood cardioplegic arrest. Running suture technique usually is performed. Alternatively, interrupted pledget-supported sutures can be used.

(Figure 26.20) [34] or the aorta when convenient. In our series of 28 patients, eight VSDs were closed through the pulmonary artery, 20 were closed through the right atrium, and none required ventriculotomy.

Many authors have reported excellent results with the arterial switch and VSD closure. Quaegebeur *et al.* [104] reported an 18% operative mortality rate in 1986, which was supported by the Congenital Heart Surgeons Society report [97] showing a 6–13% mortality rate at seven designated low-risk institutions. Reports by Yamaguchi and colleagues [191] and Planche *et al.* [192] showed that the arterial switch and VSD closure could be performed safely in neonatal and early infant time periods. The Society of Thoracic Surgeons National Congenital Heart Surgery Database Report revealed an overall mortality rate of 6.2% (22 deaths in 355 patients) in patients undergoing arterial switch for repair of TGA [193]. In the subgroup with TGA and VSD, the mortality rate was 6.3% (7 deaths in 111 patients) [193]. Follow-up studies [182,184] have confirmed the increased incidence of early mortality in patients with TGA and VSD when compared with mortality for arterial switch in patients with TGA and intact ventricular septum.

Staged Repair of Transposition of the Great Arteries with Intact Ventricular Septum

There are occasions when for one reason or another infants present late after the neonatal period when left ventricular pressure is low owing to decreased pulmonary vascular resistance. Under these circumstances a staged repair may be performed for ventricular training to induce left ventricular hypertrophy for adequate postoperative systemic circulatory support [194]. The staged repair, consisting of pulmonary artery banding, systemic-to-pulmonary artery shunt, and subsequent anatomic repair, was first described by Yacoub and colleagues in 1977 [112]. In our series of patients who have had an arterial switch, staged repair was more common among the earlier cases [195] owing to late referral or changing management (atrial switch to arterial switch) in older patients.

Surgical guidelines and techniques for left ventricular preparation at our institution have been previously published [86]. The exposure has changed from a left thoracotomy to a median sternotomy, which offers better exposure (Figure 26.21) [34]. The initial postoperative evaluation is determined by echocardiographic assessment of left ventricular wall thickness. Repeat cardiac catheterization is then performed before the arterial switch to measure

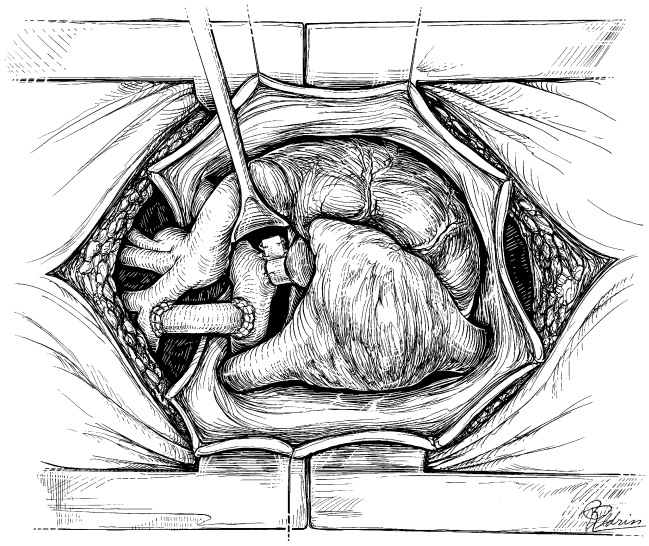

Figure 26.21 Diagrammatic representation of pulmonary artery band with a polytetrafluoroethylene systemic-to-pulmonary artery shunt for left ventricular training in preparation for arterial switch. With the band positioned but not tightened, a standard 5-mm modified Blalock-Taussig shunt (4 mm if infant's weight is <2.5 kg) is performed. The systemic blood pressure is monitored as the band is tightened sequentially until the proximal pulmonary artery approaches two thirds of the systemic pressure or until the oxygen saturation drops below 85%.

ventricular volumes, ejection fraction, and left ventricular muscle mass. Conditions favorable to successful arterial switch are 1) left ventricular wall thickness as indicated by echocardiography normal for the patient's age; 2) left ventricular to right ventricular pressure ratio greater than 70%; and 3) left ventricular volume and muscle mass normal for age.

Recent reports have advocated extending the boundaries of primary arterial switch operation in patients with TGA and intact ventricular septum outside the usual 2-week limit after birth [196,197] to as long as 2–3 months of age. This strategy has the advantage of eliminating preparatory pulmonary artery banding and systemic-pulmonary shunt, which is associated with pulmonary valve (neoaortic valve) dilatation and resultant neoaortic insufficiency after arterial switch. Adapting late arterial switch without left ventricular training, however, may lead to a period of mechanical support after arterial switch during which adaptation of the left ventricle takes place [198].

Arterial Switch Operation for Double-Outlet Right Ventricle and Subpulmonary Ventricular Septal Defect (Taussig-Bing Anomaly)

Taussig and Bing [15] first described an anatomic variation of TGA and VSD in a 5-year-old girl with a complex congenital cardiac malformation in which the aorta and pulmonary artery arose entirely from the right ventricle with the pulmonary artery overriding a VSD. This was redefined by Van Praagh [199] as a double-outlet right ventricle with semilunar valves side-by-side, a bilateral conus, and a subpulmonic VSD. Lev [200] expanded this definition to describe a spectrum of four types of hearts including the right-sided type without an overriding pulmonary trunk, the right-sided type with an overriding pulmonary trunk, an intermediate type, and the left-sided type.

A variety of operations have been used to repair the Taussig-Bing anomaly. Initial attempts at repair were aimed at anatomic correction to preserve left ventricular to aortic continuity, first described by Patrick and McGoon in 1968 [201]. This operation was refined by Kawashima *et al.* in 1971 [202], who described a similar intraventricular repair but emphasized the need for resection of the conal septum to avoid subaortic and subpulmonic stenosis. This technique may require enlargement of the VSD, tricuspid papillary muscle transfer, and/or an external valved conduit [203]. Experience with this repair is somewhat limited: Harvey and colleagues [204] reported four patients with one survivor; Kirklin *et al.* [205] reported nine patients, most of whom had external conduits, with no operative mortality and four late deaths; and Yacoub and Radley-Smith [206] reported two successful cases. We have used this intraventricular tunnel from the left ventricle to the aorta successfully in four patients with side-by-side great vessel orientation [207]. In all cases the right ventricle-to-pulmonary artery continuity was restored without a conduit. Adequate conal septum resection was of paramount importance. Yacoub and Radley-Smith [206] and Van Praagh [208] have suggested that this repair should be limited to patients with side-by-side great vessels and should not be used for those with anteroposterior relationship of the great arteries who should have arterial switch and VSD closure instead.

Another therapeutic alternative was first described by Hightower and colleagues in 1968 [209] and later applied by others [204,205,210–213]. These authors performed VSD closure to establish right ventricular-to-aortic and left ventricular-to-pulmonary artery continuity that was accompanied by an atrial baffle procedure with variable results. However successful the initial results, these patients are still left with a physiologic but nonanatomic correction, which subjects them to the known complications of the atrial baffle procedures.

There are some patients with the Taussig-Bing anomaly in whom mitral straddling with abnormal valvar attachments to the crest of the VSD occurs. This group was identified as the left-sided or intermediate type [214]. Under these circumstances closure of the subpulmonic VSD and either arterial switch or atrial baffle may lead to death from subvalvar neoaortic obstruction and left ventricular failure. Preoperative evaluation and intraoperative confirmation can determine accurately the anatomy of the mitral valve attachments and their relationship to the VSD. If unfavorable anatomy is found, an atrial baffle operation, closure of the VSD, and a left ventricle-to-pulmonary artery conduit can be performed.

A third approach to the Taussig-Bing heart employs a modification of the technique described by Damus and coworkers [215], Stansel [216], and Kaye [217]. In this procedure the VSD is closed to connect the left ventricle to the pulmonary artery. The pulmonary trunk is divided, and the proximal pulmonary artery is connected end-to-side to the ascending aorta. A valved extracardiac conduit is then placed from the right ventricle to the distal pulmonary artery [218,219]. Ceithaml *et al.* reported four patients with three survivors [220]. Although this procedure has the advantage of left ventricle-to-aorta continuity, it has the disadvantage of requiring an extracardiac conduit, and the attendant problems of multiple conduit changes during a lifetime.

The fourth choice for repair of the Taussig-Bing anomaly is VSD closure and arterial switch, which was first reported by Freedom *et al*. in 1981 [82] and by Yacoub and Radley-Smith in 1984 [206]. Our early experience with the Taussig-Bing anomaly relied on preparatory palliative operations before arterial switch and VSD closure. The initial survival was excellent but several patients required late neoaortic

valve replacements, recoarctation repair, and pulmonary outflow procedures [165,188]. Our more recent experience favors transmediastinal one-stage repair to perform arterial switch and VSD closure with or without coarctation repair and arch augmentation (see Chapter 25, *Double-Outlet Ventricles*).

Other authors [104,192,221] have had similar favorable results. An association between coarctation and Taussig-Bing anatomy has been noted previously by Parr and colleagues [222]. In their review of 105 Taussig-Bing heart patients, coarctation and/or aortic outflow tract obstruction was noted in 56 (53%); six of nine surgically treated for Taussig-Bing heart also had coarctation of the aorta.

This combined surgical experience shows that an arterial switch can be performed successfully for patients with both side-by-side and anteroposterior orientation of the great vessels, although Quaegebeur [223] cautioned that the Lecompte maneuver may not be helpful when the great arteries are side by side. In some cases it may be easier to slide the redundant pulmonary artery behind the new aorta for a direct anastomosis. He also noted that the coronary artery anatomy in the Taussig-Bing anomaly is similar to that in classic TGA. The same principles for coronary artery transfer therefore can be applied.

The arterial switch and VSD closure for the Taussig-Bing anomaly have distinct advantages of low mortality, anatomic and physiologic connections, no need for extracardiac conduits, and applicability to most patients despite the variability in coronary anatomy and great vessel orientation [224].

Staged Arterial Switch Operation for Right Ventricular Failure After the Atrial Baffle Procedures

Right ventricular failure after an atrial baffle procedure can occur in up to 10% of patients in the long-term [225] and more if patients had an associated VSD [76]. Nearly all of these have associated severe tricuspid insufficiency with varying amounts of pulmonary hypertension [226]. Surgical options for these patients include tricuspid valve replacement, staged conversion to arterial switch, and cardiac transplantation. Our experience with tricuspid valve replacement has been dismal. Of six patients who had tricuspid valve replacement for right ventricular dysfunction and tricuspid insufficiency, four died, one had subsequent cardiac transplantation, and only one had a good hemodynamic result. These results indicate that tricuspid insufficiency in these patients is a manifestation of right ventricular failure for which valve replacement has few beneficial effects. The preferable alternatives appear to be staged conversion to arterial switch or orthotopic cardiac transplantation.

Staged conversion of an atrial baffle procedure to arterial switch was first performed and reported by Mee [227] in 12 patients with the idea that pulmonary artery banding could induce left ventricular mass development in preparation for subsequent takedown of the atrial baffle, takedown of the pulmonary artery band, and an arterial switch. Twelve patients underwent pulmonary artery banding with two deaths from this procedure alone. Six patients subsequently had conversion to arterial switch with two deaths, and three patients underwent orthotopic cardiac transplantation with one late death. In a later series from the same center [228], 12 patients with failed atrial switch were reported, of whom nine proceeded to arterial switch operation with Senning or Mustard takedown and atrial reseptation. There were two postoperative deaths and one patient underwent cardiac transplantation 3 months after surgery. Others [229–231] have performed arterial switch without preparatory pulmonary artery banding in selected patients with pulmonary venous obstruction complicating a Mustard procedure. Left ventricular retraining was serendipitous as a consequence of pulmonary venous obstruction; systemic level pressure was present in the pulmonary ventricle and provided the opportunity to perform a one-stage arterial switch successfully.

Our experience [232] with staged conversion is limited to 11 patients who underwent 15 preparatory pulmonary artery banding procedures: four eventually had orthotopic cardiac transplantation for biventricular failure; six had an arterial switch procedure (atrial arrhythmias were treated concomitantly in two patients with cryoablation techniques). There were two early deaths (33%) and no late deaths in the six patients who underwent arterial switch operation. There were no early deaths in the transplanted patients and one late death 7 years after transplant from chronic rejection. The two deaths in the arterial switch group were related to an untransferred paracommissural coronary artery in one patient with resultant myocardial infarction and unanticipated postoperative left ventricular dysfunction in another patient secondary to presumed inadequate left ventricular hypertrophy. Postmortem examination revealed the left ventricular posterior wall had 7 mm of muscle and 3 mm of fibrous tissue, not 10 mm of muscle. One patient awaits arterial switch conversion.

Staged conversion from atrial baffle to arterial switch begins with the pulmonary artery banding to achieve proximal pulmonary artery pressure equal to 75% of the aortic or right ventricular pressure. Pressor support and mechanical ventilation usually are required for the first few days. Postoperative surveillance is performed by serial echocardiography and cardiac catheterization to determine left ventricular volume, pressure, and muscle mass. When these parameters are close to normal for the child's age, the child undergoes an arterial switch. The arterial switch technique is performed in the usual manner after atrial baffle takedown (Figures 26.22–26.24) [88], pulmonary artery band removal, and proper coronary artery identification.

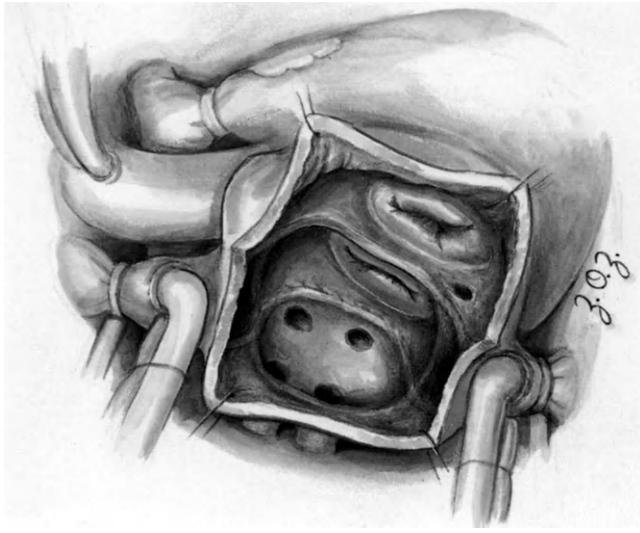

Figure 26.23 Diagrammatic representation of the common atrium after pericardial baffle excision. (Reproduced with permission from Mavroudis *et al.* [88].)

We found that an extension graft is necessary to provide continuity between the proximal neopulmonary artery and the distal pulmonary artery because of inadequate pulmonary artery length caused by dense scarring from the multiple procedures. Severe right ventricular dysfunction after an atrial baffle procedure for TGA does not improve after tricuspid valve replacement. Staged conversion to the arterial switch can improve right ventricular function and provide anatomic repair with left ventricle-to-aorta continuity. Orthotopic cardiac transplantation may be the only

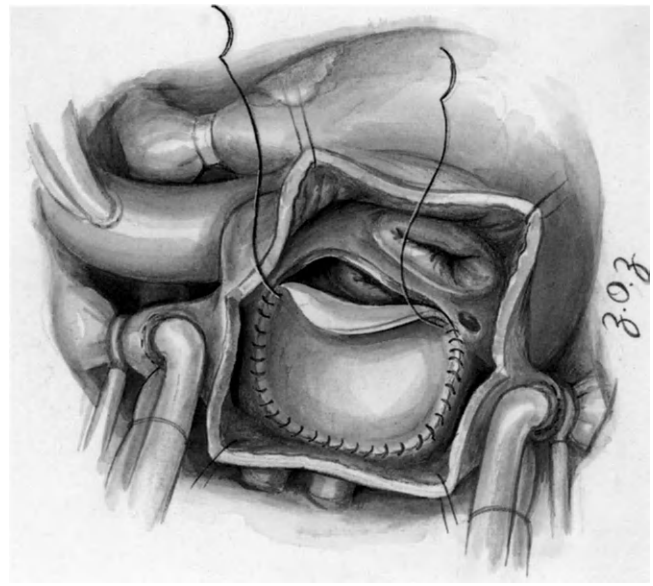

Figure 26.24 Atrial septation with polytetrafluoroethylene to reconstruct the right and left atria anatomically and physiologically. (Reproduced with permission from Mavroudis *et al.* [88].)

alternative if the left ventricle does not respond to pulmonary artery banding.

Late Complications and Reoperations Following the Arterial Switch Operation

Acquired Supravalvar Pulmonary Stenosis

Theoretical long-term complications after successful arterial switch include great vessel anastomotic constriction, neoaortic valvar insufficiency, and coronary insufficiency. These complications have manifest over time, requiring interventions in a small percentage of patients [165,188,232]. The most common cause for reoperation early on in the collective experience has been supravalvar pulmonic stenosis. Yacoub *et al*. [110] first recognized this problem (1982), which has since been confirmed by others [104,110,233,234]. Several groups [104,110,234] have documented residual right ventricular-to-pulmonary artery pressure gradients mostly caused by constrictions at the supravalvar anastomotic site, presumably resulting from pericardial patch constriction, anastomotic tension, or suture purse-string. Supravalvar pulmonary artery stenosis can also occur more peripherally owing to inadequate dissection or unfavorable anatomy as a result of the maneuver of Lecompte [91]. With increasing experience [130,233,235] acquired pulmonary artery stenosis has been quite low (<10%) and does not appreciatively change over time. A single pantaloon patch of fresh autologous pericardium is the preferred method of

neopulmonary artery reconstruction [84] and in contrast to earlier reports [104,235] side-by-side great vessel anatomic configuration did not affect coronary transfer or future incidence of pulmonary stenosis. The Congenital Heart Surgeons Society Transposition Study has underlined these findings, showing a low incidence of supravalvar pulmonary stenosis (6%).

We have reoperated on only six patients for pulmonary stenosis in our combined series of patients [165,188]. We attribute these results to the use of large pericardial patches (early in the series) and a single large pantaloon pericardial patch (later in the series) to fill out the dissected sinuses of Valsalva of the neopulmonary artery. When required, reoperation should be uncomplicated (Figure 26.25) [34]. The multiple refinements with neopulmonary artery reconstruction have fulfilled their theoretical expectations. More information will become available as these children grow into adulthood.

Postoperative Arrhythmias

It was initially thought that atrial and ventricular arrhythmias, which were frequently seen with the atrial baffle operations, would not occur in patients who had arterial switch. Longer follow-up and critical review, however, have uncovered several physiologic and anatomic problems leading many authors to recommend lifelong surveillance. Hayashi and associates [236] noted a small but measurable incidence of late-onset atrial and ventricular arrhythmias in TGA patients treated with arterial switch, especially in those who had associated VSD closure. Angeli *et al*. [237] identified RVOT obstruction, coronary artery obstructions, and neoaortic root dilation with neoaortic insufficiency as rare causes for reoperation. These same themes have been highlighted by others involving coronary obstructions and neoaortic regurgitation [238–241]. It is clear that patients who have had arterial switch for TGA will require lifelong follow-up for rare but identifiable complications [125].

Neoaortic Insufficiency and Neoaortic Anastomotic Stenosis

Early angiographic and echocardiographic evaluation [127,130,234,242] has not demonstrated significant supravalvar neoaortic stenosis. There is also a low incidence of

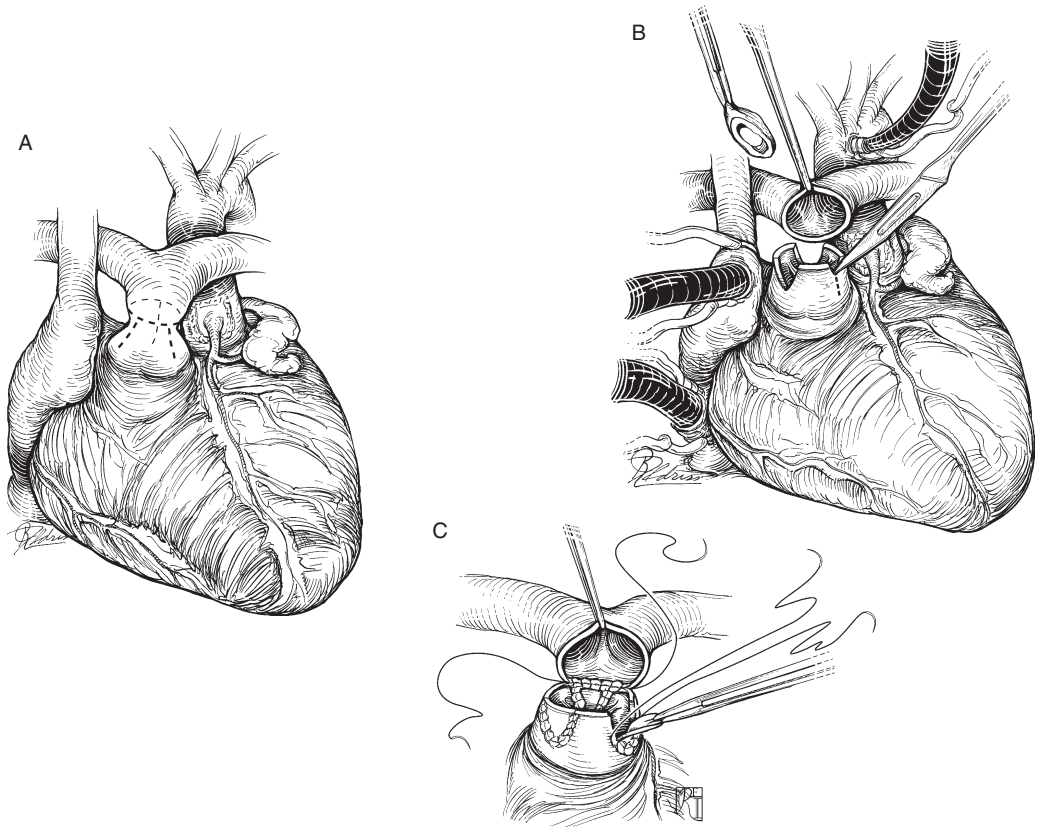

Figure 26.25 **A,** The proposed longitudinal incisions across the stenosis into all sinuses of Valsalva of the neopulmonary artery are shown. **B,** The supravalvar stenotic area is excised and incisions are made into the respective sinuses of Valsalva. **C,** Pericardial or synthetic patches are sutured into the enlarged sinuses of Valsalva; this is followed by neopulmonary artery reconstruction.

neoaortic valvar insufficiency, which when present usually does not progress [78,243]. We also have found a low incidence of neoaortic valvar insufficiency in our patients, resulting in 12 patients who had neoaortic valvuloplasty or replacement. Some of these patients required further reoperations resulting from failed valvuloplasty procedures or somatic growth [165]. Many of these patients had a pulmonary artery band before the arterial switch or complex arterial switch associated with VSD, aortic interruption, or Taussig-Bing anomaly. The speculation is strong that pulmonary artery banding under these circumstances causes proximal pulmonary artery and annular dilatation that can lead to neoaortic insufficiency after arterial switch [237–241]. The trend away from the use of pulmonary artery banding should help to minimize this problem in the future. However there will be patients who require pulmonary artery banding such as those born with low birthweight, those with low left ventricular mass, and those with right ventricular failure after atrial baffle. Care must be taken to minimize the time between the pulmonary artery banding and the arterial switch to avoid the annular dilatation effects of the pulmonary artery band. Technical aspects of neoaortic valve operations require extensive exposure of the neoaorta, which can be quite challenging in light of the preexisting Lecompte maneuver. We have found that proximal right pulmonary artery transection and main neopulmonary artery retraction results in excellent exposure of both the neoaortic valve and transferred coronary arteries. Figure 26.26 [165] demonstrates the exposure for neoaortic valvuloplasty (David operation). Because the neoaortic valve repair/replacement occupies more space, an interposition graft is placed between the main neopulmonary trunk and the distal right pulmonary artery (Figure 26.26E) [165].

Coronary Artery Problems

The most common cause of acute failure of the arterial switch operation is coronary artery obstruction caused by anastomotic problems, anatomic subtypes, and intramural courses. With increasing experience involving thorough coronary dissection, mobilization, and accurate coronary button transfer to the neoaorta, the incidence of acute coronary insufficiency has decreased. Long-term ischemic complications, however, have been reported [125,165], which have required proximal aortacoronary artery patch arterioplasty (using pericardium or a harvested pulmonary artery wall graft) and/or internal thoracic to coronary artery bypass grafts (Figure 26.27) [165]. It is not always known, preoperatively, whether proximal arterioplasty will treat the problem, leaving authors [125] to use both strategies to ensure revascularization.

Recently, we had experience [165] with an 18-year-old male patient who had an uncomplicated neonatal switch operation for TGA and intact ventricular septum. At the time of the arterial switch operation, an intramural coronary was transferred without being unroofed. Eighteen years later, he suffered an ischemic cardiac arrest, resuscitation using ECMO, and eventual reoperation to unroof the intramural course of the coronary artery (Figure 26.28) [165]. Postoperative CT scan (Figure 26.29) [165] reveals an excellent result; moreover he retained neurologic and myocardial function despite undergoing a below-the-knee amputation as a result of ECMO. This experience further underlines the idea that coronary unroofing should be performed at the initial operation.

Damus-Stansel-Kaye Procedure

As noted previously, an alternative anatomic and physiologic correction for patients with TGA was suggested by Damus [244], Stansel [216], and Kaye [217] and subsequently successfully applied by Danielson and colleagues [245] and Damus *et al.* [215]. Unlike the arterial switch operation the coronary arteries are not transferred to a neoaorta. Instead flow from the left ventricle to the aorta is established by connecting the proximal cut-end portion of the pulmonary artery end-to-side into the ascending aorta. The right ventricle is connected to the distal pulmonary artery by a valved conduit. The VSD, if present, can be closed through the right ventriculotomy in the usual fashion without an internal baffle. The aortic valve, which still arises from the right ventricle, is kept closed by the aortic pressure, which is greater than the right ventricular pressure. This procedure has been especially useful in patients who are undergoing staged conversion from atrial baffle procedure to systemic correction because dense adhesions after multiple operations may prohibit coronary transfer and arterial switch [246]. Others have used this approach for patients with Taussig-Bing anomaly with good results. The disadvantages of this operation are 1) the fate of the aortic valve, which is situated over the right ventricle in a static closed position and is subject to leaking and clot formation; and 2) the obvious need for periodic conduit changes as the child grows.

TGA, VSD, and Pulmonary Stenosis

The therapeutic alternatives for patients with TGA, VSD, and pulmonary stenosis are dependent on the severity and type of pulmonary stenosis and the size and location of the VSD. The more severe the pulmonary stenosis and the smaller the VSD, the earlier in life that cyanosis is detected. Several treatment options for these patients center on the initial palliative options and the corrective operations are generally performed later in life. If the patients show symptoms of severe cyanosis, a systemic-to-pulmonary artery shunt and balloon or surgical septectomy may be

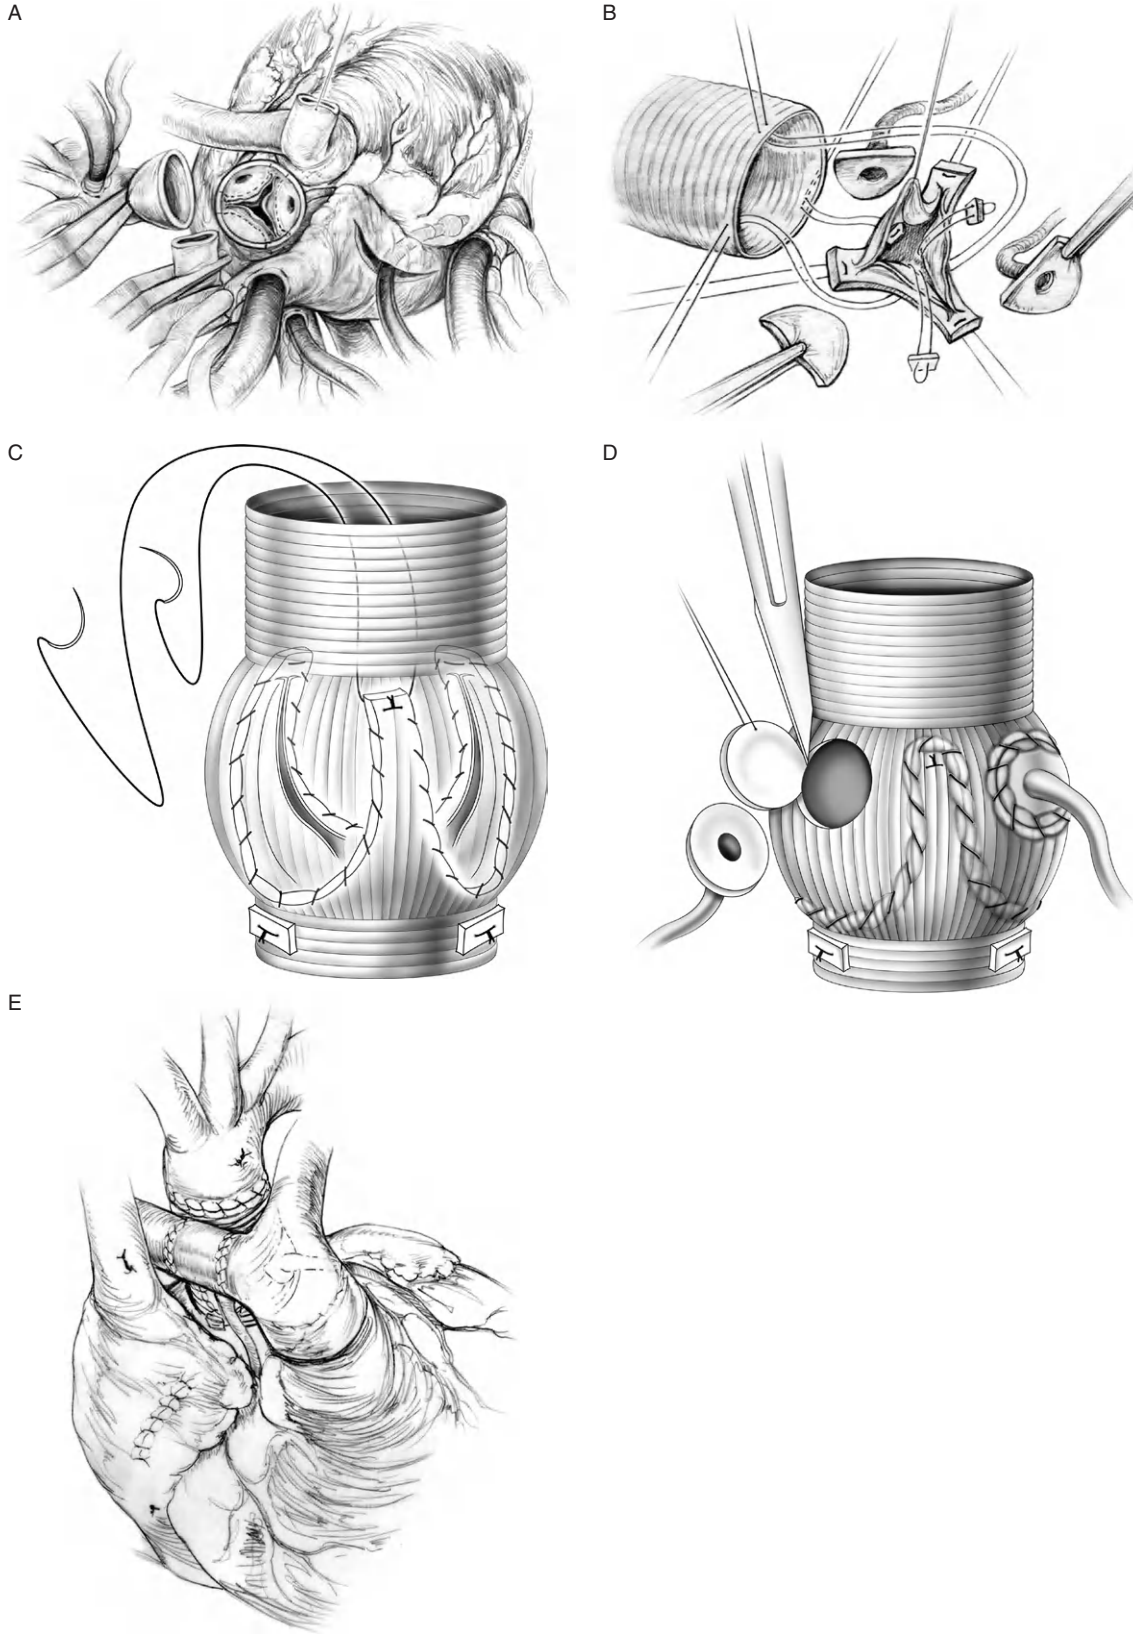

Figure 26.26 Neoaortic valve-sparing operation as modified after the David procedure. **A,** Neoaortic exposure after right pulmonary artery transection, main neopulmonary artery retraction, cardioplegic arrest, and neoaortic transection. necessary to increase mixing. Others with a more balanced combination of defects may do well for months without palliation.

The classic corrective procedure for these patients has been the Rastelli operation (Figure 26.30) [34,51], which diverts left ventricular flow via an intraventricular baffle to the aorta and establishes right ventricular-to-pulmonary artery continuity by a valved conduit. Ideally the VSD should be large and doubly committed to avoid the development of baffle-induced subaortic stenosis. Occasionally intraventricular alterations must be performed to ensure adequate left ventricular-to-aortic flow, including 1) enlargement of the VSD; 2) subaortic muscle resection; and 3) reattachment of obstructive tricuspid papillary muscles. Because of these possibilities most surgeons prefer to delay this procedure until after 6–12 months of life, performing palliative procedures as necessary in the early stages of life. Mortality rates between 10% and 29% [247–249] have been reported for the initial procedure. However, statistics for long-term survival show a continued risk of death owing to reoperations for conduit stenosis and left ventricular dysfunction in some patients.

In an effort to decrease the subsequent operations required for conduit replacements, Lecompte introduced a method to reconstruct the pulmonary outflow tract without a prosthetic conduit [52], which he termed the REV procedure [250]. The procedure is comprised of 1) infundibular resection to enlarge the VSD; 2) intraventricular baffle to direct left ventricular flow to the aorta; 3) aortic transection in order to perform the maneuver of Lecompte; and 4) direct pulmonary artery to right ventricular reconstruction using an anterior patch (Figures 26.31 and 26.32) [34]. Lecompte reported on 50 patients (4 months to 15 years, mean 3.8 years) who had this operation with an 18% operative mortality rate and no late death [250]. Six patients had reoperations: two for recurrent pulmonary stenosis and the other four for residual VSDs. The long-term results of this operation were recently reported by DiCarlo and associates [251]. They reviewed 205 patients who underwent the REV procedure between 1980 and 2003. Hospital mortality was 12%. Overall survival and freedom from any reoperation at 25 years were 85% and 45%, respectively. They concluded that their results were more favorable than those reported for the Rastelli operation in terms of survival and need for reoperation for left or right outflow tract obstruction [251].

Another option for patients with TGA, VSD, and pulmonary stenosis is the arterial switch. There are selected patients who have well developed pulmonary valves and annuli, based on data from echocardiography and angiography, with subpulmonic obstruction owing to prolapsed tricuspid valvar tissue through the VSD (Figure 26.33) [34]. Under these circumstances it is possible to reduce the accessory valvar tissue back through the VSD into the right ventricle, close the VSD, and complete the arterial switch. We have successfully performed an arterial switch in three such patients, each time reducing the accessory tricuspid tissue through the VSD and out of the left ventricular outflow tract. The decision to progress with the arterial switch was based on favorable transpulmonary artery left ventricular outflow tract evaluation at the time of operation before aortic transection. This way the Rastelli operation can still be performed in the event of unfavorable left ventricular outflow tract evaluation. Careful preoperative consideration must be given to both arterial switch and Rastelli operations to maximize the probability of a successful outcome.

The Nikaidoh procedure and the various manifestations relating thereto [252–257] have offered surgeons a new approach to TGA, VSD, and pulmonary stenosis. The rationale for this operation is based on the shortcomings of the Rastelli procedure. While the Rastelli operation is a reasonable option, it is not ideal because the left ventricular to aortic tunnel will 1) often require septal resection; 2) often result in subaortic/tunnel stenosis; and 3) reduce the size of the right ventricular cavity. The aortic translocation repair (Nikaidoh operation), on the other hand, provides an unobstructed pathway from the left ventricle to the neoaorta while limiting the need for septal resection and the large right ventriculotomy necessary for the Rastelli

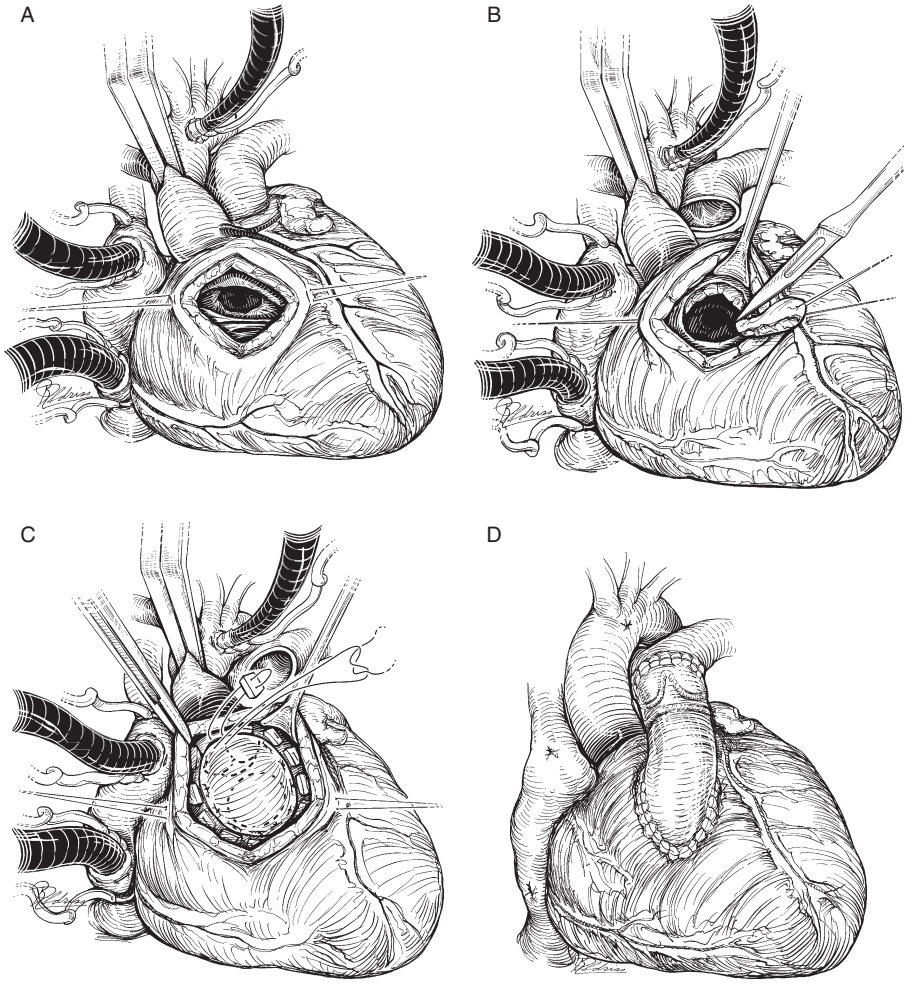

Figure 26.30 The Rastelli operation. **A,** A right ventricular incision is made with due regard to the tricuspid valve attachments, the ventricular septal defect anatomy, coronary artery distribution, and intended position of the conduit. **B,** A comprehensive infundibular resection is performed to maximize left ventricular-to-aortic continuity. **C,** The ventricular septal defect is closed with a large patch, creating an ample tunnel to the aorta. The distal pulmonary artery is opened at the most appropriate site for the distal conduit anastomosis. **D,** The valved conduit is in place after separation from cardiopulmonary bypass.

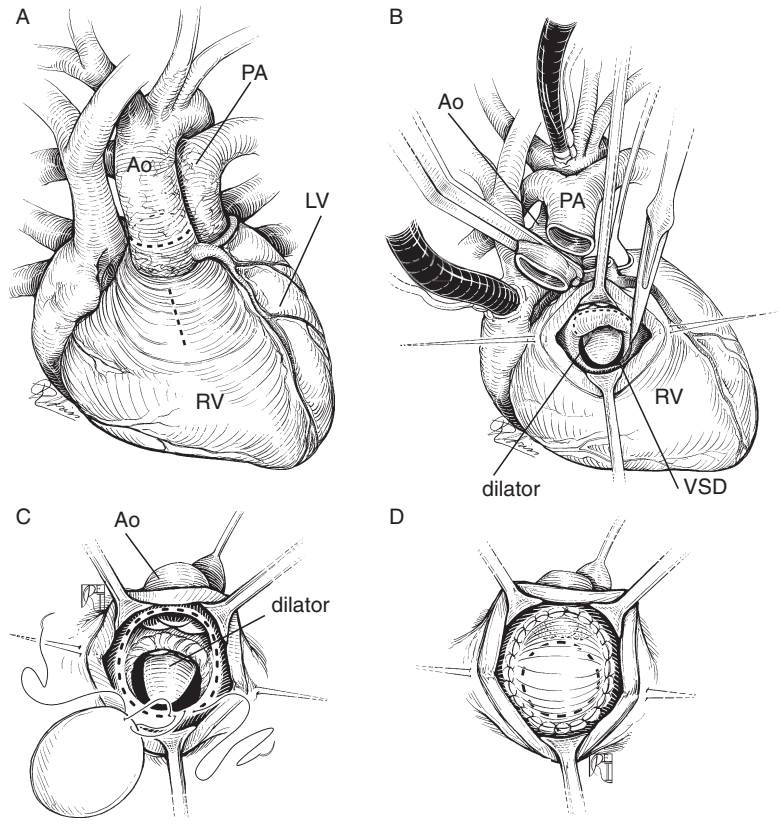

Figure 26.31 Correction of transposition of the great arteries with ventricular septal defect and pulmonary stenosis, the réparation à l'étage ventriculaire procedure. **A,** The *dotted lines* indicate the planned aortic and right ventricular incision sites. **B,** After right atrial and aortic cannulation and initiation of cardiopulmonary bypass, the aorta and pulmonary artery have been transected, and the ventricular septal defect is exposed. *Dotted lines* indicate the portion of the infundibular septum to be excised. The dilator is introduced through the pulmonary outflow tract to define the infundibular septum for resection. **C,** The Dacron patch is placed to direct left ventricular flow to both the aorta and pulmonary artery. The proximal pulmonary artery (not shown) is oversewn, thereby ensuring left ventricular flow only to the aorta. **D,** The left ventricle-to-aorta internal baffle is shown completed. (Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle; VSD, ventricular septal defect.)

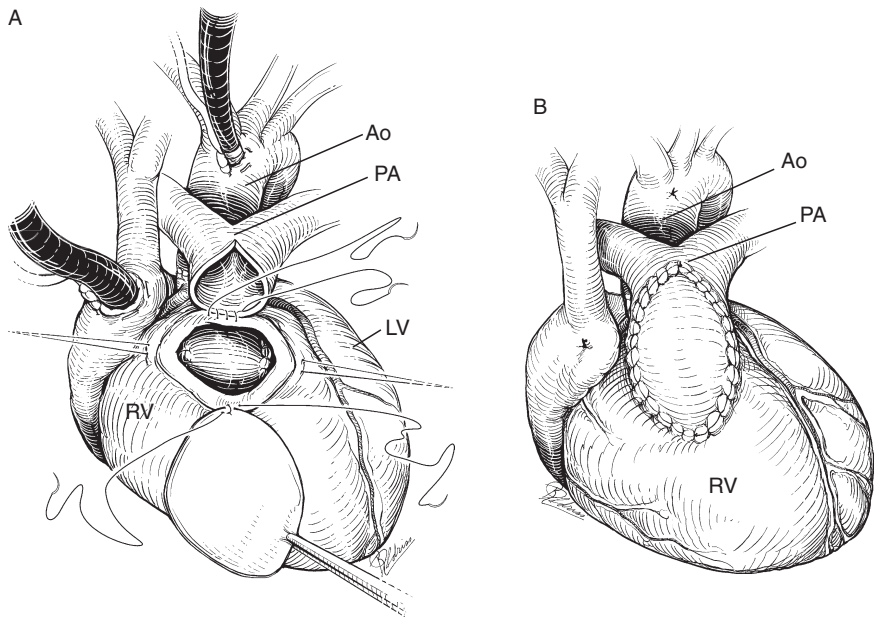

Figure 26.32 A, The superior portion of the right ventriculotomy is sutured directly to the posterior portion of the main pulmonary artery. **B,** A pericardial or synthetic patch is used to complete the right ventricle-to-pulmonary artery reconstruction. Sometimes a monocusp is placed within this reconstruction to create pulmonary valvar competence. (Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle; VSD, ventricular septal defect.)

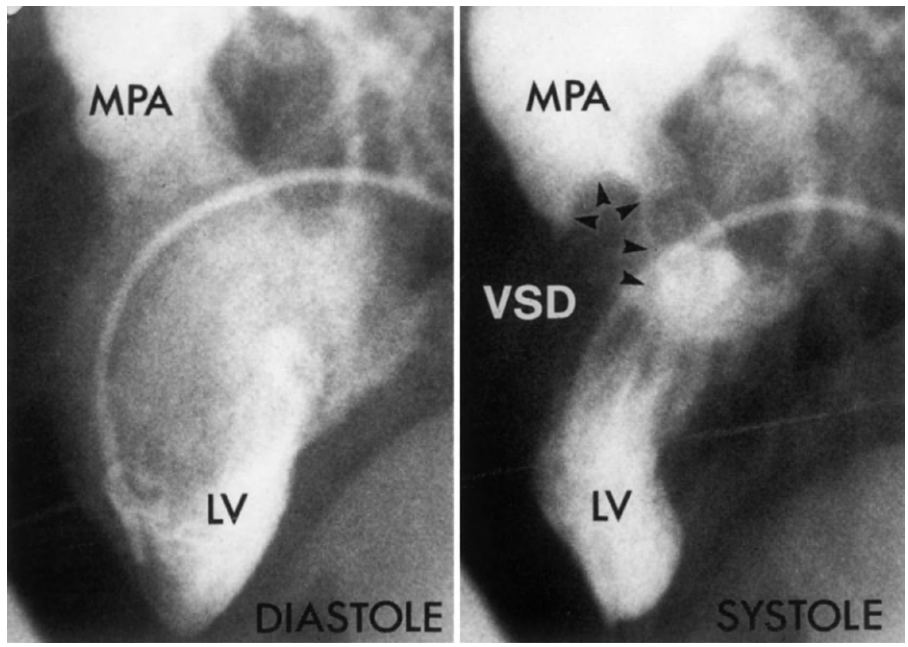

Figure 26.33 Cine cardioangiogram in diastole (left) and systole (right) of a patient with transposition of the great arteries, ventricular septal defect, and subpulmonic stenosis caused by a prolapsed tricuspid valve pouch through the ventricular septal defect. Arrowheads show the extent of prolapse of the tricuspid pouch causing left ventricular outflow obstruction. The pouch was reduced through the ventricular septal defect into the right ventricle, thereby relieving the subpulmonic obstruction. Successful arterial switch and ventricular septal defect closure was accomplished. (MPA, main pulmonary artery; VSD, ventricular septal defect; LV, left ventricle.)

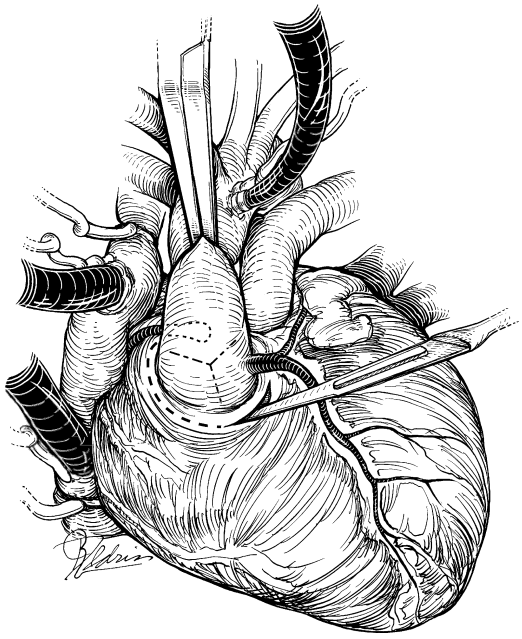

Figure 26.34 Aortic translocation or the Nikaidoh procedure involves aortic root immobilization. The aortic cannula above the cross-clamp is shown. The subaortic right ventricular space is entered through the transverse incision. Coronary arteries can be probed via the coronary ostia to localize the trunks and major branches of the coronary arteries, if necessary.

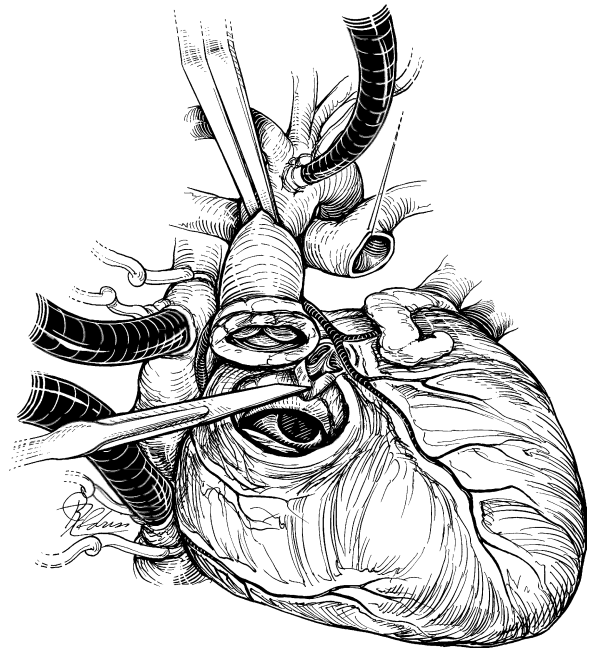

Figure 26.35 The ventricular septal defect is visualized. On completion of the aortic root mobilization, the main pulmonary artery is transected. The left ventricular outflow tract is opened and the subpulmonic stenosis is resected. Simple anterior division of the pulmonary annulus opens the left ventricular outflow tract widely, because there is often no separating muscular structure between the two semilunar valves.

operation (Figures 26.34–26.39) [34]. To date, experience with this surgical strategy is impressive but limited [252–257]. Significant potential long-term complications include neoaortic insufficiency, coronary obstructions, and pulmonary regurgitation.

TGA-VSD-Coarctation/Interrupted Aortic Arch

Perhaps the most challenging form of TGA is that which is associated with VSD and coarctation or interrupted aortic arch (see also Chapter 15, *Interrupted Aortic Arch*). The anatomic proportions are particularly vexing because the ascending aorta is often 50% smaller than the pulmonary artery trunk, the transverse arch is small, and the VSD is often malaligned. Early on in the collective surgical experience, surgeons applied a two-staged repair, preferring to address the coarctational interrupted aortic arch through a left thoracotomy, which was often combined with a pulmonary artery band [258,259]. After somatic growth, a complete repair through a median sternotomy was accomplished. Subsequent authors [260,261] found that a one-stage approach through a median sternotomy could be performed with acceptable mortality without the intervening problems that were associated with staged repair such as

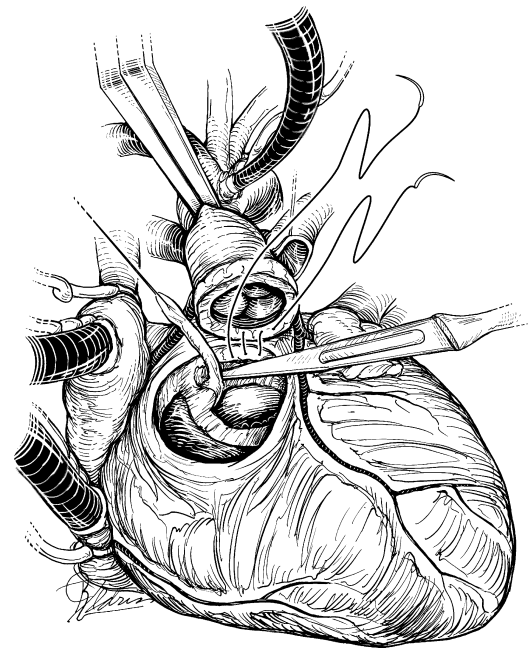

Figure 26.36 Left ventricular outflow reconstruction is shown by repositioning of the aortic root posteriorly and by resection of the infundibulum.

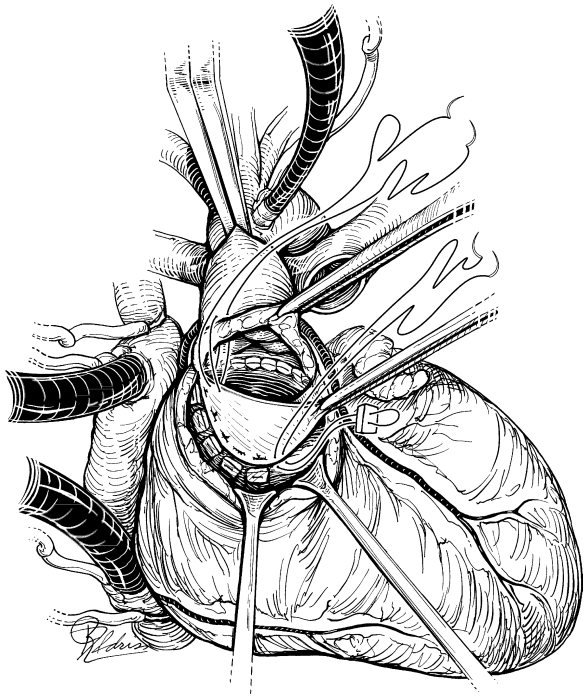

Figure 26.37 Closure of the ventricular septal defect by a patch. The posterior wall of the aortic root is sutured in two layers to the open orifice of the pulmonary annulus. The retractor is in the wide opening of the right ventricular outlet.

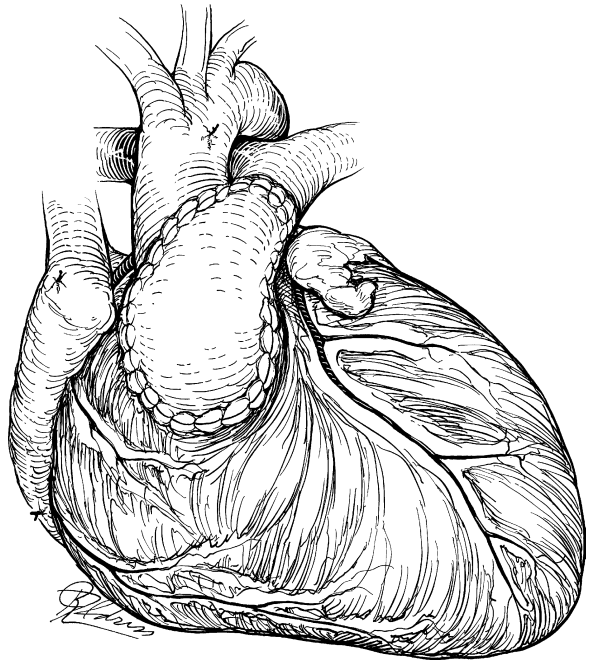

Figure 26.39 Completed reconstruction is shown.

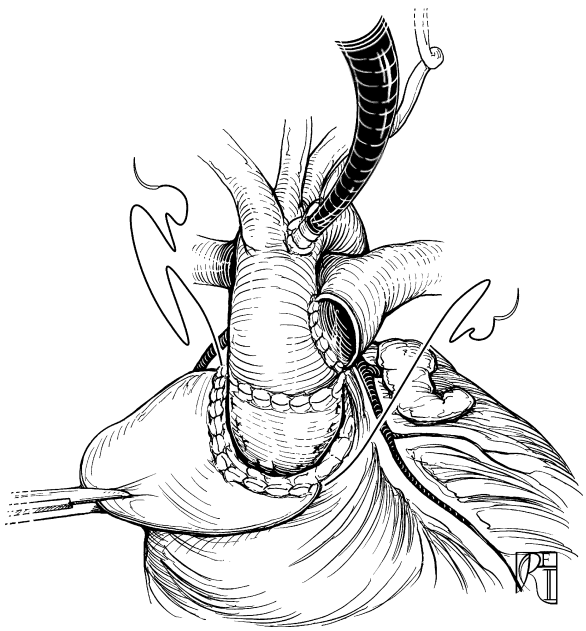

Figure 26.38 The distal segment of the main pulmonary artery is fixed to the aorta. The right ventricular outflow tract is reconstructed with a pericardial gusset. The atrial septal defect is closed through a right atriotomy (not shown).

neoaortic insufficiency caused by the preexisting pulmonary artery band and left ventricular outflow tract obstruction [260]. During the refinement of the operation, special attention was paid to neoaortic-aortic mismatch, neoaortic insufficiency, and transverse arch-descending aorta restenosis. In particular, Mohammadi and colleagues [260] reviewed 109 survivors out of 120 patients with TGA, VSD, coarctation/interrupted aortic arch in three groups of patients: 1) those who had a two-stage repair; 2) those who had a one-stage repair using extended end-to-end repair for the coarctation/interrupted aortic arch; and 3) those who had pulmonary homograft arch patch augmentation to more accurately size match the neoaortic reconstruction. Not surprisingly, the group that had aortic patch augmentation had the highest short- and long-term survival, the lowest incidence of recoarctation, and the lowest incidence of neoaortic regurgitation, leading the authors to extol the virtues of neoaortic patch augmentation for these patients in association with arterial switch and VSD closure.

The conduct of cardiopulmonary bypass is usually performed with double arterial cannulation (ascending aorta and ductus arteriosus). Alternatively, the ascending aorta can be perfused through a Gore-Tex graft that is anastomosed into the side of the innominate artery in concert with the ductal arterial catheter. This allows regional perfusion techniques to be used in the event that the surgical team wants to avoid deep hypothermia and circulatory arrest.

The descending, transverse, and ascending aortic arch can be augmented with a pulmonary homograft, which will ensure adequate outflow and a better anatomic match to the proximally reconstructed neoaorta. These techniques have been shown to increase survival and decrease the need for future reoperations in these infants.

CHAPTER 27

Congenitally Corrected Transposition of the Great Arteries

Eric J. Devaney[1] and Edward L. Bove[2]

[1]Rady Children's Hospital at the University of California, San Diego, CA, USA
[2]C.S. Mott Children's Hospital at the University of Michigan, Ann Arbor, MI, USA

Congenitally corrected transposition of the great arteries (CCTGA) is a complex congenital heart defect characterized by both atrioventricular and ventriculoarterial discordance (Figure 27.1) [1]. In other words, the morphologic right atrium receiving the systemic venous return is connected to the morphologic left ventricle via a mitral valve while the morphologic left atrium which receives pulmonary venous return is connected to the morphologic right ventricle via a tricuspid valve; concurrently, the connections between the ventricles and great arteries are transposed with the left ventricle connected to the pulmonary artery and the right ventricle connected to the aorta. The end result is a physiologically "normal" circulation with deoxygenated systemic venous blood flowing to the lungs and oxygenated pulmonary venous blood being delivered to the systemic circulation.

Although some cases of CCTGA may remain clinically silent, the majority of cases present with symptoms, usually due to the nearly universal occurrence of associated defects, principally ventricular septal defects (VSDs), pulmonary stenosis or atresia, and tricuspid valve abnormalities. The conduction system in CCTGA is notably abnormal, and there is a high incidence of spontaneous heart block. Congenitally corrected transposition may occur with situs solitus (normal atrial situs) or situs inversus. Due to the anatomic complexities associated with CCTGA, it is important to adhere to strict terminology in describing the cardiac chambers and their connections. For example, we will describe the morphologic right or left ventricle based upon its pure anatomic characteristics and not simply by its location in the thoracic cavity. A segmental nomenclature has also been proposed which uses a three letter code to describe the three cardiac segments, respectively, the atrial situs (S, situs solitus; I, situs inversus; or A, situs ambiguous), the ventricular looping (D, dextro-transposed; L, levo-transposed), and the great artery position (S, normally related great arteries; D, dextro-transposed; or L, levo-transposed). Using this system, a normal heart is coded (S,D,S), while CCTGA in situs solitus is described as (S,L,L) and in situs inversus as (I,D,D). The limitation of the segmental system is the absence of an explicit description of chamber connections. Other terms used to describe CCTGA include corrected transposition, L-transposition, and atrioventricular discordance with transposition. As noted, the clinical presentation of CCTGA is dictated by the associated cardiovascular abnormalities, and, in turn, these will determine the progression of symptoms and the surgical management of this complex lesion.

History

Congenitally corrected transposition is a rare defect which represents less than 1% of all forms of congenital heart disease. The pathologist von Rokitansky first described this lesion in 1875 [2]. He recognized its physiologic significance and described it as "corrected transposition." A number of anatomists including Anderson, Lev, and van Praagh have since characterized the anatomic features of CCTGA including the anomalous conduction system [3–12]. Classical surgical repair of CCTGA was first reported in a series from the University of Minnesota in 1957 [3]. The anatomic repair of CCTGA was introduced by Imai and colleagues in 1989 [13] and subsequently by Mee *et al*. [14] and Ilbawi and coworkers [15].

Anatomy

Congenitally corrected transposition occurs in situs solitus in about 90% of cases and situs inversus in the remainder

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

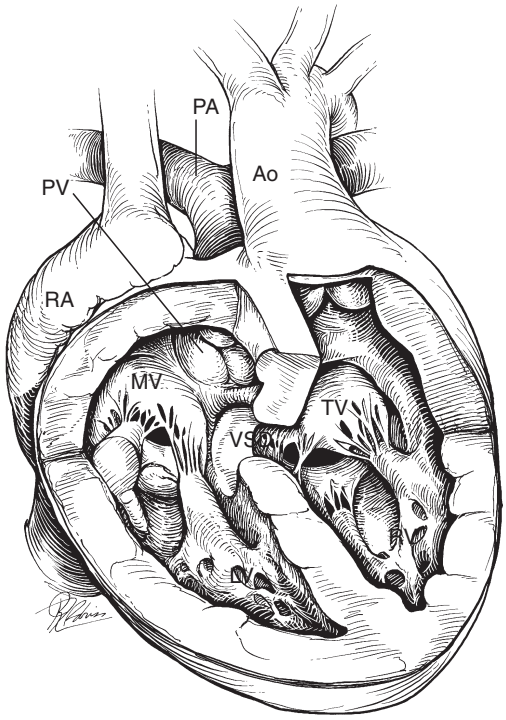

Figure 27.1 The typical anatomy of congenitally corrected transposition of the great arteries with VSD is demonstrated in this cut-away view of a heart in situs solitus. Note the anterior and leftward position of the aorta. The discordant atrioventricular and ventriculoarterial connections are clearly demonstrated. (Ao, aorta; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; PV, pulmonary valve; RA, right atrium; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect.)

[16]. In situs solitus, the morphologic right ventricle is anatomically positioned to the left of the morphologic right ventricle. Levocardia is usually present, but occasionally, the apex of the heart is directed to the right, resulting in dextrocardia. In situs inversus, the relationships are inverted in a mirror image fashion and dextrocardia is typically present.

Associated defects occur in 98% of cases [16]. Ventricular septal defect is the most common anomaly, found in over 75% of cases. The VSD is usually perimembranous and nonrestrictive in nature. Most commonly, the VSD is subpulmonic. Occasionally, multiple VSDs are present. The left ventricular (pulmonary) outflow tract is stenotic or atretic in 50% of cases, and the obstruction may occur at a valvar or subvalvar level. Tricuspid valve abnormalities, including Ebstein's malformation, are common, occurring in over 50% of cases. These are especially significant as the tricuspid valve is the systemic atrioventricular valve in CCTGA. Straddling of either the mitral or tricuspid valve across a VSD may occur, and this may result in right or left ventricular hypoplasia preventing the performance of a biventricular repair. Left ventricular hypoplasia may also occur as a result of the combination of pulmonary atresia with an intact ventricular septum (or restrictive VSD).

The aorta is typically positioned anterior and to the left of the pulmonary artery in cases of CCTGA with situs solitus. The coronary artery anatomy is usually a mirror image pattern of normal with the morphologic left coronary artery arising from the right facing sinus and giving rise to the left anterior descending and circumflex branches and the morphologic right coronary artery arising from the left facing sinus. The pattern is reversed in situs inversus. In situs solitus, the conduction system is abnormally positioned due to abnormal ventricular looping with resultant malalignment of the atrial and ventricular septa (Figure 27.2) [1,4–6,8,9]. This results in a superiorly displaced AV node which is positioned anteriorly on the atrial septum near the junction of the superior limbus and the atrioventricular (mitral) valve. The bundle of His leaves the node and travels anterior to the pulmonary valve. The bundle travels in the subendocardium of the morphologic (right-sided) left ventricle. It has been postulated that heart block may result from the long course of the bundle of His which predisposes it to damage from ischemia or stretch. Interestingly, in cases of CCTGA with situs inversus (with associated D-looping of the ventricles), the anatomy of the conduction tissue is normal, albeit in mirror image orientation.

Natural History and Physiology

Even in the absence of associated defects, the life expectancy of patients with isolated CCTGA is diminished [17]. Natural history studies have shown that any dysfunction of the systemic (morphologic right) ventricle or systemic atrioventricular (tricuspid) valve tends to develop and worsen over time, leading to significant morbidity and mortality [17–20]. Tricuspid valve regurgitation is an important determinant of long-term outcome. Prieto and colleagues found tricuspid valve regurgitation to be an independent risk factor for death [20]. Survival at 20 years was 93% in the absence of significant regurgitation, but only 49% when regurgitation was present. Tricuspid valve regurgitation may result from anatomic malformation of the valve, including Ebstein's malformation, or it may occur as a result of annular dilation from progressive right ventricular dysfunction. More recently, it has been recognized that shift of the ventricular septum to the right (towards the morphologic left ventricle), results in tricuspid regurgitation. In fact, tricuspid regurgitation has been shown to improve after pulmonary artery banding which increases left ventricular pressure and shifts the ventricular septum back to the left (towards the morphologic right ventricle) [21]. In a longitudinal study of adult patients

with isolated CCTGA, Presbitero found that significant tricuspid insufficiency occurred in 50% of patients and tended to appear in the third decade of life [17]. Graham and colleagues authored a multi-institutional study which assessed the long-term outcomes of adults with CCTGA [18]. This study reported that by the age of 45, congestive heart failure was much more common in patients having associated defects in comparison to those with the isolated form of the defect. Moreover, congestive heart failure was noted to become more prevalent in all patients with advancing age. Although some authors have found normal right ventricular function in patients with CCTGA [22,23], others have documented defects under stressed conditions. Using exercise radionuclide stress testing, Hornung *et al*. [24] found that right ventricular dysfunction and perfusion abnormalities were common findings in patients with CCTGA. Fredriksen *et al.* evaluated exercise capacity in adults with CCTGA and found reduced aerobic capacity and impaired right ventricular function with exercise despite normal function at rest [25].

Most patients with CCTGA will present as a result of an associated defect. Patients with significant obstruction of the left ventricular outflow tract (pulmonary stenosis or atresia) will present early in life with cyanosis. Those with significant tricuspid regurgitation or a large VSD will develop early congestive heart failure. Bradycardia from spontaneous heart block can occur early or late and lead to symptoms including heart failure [26–28]. The incidence of heart block has been estimated at 2% per year following the diagnosis of CCTGA, and the rate is higher in patients with an intact ventricular septum [29]. Late tricuspid insufficiency and right ventricular dysfunction occur with increasing frequency throughout life [18].

Diagnosis

The diagnosis of CCTGA is usually made by echocardiography. Assessment of the left ventricular outflow tract and the atrioventricular valves can be performed and the anatomic location of any VSD may be characterized. It is important to identify any straddling of atrioventricular valves, as this will have an impact on the subsequent surgical repair. Cardiac catheterization may provide additional anatomic information as well as hemodynamic data. Magnetic resonance imaging is an emerging modality which can provide valuable complementary data.

Surgical Management

The traditional approach to the repair of CCTGA has been directed at the treatment of the associated defects, e.g. VSD closure (Figure 27.2) [1], tricuspid valve repair or replacement, or placement of a conduit between the left ventricle and pulmonary artery to bypass left ventricular outflow tract obstruction (Figure 27.3) [1]. This approach leaves the right ventricle as the systemic ventricle and the tricuspid valve as the systemic atrioventricular valve. Although the

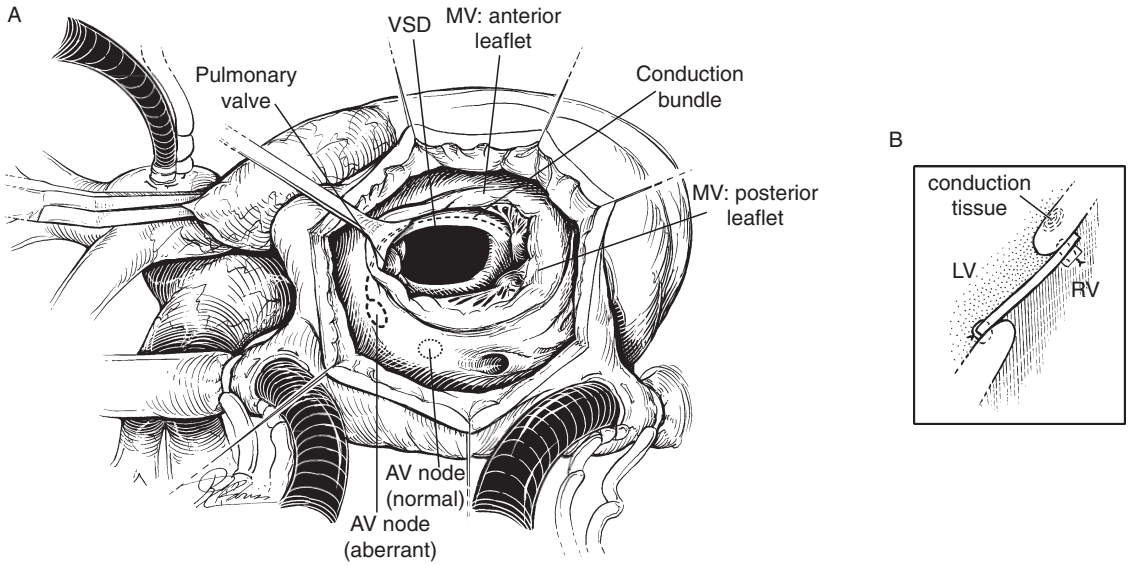

Figure 27.2 Transatrial closure of the ventricular septal defect. This technique may be used for both classic and anatomic repairs. **A,** Right atriotomy exposes the mitral valve which can be retracted to reveal the VSD which is usually perimembranous in location. Note the abnormal location of the AV node and the pathway of the bundle of His passing anterior to the pulmonary annulus and along the morphologic left ventricular side of the crest of the ventricular septum. **B,** Sutures must be taken on the opposite side of the septum in the area of the conduction tissue. (AV, atrioventricular; LV, left ventricle; MV, mitral valve; RV, right ventricle; VSD, ventricular septal defect.)

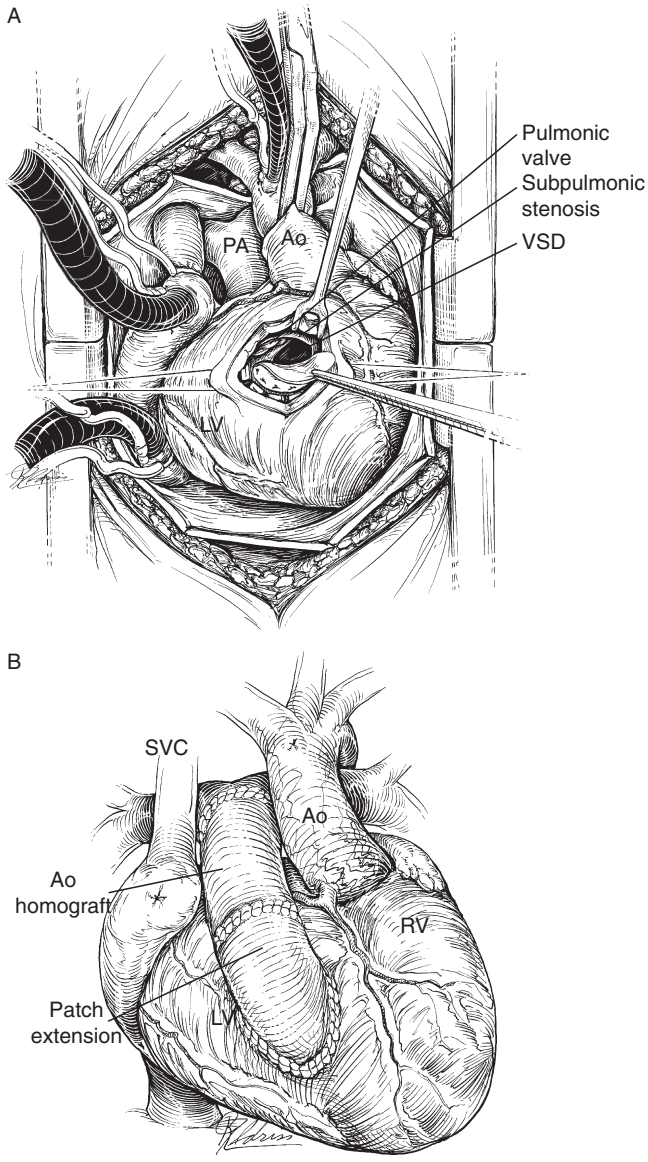

Figure 27.3 Classic repair of congenitally corrected transposition of the great arteries with left ventricular outflow tract obstruction. **A,** The ventricular septal defect (VSD) may be closed transatrially or through a left ventriculotomy as shown here. Again, sutures must be taken on the morphologic right ventricular side of the septum in the area of the conduction tissue to avoid heart block. **B,** A valved conduit is then implanted between the left ventricle and the pulmonary artery, while the native pulmonary artery is oversewn. When an allograft is used, a patch extension or hood is frequently utilized to allow a better fit. (Ao, aorta; PA, pulmonary artery; RV, right ventricle SVC, superior vena cava.)

early results associated with this classic approach have improved, the late results are associated with significant morbidity and mortality, primarily due to complications related to failure of the right ventricle and the systemic atrioventricular valve.

Recently, an alternative surgical approach of anatomic repair has been developed, with the goal of restoring the left ventricle as the systemic ventricle and the right ventricle as the pulmonary ventricle. This can be accomplished by performing a double switch operation which combines an atrial switch (Figure 27.4) and arterial switch procedure (Figure 27.5) for patients with CCTGA without pulmonary stenosis. Patients with a large VSD are excellent candidates for this approach as the left ventricle is already at systemic pressure and can tolerate the arterial switch. Patients with CCTGA and intact ventricular septum who have significant tricuspid regurgitation or right ventricular dysfunction are also candidates for the double switch, but these patients will require a period of left ventricular retraining which can be accomplished by placement of a pulmonary artery band in a fashion completely analogous to patients with classic transposition and intact ventricular septum. When initially placing the band, a reasonable goal is to achieve a left ventricular pressure of 50% systemic. This is frequently accompanied by a shift of the ventricular septum to the left with an associated improvement in tricuspid valve function. Typically it is not possible to achieve higher left ventricular pressures at the initial banding due to the development of left ventricular dysfunction. Repeat band tightening will be required for sufficient left ventricular retraining. Anatomic repair can be carried out when the left ventricular pressure equals or exceeds 80% systemic and left ventricular function is normal. Alternatively, for patients with CCTGA with VSD and left ventricular outflow tract obstruction, an atrial switch is combined with a Rastelli procedure (baffling the VSD to the aorta and placement of a right ventricle to pulmonary artery conduit) (Figure 27.6) [1]. In these cases, left ventricular retraining is usually not necessary. In some cases, the VSD may need to be enlarged to allow unobstructed left ventricular outflow.

Classic Repair

VSD Closure

Repair is performed via median sternotomy (Figure 27.2) [1]. Cannulation of the distal ascending aorta and both vena cavae is accomplished. Cardiopulmonary bypass with mild hypothermia is established, followed by cardioplegic arrest. A conventional right atriotomy is performed, and the ventricular septum is exposed through the mitral valve. The VSD is usually located in a perimembranous position, although it can be elsewhere. The key anatomic feature to remember is that the conduction tissue passes along the anterior and superior margin of the defect in the subendocardium of the morphologic left ventricle. The implication of this anatomic fact is that sutures must be taken on the opposite side of the septum (from the surgeon's point of view) to avoid injury to this region [30,31].

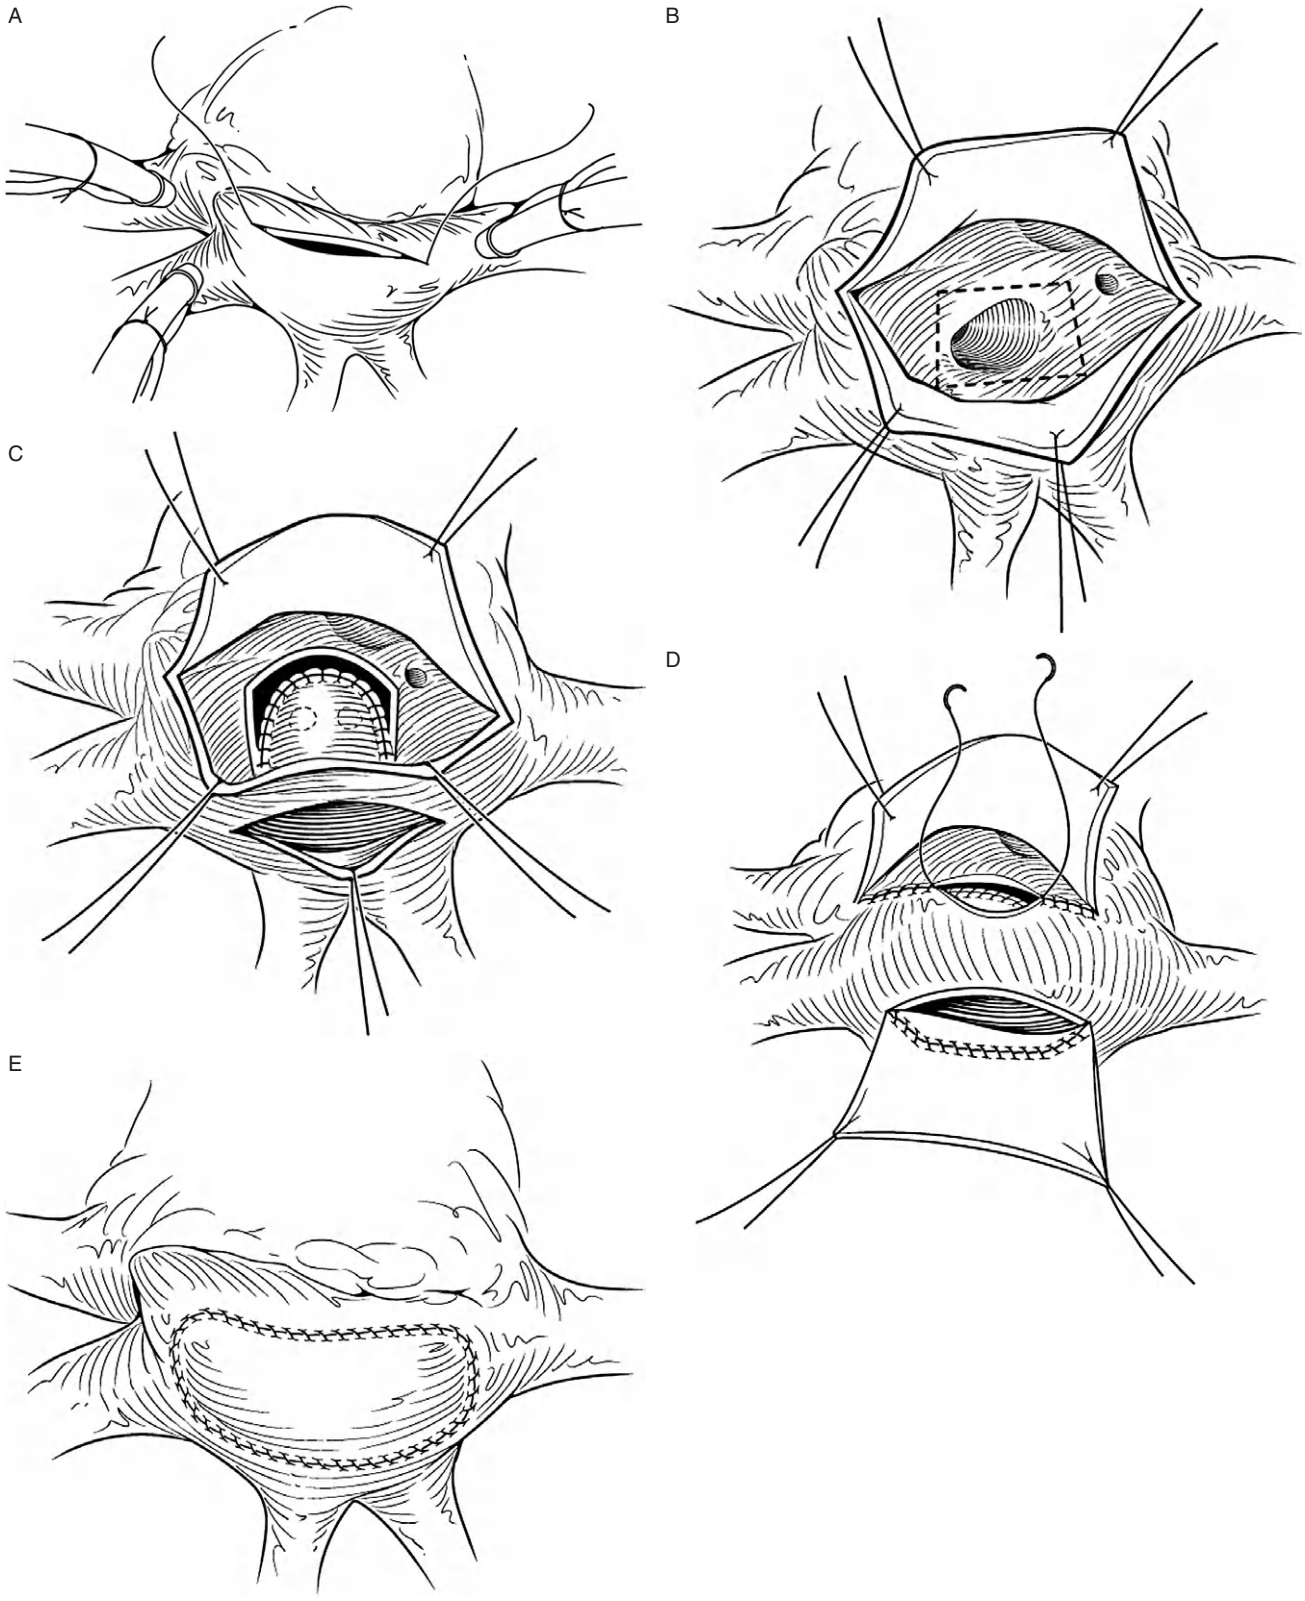

Figure 27.4 The Senning operation in CCTGA. **A,** Right atriotomy is made. In this technique, the precise location of the atriotomy is not critical since the pulmonary venous pathway will be patch augmented. **B,** The atrial septum is mobilized on a lateral (posterior) pedicle. **C,** The atrial septum is sutured to the floor of the left atrium around the pulmonary veins, and a longitudinal left atriotomy is made. **D,** The posterior edge of the right atriotomy is then folded into the right atrium and sewn along the inner atrial wall and along the divided edge of the atrial septum. This redirects the caval flow across the atrial septum. The pulmonary venous pathway is augmented using a patch (preferably homograft tissue) which is sewn posteriorly to the lateral edge of the left atriotomy. **E,** The patch is then sewn along the outer wall of the right atrium to connect with the anterior edge of the original right atriotomy.

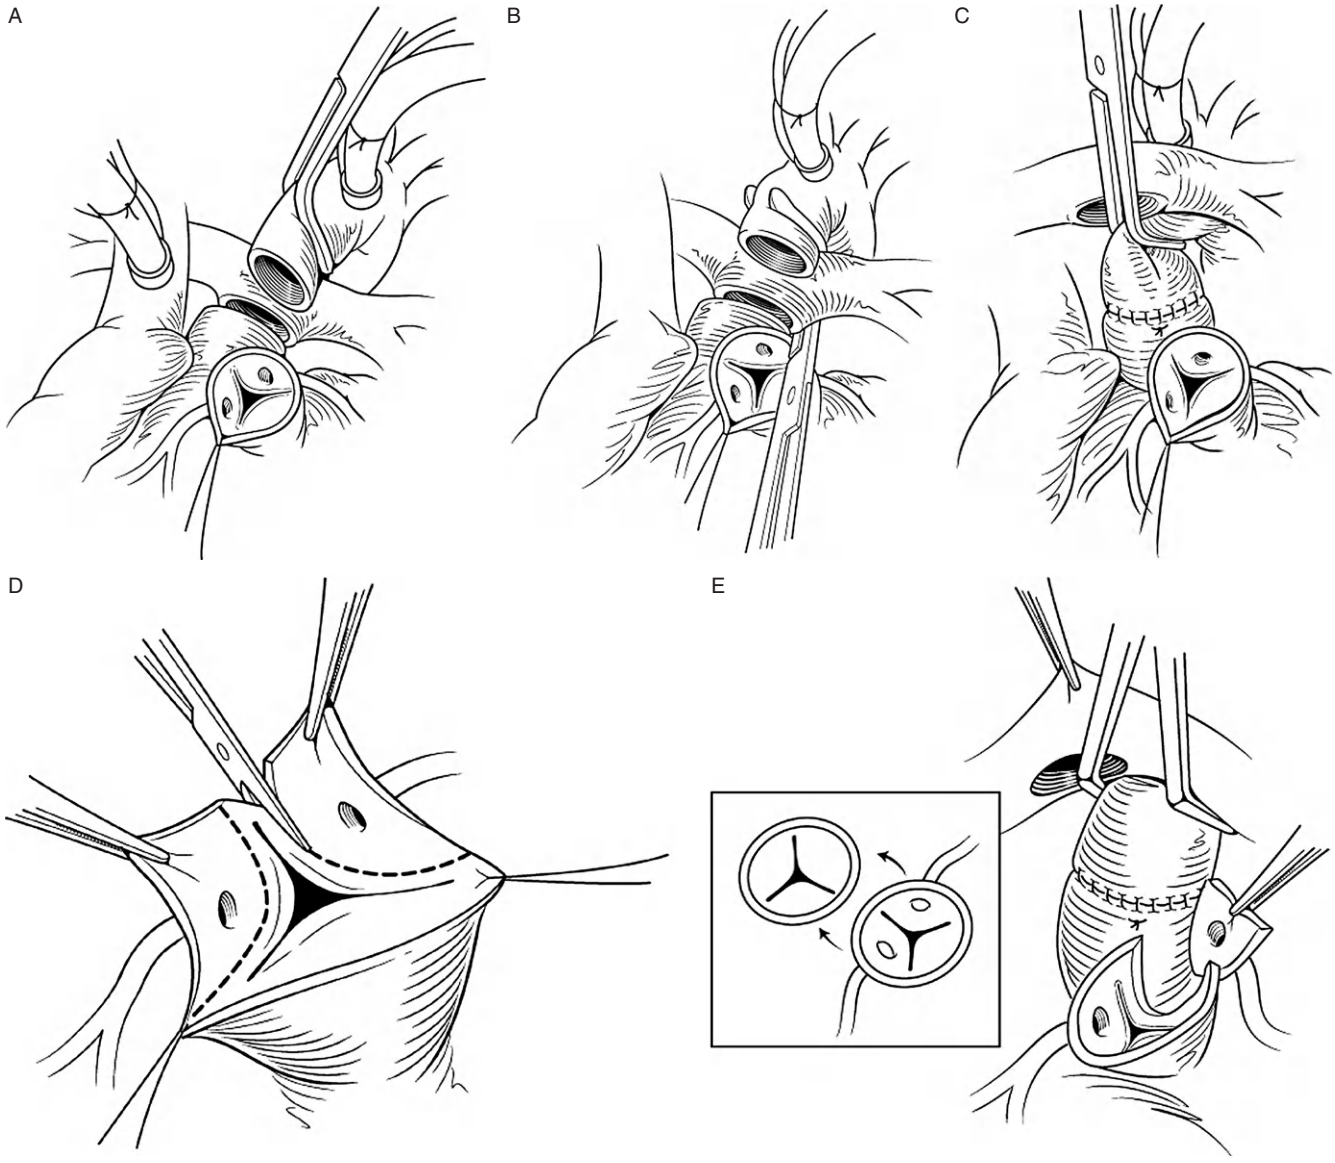

Figure 27.5 The arterial switch procedure in anatomic repair of CCTGA. **A,** The pulmonary artery is transected at its bifurcation and the aorta is divided several millimeters beyond this point. Note the morphologic left coronary artery arising from the right facing sinus and the morphologic right coronary from the left. **B,** The Lecompte maneuver is performed. **C,** The neoaortic anastomosis is performed. The superior extents of the neoaortic valve commissures are marked externally with sutures to identify the valve. **D,E,** Coronary buttons are mobilized for coronary transfer. **F,** Using the closed technique, the neoaorta is briefly pressurized, and the optimal site for coronary implantation is identified. In most cases, direct coronary transfer is possible, but when tension or distortion is likely, a trapdoor technique can be used using a pericardial patch. **G,** The defects created by removal of the coronary buttons are reconstructed using an autologous pericardial patch which is cut into a trouser shape. In order to avoid distortion, the orifice of the pulmonary bifurcation is shifted to the left as shown. **H,** The completed arterial switch.

Once the posterior and inferior margin of the defect is reached, sutures may be taken on the morphologic left ventricular side as this area is free of all conduction tissue. The suture line can be completed along the base of the posterior mitral leaflet. The defect is usually closed using a polytetrafluoroethylene patch and a running polypropylene suture, although an interrupted suture technique may also be used.

Left Ventricular Outflow Tract Repair

The nature of left ventricular outflow tract obstruction is usually valvar or subvalvar. In CCTGA, the pulmonary

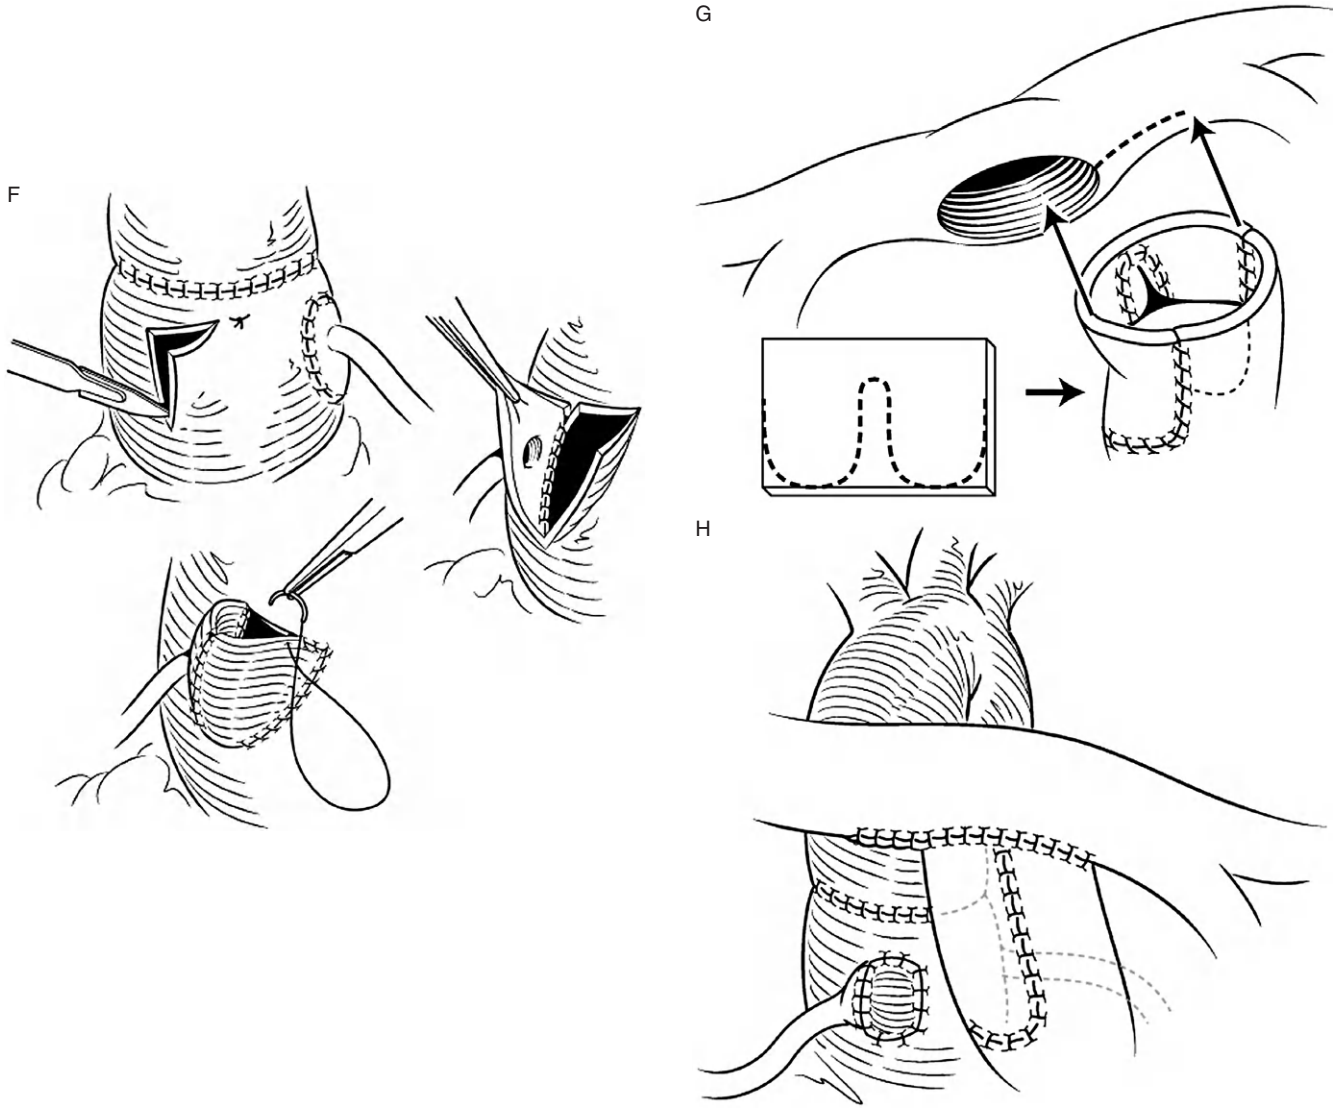

Figure 27.5 (*Continued*)

valve occupies a posterior wedged position between the mitral and tricuspid valves. This limits exposure of this area. In addition, the presence of conduction tissue traveling along the anterior border of the pulmonary valve limits any attempts to directly enlarge this area without creating heart block. In some cases it is possible to relieve the obstruction by simply resecting some subvalvar muscle or extraneous chordal tissue. In general, however, the area of obstruction must be bypassed using a conduit placed between the left ventricle and the pulmonary artery (Figure 27.3) [1]. Care must be taken in making the ventriculotomy to avoid injury to the coronaries or the mitral valve apparatus. In these cases, the VSD may optionally be closed via the ventriculotomy. The procedure is performed under cardioplegic arrest. The choice of conduit is a matter of personal choice, but the most common options include the use of a heterograft, pulmonary homograft, or bovine jugular venous graft.

Tricuspid Valve Procedures

Patients with significant tricuspid valve abnormalities are candidates for tricuspid valve repair or replacement. Exposure of the tricuspid valve is analogous to exposure of the mitral valve in the normal heart. The interatrial groove is widely developed before cardioplegic arrest of the heart. The left atrium is entered and the use of a dedicated retractor aids in exposure of the tricuspid valve. Due to abnormal ventricular looping, it may still be difficult to visualize the tricuspid valve, and in some cases, transection of the superior vena cava will allow for improved expo-

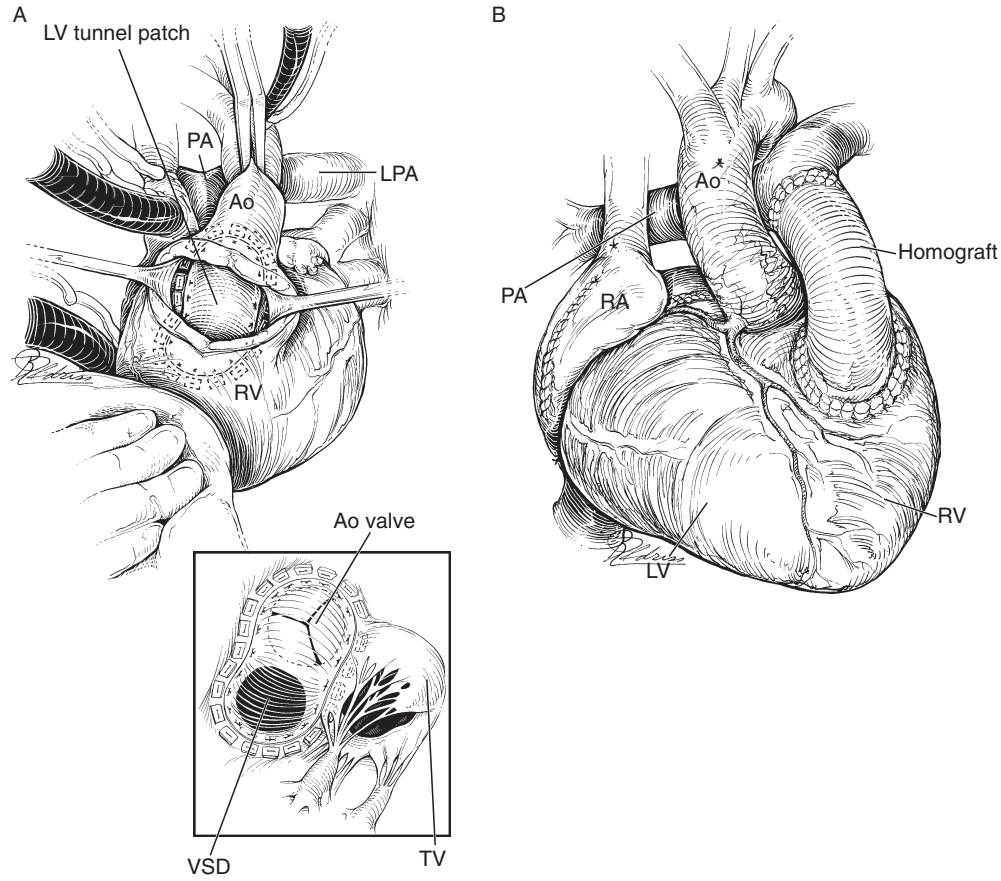

Figure 27.6 The Rastelli procedure in anatomic repair of CCTGA. **A,** With the apex of the heart elevated, a right ventriculotomy is made and an intraventricular baffle is created to connect the VSD to the aortic valve. The inset provides more detail illustrating the intraventricular baffle. **B,** A valved conduit is then implanted between the right ventriculotomy and the pulmonary artery. (Ao, aorta; LPA, left pulmonary artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect.)

sure. Valvuloplasty may be considered when the mechanism of insufficiency is clear, but it should be noted that the repair of Ebstenoid valves is very difficult in this setting, and tricuspid valve replacement using a bioprosthetic or mechanical valve may be preferred.

Anatomic Repair

Senning and Arterial Switch Procedure (Double Switch)

In the absence of significant left ventricular outflow tract obstruction, a double switch procedure may be performed. Candidates for this procedure include patients with CCTGA and concurrent VSD, right ventricular dysfunction, or tricuspid valve insufficiency. In addition, patients must have adequate left ventricular hemodynamics to tolerate the arterial switch. Exclusion criteria include ventricular hypoplasia and straddling atrioventricular valves. Due to the complexity of the procedure, the double switch is usually performed at 6–8 months of age, although it can be accomplished in the neonate. When a large VSD is present, pulmonary artery banding may be necessary as an initial intervention to limit congestive heart failure while waiting for definitive repair.

The double switch is performed with bicaval venous cannulation (taking care to cannulate each vena cava quite distally) and cardiopulmonary bypass with moderate hypothermia. A patch of autologous pericardium is harvested and treated with glutaraldehyde for later use. The Senning operation is the preferred atrial switch procedure (Figure 27.4). This technique uses a flap of autologous atrial tissue to redirect venous return at the atrial level. The interatrial groove is extensively developed. Following cardioplegic arrest, a conventional right atriotomy is performed, and the VSD (if present) can be closed as previously described. The atriotomy is extended superiorly and inferiorly to within 1 cm of each cavoatrial junction. The atrial septum is then mobilized as a laterally based flap which is

then dropped into the left atrium and sewn around the origins of the pulmonary veins. If the atrial septum is deficient, it can be augmented using a polytetrafluoroethylene patch. The coronary sinus is usually cut back for a length of 1–2 cm. Next, a longitudinal left atriotomy is made. The systemic venous pathway is completed by folding the posterior edge of the previous right atriotomy over the caval orifices and along the original line of the atrial septal attachment. This maneuver redirects systemic venous return across the atrial septum to the tricuspid valve. The pulmonary venous pathway is then routinely augmented using a generous patch of pulmonary allograft tissue which is sewn along the posterior edge of the left atriotomy, along the outer wall of the right atrium, and terminating along the anterior edge of the original right atriotomy. More recently, the pulmonary venous pathway has been augmented using a posteriorly based autologous flap of pericardium, either alone or in combination with a patch of pulmonary allograft. The Senning procedure can be performed even in the presence of dextrocardia. When dextrocardia is present, the heart is completely mobilized and the left pleural space is widely opened. The heart may then be displaced into the left chest to improve exposure.

The arterial switch operation is performed using standard techniques employed for patients with classic transposition (Figure 27.5). The aorta and pulmonary arteries are transected around the level of the pulmonary bifurcation. The coronaries are mobilized with generous buttons of arterial wall. In most cases, a Lecompte maneuver is performed with translocation of the distal pulmonary artery anterior to the aorta. The neoaortic anastomosis is then accomplished and coronary implantation is performed using the closed technique. The resected sinuses of the neopulmonary artery are reconstructed using the previously harvested autologous pericardium. Next, it is usually necessary to shift the orifice of the distal pulmonary artery towards the left to prevent distortion in the neopulmonary artery and provide an easier fit. This is readily accomplished by incising the pulmonary artery orifice well onto the left pulmonary artery and simply oversewing the original orifice. The operation is completed with the performance of the neopulmonary anastomosis.

Senning and Rastelli Procedure

Patients with significant, unresectable left ventricular outflow tract obstruction or pulmonary atresia are not candidates for an arterial switch. For these patients, a combined Senning and Rastelli procedure is employed (Figure 27.6) [1]. When significant cyanosis is present, an initial shunt procedure is usually performed. Definitive repair is then deferred until 6–8 months of age. The Senning procedure is performed as previously described. A right ventriculotomy is created and an intraventricular baffle (polytetrafluoroethylene) is inserted to channel the VSD (and left ventricular outflow) to the aorta. A right ventricle to pulmonary artery conduit is then implanted. As always, care must be taken to avoid injury to the conduction tissue. In some cases enlargement of the VSD must be performed to allow unobstructed left ventricular outflow. To avoid heart block, the VSD is enlarged along its posterior and inferior margin.

Results

Classic Repair

The reported mortality for classic repair of defects associated with CCTGA ranges widely, largely dependent on the era of each study [32–37]. The Mayo Clinic found that during the 1970s and early 1980s early mortality varied from 18% to 26%, while for more recent cohorts of patients, the mortality was 3% [32]. Long-term follow up of survivors revealed an overall survival of 77% at 5 years and 67% at 10 years. Yeh *et al.* from Toronto reported a large series of CCTGA patients undergoing surgical repair and reported an operative mortality of 6% [38]. At 20-year follow-up of these patients, survival was 48%. For tricuspid valve insufficiency, repair can be performed with a low mortality, but a recurrence rate of up to 50% has been reported [21,33]. The results of tricuspid valve replacement have been reviewed by van Son and colleagues who found an early mortality of 10% and a 10-year survival of 68% [36]. In this series, all early and late deaths were secondary to right ventricular failure. Other reports have similarly documented a substantial late mortality from systemic ventricular failure [35,39]. Despite the recognition of the anatomy of the anomalous conduction tissue, the complication of postsurgical heart block remains as high as 20% [34,35].

Patients who have undergone an atrial switch repair of classic transposition also have a right ventricle in the systemic position. This large historical cohort of patients provides an opportunity to evaluate the long-term functional status of the systemic right ventricle. A number of studies have demonstrated that adult survivors remain at risk for premature death due to late systemic ventricular failure which occurs in over 10% of patients and is responsible for nearly half of all late deaths [40–44]. Interestingly, the incidence of late tricuspid insufficiency appears to be much lower than in corrected transposition, probably due to the absence of intrinsic valvar abnormalities which are common in corrected transposition.

Anatomic Repair

Anatomic repair of CCTGA has been pursued by a number of large centers, and the results have been encouraging [14,45–52]. The largest reported series to date comes from the Birmingham group, which has performed anatomic repair in 51 patients with CCTGA [50]. In this group, 29 patients underwent a Senning/arterial switch while 22 had

a Senning/Rastelli. The early mortality was 5.6%, and actuarial survival at 9 years was 95% (excluding early mortality) with 94% of the survivors in New York Heart Association (NYHA) functional class I. Left ventricular retraining was required in 31%. Outcomes for this group were comparable to the group not requiring retraining, although the need for retraining remained a statistically significant risk factor for late cardiac failure [53]. Other groups have reported large series of patients with no early mortality [46,48,51]. Jahangiri and colleagues [21] examined tricuspid valve function following various surgical procedures for CCTGA and observed that tricuspid insufficiency decreased postoperatively following pulmonary artery banding and following anatomic repair. On the contrary, tricuspid insufficiency typically worsened following placement of a systemic to pulmonary artery shunt. Following classic repair techniques, early tricuspid valve function was unchanged but late reintervention for tricuspid valve intervention was frequent and was associated with a high mortality. In a contemporary series, Shin'oka *et al.* reported similar early results for both classic and anatomic repair of CCTGA in the absence of significant tricuspid valve insufficiency [54]. When CCTGA was accompanied by tricuspid insufficiency, patients undergoing anatomic repair demonstrated superior results over those having classic repair.

At the University of Michigan, a total of 55 patients have undergone anatomic repair of CCTGA (Senning and arterial switch, n = 30; Senning and Rastelli, n = 25). A previous report summarizes the results of an earlier cohort [45]. The overall hospital survival was 95% with one death following the Senning/arterial switch and two deaths following Senning/Rastelli. There were no new cases of complete heart block although four patients had preoperative heart block. One 7-year-old patient who underwent left ventricular retraining developed left ventricular dysfunction following double switch. This resulted from pure diastolic dysfunction, and the patient ultimately required cardiac transplantation. Late reoperations have included conduit replacement (n = 1), relief of superior vena cava obstruction (n = 1), and relief of pulmonary venous obstruction (n = 1). Neoaortic insufficiency, coronary obstruction, and left ventricular outflow tract obstruction have not been seen in this patient cohort. Tricuspid valve insufficiency, when present, was noted to significantly improve following anatomic repair ($p = 0.001$).

Conclusion

Corrected transposition of the great arteries is a rare defect and frequently accompanied by associated cardiac defects, which modify its physiology, mode of presentation, and natural history. Even in the absence of associated defects, corrected transposition is associated with a poor survival resulting from the development of right (systemic) ventricular failure and tricuspid (systemic atrioventricular) valve insufficiency. Corrected transposition of the great arteries presents a challenge for surgical repair. Classic repair strategies address the associated defects and leave the right ventricle and tricuspid valve on the systemic side of the circulation. As a result, classic repair is complicated by early and late right ventricular and tricuspid valve dysfunction. Anatomic repair restores the right and left ventricles (and their atrioventricular valves) to the pulmonary and systemic circulations, respectively, and, despite its early risk, may improve long-term outcomes for these patients, although longer-term follow up will be necessary to confirm this hypothesis.

CHAPTER 28

The Functionally Univentricular Heart and Fontan's Operation

Marshall L. Jacobs
Cleveland Clinic Children's Hospital, Cleveland, OH, USA

Background

Among the most challenging of congenital cardiac anomalies is the broad category of hearts that lack two well developed ventricles. As challenging as they are to manage medically and surgically, they are at least as difficult to describe and classify. The most commonly applied terms *single ventricle* and *univentricular heart* are imprecise and spark heated debate among morphologists and embryologists. Only rarely do hearts posses a true solitary ventricle. Yet there is a variety of circumstances where a single, well developed ventricle is associated with an additional incomplete, rudimentary or hypoplastic ventricle. Ultimately, the principles that have evolved for the medical and surgical management of hearts that are not septatable are consistent with the idea of a functionally univentricular heart.

As opposed to the common circumstance where there are two atria, and each atrium is connected to its own ventricle, the hearts considered in this chapter are those in which the atrial chambers connect to only one ventricle that is well developed and dominant. The features of a well developed ventricle include an inlet portion, supporting the subvalvar tensor apparatus, a trabecular zone, and an outlet portion to a great artery. Most often in functionally univentricular hearts, there is an additional incomplete, rudimentary or hypoplastic ventricle that lacks an atrioventricular connection. The obligatory physiology in the setting of a functionally univentricular heart is that the systemic and pulmonary circulations are arranged in parallel fashion, rather than in series as in the normal heart. This results in a drastically altered natural history, which without surgical intervention most often culminates in death of the patient, anywhere from the first days of life to the second decade of life. The evolution of palliative and reconstructive cardiac operations has impacted enormously on the life expectancy and quality of life of such individuals. It has therefore become increasingly important to precisely and thoroughly describe and classify these anomalies. In this chapter, we consider the functionally univentricular heart to encompass those anomalies that are characterized by the lack of two completely well developed ventricles. Hypoplastic left heart syndrome, which is the most common of the functionally univentricular cardiac malformations, is considered separately in Chapter 31, *Hypoplastic Left Heart Syndrome*. Also covered elsewhere in this text are those cardiac anomalies where, even in the presence of two well developed ventricles, the heart may be considered nonseptatable and thus lend itself to treatment strategies that are described here.

Nomenclature and Classification

Before the era of surgical therapy for these complicated malformations, the study of incomplete hearts was largely descriptive. Pathologists and anatomists debated the questions of what constitutes a *single ventricle*, or a univentricular heart, and the debate continues today. There is no one system of nomenclature that has been accepted by all practitioners in the field. Historically, the terms *single ventricle* and *common ventricle* were employed interchangeably by Abbott [1], Taussig [2], and Edwards [3]. Lev [4] used the designation *single ventricle* when an outlet chamber was present and the term *common ventricle* when an outlet chamber was absent. Most often, there is an incomplete or rudimentary outlet chamber. The connection between the main ventricular chamber and the outlet chamber has been given a variety of names: ventricular septal defect, bulboventricular foramen, outlet foramen, trabecular septal defect, and interventricular communication.

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.
© 2013 Blackwell Publishing Ltd. Published 2013 by Blackwell Publishing Ltd.

Most single ventricle anomalies are currently described using Van Praagh's segmental anatomy approach [5] or Anderson's system of sequential chamber localization [6]. There are important and fundamental differences. According to Van Praagh and colleagues [7], a single or common ventricle is one ventricular chamber that receives both the tricuspid and mitral valves or a common atrioventricular valve. Thus, this system excludes tricuspid and mitral atresia from single ventricle anomalies. Anderson *et al.* also emphasize the nature of the connections between the atrial and ventricular structures but assert that the unifying criteria for univentricular hearts is that the entire atrioventricular junction is connected to only one chamber in the ventricular mass [6]. A second ventricular chamber, if present, will lack any atrioventricular connection and be rudimentary. Hence the term *univentricular atrioventricular connection* is used by Anderson to describe the functionally single ventricle. The acknowledgement that in the vast majority of cases a single, well developed ventricle exists in association with a second hypoplastic or rudimentary ventricle, calls for terminology that is descriptively accurate but does not deny ventricular status to the chamber, which is not completely developed. Thus, in 2006, Jacobs and Anderson applied the term "functionally univentricular," which is applicable whenever one or the other ventricle is incapable, for whatever reason, of supporting either the systemic or the pulmonary circulation [8].

In 2000, a consensus was reached by the Society of Thoracic Surgeons International Congenital Heart Surgery Nomenclature and Database Project [9] that the nomenclature proposed for functionally univentricular hearts would encompass hearts with double-inlet atrioventricular connection (both double-inlet left ventricle [DILV] and double-inlet right ventricle [DIRV]), hearts with absence of one atrioventricular connection (including tricuspid atresia and mitral atresia), hearts with a common atrioventricular valve and only one completely well developed ventricle (unbalanced common atrioventricular canal defect), hearts with only one fully developed ventricle and heterotaxy syndrome, and finally other rare forms of univentricular hearts that do not fit in one of the specified major categories. As in the organization of this textbook, separate status was accorded to hypoplastic left heart syndrome, while still acknowledging that it is a common form of functionally univentricular heart.

Anatomy

Double-Inlet Ventricle

Double-inlet ventricle (DIV) is a congenital cardiac malformation in which both atria connect to only one ventricular chamber by either two separate atrioventricular valves or a common atrioventricular valve. Rarely does the ventricular mass consist only of a solitary ventricle. In addition to one fully developed ventricle there is usually an additional ventricle, which is incomplete (rudimentary) in addition to being hypoplastic. There may be no atrioventricular connection to the incomplete ventricle, or the incomplete ventricle may be connected to an atrium by way of overriding of one of the atrioventricular valves. The term DIV applies if more than 50% of the overriding valve lies over the dominant ventricle.

The dominant ventricle in DIV may have left ventricular internal architecture, right ventricle internal architecture, or indeterminate architecture (rare). The hypoplastic rudimentary chamber, when present, is always of the opposite architecture to the dominant ventricle. The nondominant chamber is referred to as rudimentary (incomplete) because it lacks one or more of its component parts. Generally the inlet portion is absent. Occasionally the outlet portion is lacking as well, leaving only the trabeculated part. The rudimentary chamber is connected to the dominant chamber by an interventricular communication (ventricular septal defect or bulboventricular foramen) of size which may vary from small and physiologically restrictive of flow to large and nonrestrictive. Occasionally, both ventricles are incomplete, as for example where there is double inlet to one chamber and double outlet from the other.

Atrial arrangement is variable, though in DILV atrial situs solitus predominates. In DIRV or indeterminate ventricle, about half have situs solitus, and half have atrial isomerism, predominantly right isomerism. There are usually two atrioventricular valves, both opening into the dominant ventricle. In about 20% of cases one of the two atrioventricular valves overrides the remnant of ventricular septum, or the tensor apparatus of one of the atrioventricular valves may straddle the septum. The anatomy of the atrioventricular valves and conduction system is abnormal in DIV. The atrioventricular node can be anywhere around the perimeter of the right-sided atrioventricular valve. In general, two separate coronary arteries arise from the two aortic sinuses facing the pulmonary trunk. There are usually prominent epicardial branches, which delineate the points of attachment of the septum to the ventricular free wall, and therefore indicate the boundaries of the rudimentary ventricular chamber.

Double-inlet left ventricle is the most common anatomic subtype. The dominant ventricle is of left ventricular morphology. The rudimentary chamber is of right ventricular morphology, with coarse apical trabeculations and frequently a septal band (trabecula septomarginalis) bordering the ventricular septal defect anteriorly. When the rudimentary chamber gives rise to one or both great vessels, a smooth-walled infundibulum is present. The rudimentary chamber is usually situated anterosuperiorly with respect to the dominant ventricle and is more often to the left but may be to the right. Of DILVs, the largest subtype is DILV with ventricular

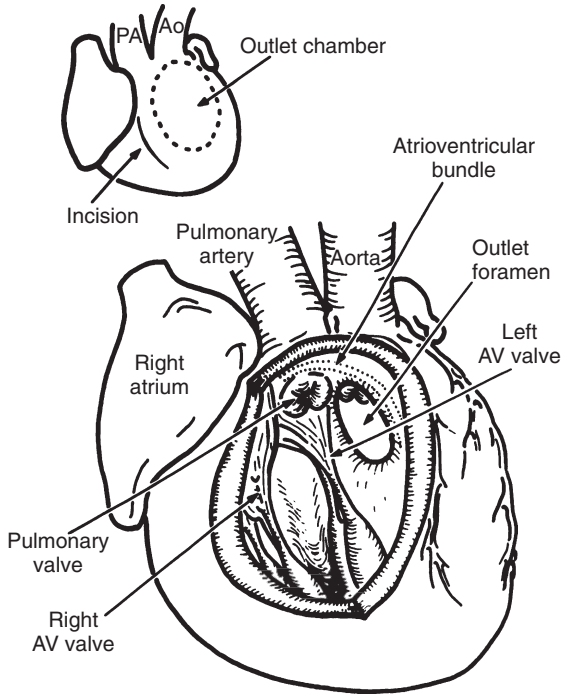

Figure 28.1 The relationships of the intracardiac structures and the disposition of the conduction tissue in double-inlet left ventricle with left-sided rudimentary right ventricle. (Ao, aorta; AV, atrioventricular; PA, pulmonary artery.) (Reproduced with permission from L. H. S. Van Mierop *et al.* [143].)

L-loop, left-sided rudimentary right ventricle, and ventriculoarterial discordance (single left ventricle {S, L, L}) (Figure 28.1) [10]. As the descriptive nomenclature implies, there is a right-sided dominant morphologic left ventricle, which receives right-sided and left-sided atrioventricular valves. The aorta arises from the rudimentary left-sided right ventricle. The pulmonary trunk arises from the base of the left ventricle. Uncommonly, there may be valvar or subvalvar pulmonary stenosis and rarely pulmonary atresia. The ventricular septal defect, or bulboventricular foramen, lies beneath the infundibular septum and may be of any size. When it is large, the aorta is usually well developed. When the ventricular septal defect is restrictive it produces subaortic stenosis, and there is commonly hypoplasia of the aortic arch, coarctation or interrupted aortic arch. Double-inlet left ventricle with ventricular D-loop, right-sided rudimentary right ventricle, and ventriculoarterial concordance occurs in about 10% of cases. Also known as Holmes heart, this type of functional single ventricle consists of a large left ventricle, which is leftward and posterior, and a small rudimentary right ventricle, which is situated to the right, anteriorly and superiorly. There are generally two atrioventricular valves, often with the right-sided valve straddling. Pulmonary stenosis is common.

In DIRV both atria connect to a morphologically right ventricle. The rudimentary left ventricular chamber lies posteriorly and inferiorly (in the hip pocket) with relation to the dominant right ventricle. Most often the hypoplastic ventricle communicates with the main chamber by a very small ventricular septal defect and lacks an outflow to any great vessel. In these cases the ventriculoarterial connection is either double-outlet right ventricle or right ventricular aorta with pulmonary atresia. There may be two atrioventricular valves entering the right ventricle, with or without the left one straddling, or there may be a common atrioventricular valve. Double-inlet indeterminate ventricle refers to the rare instance of a primitive ventricular heart without an outlet chamber [11].

Tricuspid Atresia

The term tricuspid atresia refers to univentricular hearts with absent right atrioventricular connection. The anatomic hallmark is the lack of a direct connection between the right atrium and right ventricle. Most often the tricuspid valve is totally absent, the floor of the right atrium being constituted of muscular tissue. Less often there is membranous atresia of the right atrioventricular connection, with the floor of the right atrium occupied by a primitive or vestigial valve-like structure that is imperforate, though there may be rudimentary chordae on the right ventricular side. Still less commonly, an Ebstein's type of tricuspid valve is present with complete fusion of leaflets.

In tricuspid atresia, the right atrium may be moderately enlarged, and is thickened in comparison to normal. The only outlet from the right atrium is the atrial septal defect, which is almost always of the ostium secundum type and is generally large (the exception being the presence of a restrictive atrial septal defect in about one half of cases of tricuspid atresia with transposition of the great arteries [TGA]). Occasionally a redundant aneurysm of septum primum may prolapse into the left atrium, with theoretical potential to obstruct mitral inflow. Rarely, the atrial septal defect may be restrictive. The Eustachian valve of the inferior vena cava may be very prominent and occasionally appears to subdivide the right atrium (cor triatriatum dexter). The left atrium is dilated but is usually morphologically normal. There is univentricular atrioventricular connection consisting of a left-sided mitral valve between the morphologically left atrium and left ventricle. There is nearly always atrial situs solitus with ventricular D-loop. While the left ventricle is large and well developed, Becker and Anderson [12] argue that it is not a normal ventricle. The septum separating it from the right ventricular chamber does not extend to the crux of the heart, and because the right atrioventricular connection is absent, there is no inlet septum. There is a crevice in the posterior part of the left ventricular chamber into which a dimple, generally present

in the muscular floor of the right atrium, points. The right ventricular chamber in tricuspid atresia has no inlet portion and is connected to the dominant left ventricle by a ventricular septal defect with entirely muscular rims. The size of the trabecular portion and the outlet portion of the rudimentary right ventricle is determined by the size of the ventricular septal defect and the nature of the ventriculoarterial connections.

In tricuspid atresia, coronary artery patterns are usually normal. Systemic venous connections are generally normal, though a persistent left superior vena cava is present in 10–15% of cases. The sinoatrial node is in the normal position. The atrioventricular node is situated to the right of the central fibrous body, and the course of the atrioventricular conduction system depends on the location of the ventricular septal defect; it is generally inferior and posterior to the defect.

Anatomic subtypes of tricuspid atresia are generally classified based on morphology and physiology as originally proposed in 1906 by Kühne [13] and later modified by Edwards and Burchell in 1949 [14]. Tandon *et al*. [15] further refined the system of classification in 1974 to encompass rarer types of ventriculoarterial connection. The fundamental categories are type I: those with normally related great arteries (approximately 70%); type II: those with D-TGA (approximately 30%); and type III: those with L-TGA (rare). Each of these groups is further subdivided based on the degree of obstruction to pulmonary blood flow: type A pulmonary atresia, type B pulmonary stenosis or hypoplasia (moderate pulmonary blood flow), and type C pulmonary artery and valve with no obstruction (increased pulmonary blood flow) (Figure 28.2) [16].

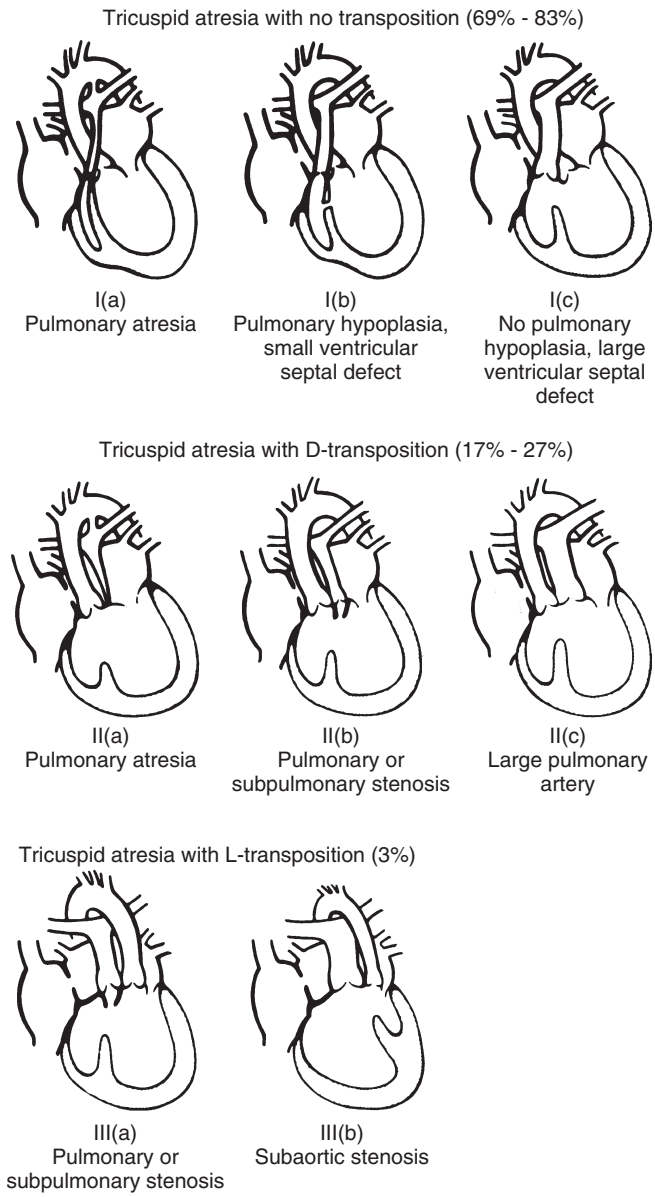

Figure 28.2 The anatomic classification of tricuspid atresia, as suggested by Tandon and Edwards in 1974. (Reproduced with permission from Pearl *et al.* [16].)

Mitral Atresia

As with absence of the right atrioventricular connection, absent left atrioventricular connection can occur with any of the morphologies possible in univentricular heart. The classical example of mitral atresia is univentricular heart of right ventricular type with absent left atrioventricular connection. As in tricuspid atresia, the atretic valve may be imperforate with immature chordal apparatus beneath, but more commonly the atrioventricular connection is truly absent, the floor of the atrium being separated from the ventricle by fibro-fatty tissue [17]. When mitral atresia and aortic atresia are both present, those hearts are considered a category of hypoplastic left heart syndrome. Mitral atresia with a patent aortic outlet is generally characterized by atrial situs solitus, ventricular D-loop, a dominant right ventricle connected to the right atrium by a patent right-sided (generally tricuspid) valve and a hypoplastic left ventricle situated posteriorly and to the left. Various conotruncal arrangements are possible. The two most common are (1) double-outlet right ventricle in which case the small left ventricle is a blind chamber connected to the right ventricle by a ventricular septal defect but with no outlet to a great vessel; or (2) concordant ventriculoarterial connection in which case the hypoplastic left ventricle functions as an outlet chamber giving rise to the aorta. Frequently the ventricular septal defect is restrictive, causing subaortic obstruction, and the hypoplastic left ventricle gives rise to a small aorta with aortic arch hypoplasia, coarctation, or rarely, interruption. The interatrial communication is frequently restrictive. Mitral atresia with

ventriculoarterial discordance and patent aortic root is a rare entity but has been described.

Another, less common arrangement with left atrioventricular valve atresia (but not mitral atresia) is that of atrial situs solitus, ventricular L-loop with a patent right-sided atrioventricular valve emptying into a right-sided dominant left ventricle, with a rudimentary left-sided right ventricle above which is an atretic left-sided atrioventricular valve. The conotruncal anatomy is either ventriculoarterial discordance (aorta from rudimentary right ventricle), or double-outlet left ventricle. The ventricular septal defect may be restrictive.

Unbalanced Common Atrioventricular Canal Defect

This is a rare subset of hearts with common atrioventricular junction in which there is clear dominance of one ventricular chamber and hypoplasia of the other. Unlike most other functionally univentricular hearts, the less developed hypoplastic ventricle in unbalanced common atrioventricular canal defect is generally not rudimentary, but rather hypoplastic, as a consequence of inflow from the atria being directed preferentially to the dominant ventricle. The anatomy is thought to be the consequence of malalignment of the common atrioventricular valve with respect to the ventricular mass. This may occur in either the complete form of common atrioventricular canal defect with a large nonrestrictive ventricular septal defect, or in the intermediate form, with a restrictive ventricular septal defect. The position of the common atrioventricular valve in relation to the plane of the ventricular septum determines the degree of imbalance and thus the degree of hypoplasia of one ventricle. In the right dominant form of common atrioventricular canal defect the right ventricle is large, the left ventricle is smaller than normal, and the position of the common atrioventricular valve in relation to the septum is rightward. In the left dominant form, the left ventricle is larger than normal, the right ventricle is smaller than normal, and the position of the common atrioventricular valve is leftward. In this form, right ventricular hypoplasia is readily apparent. In the right dominant form it may be difficult to distinguish right ventricular dominance and left ventricular hypoplasia from the common scenario of flow-related right ventricular enlargement seen in balanced or nonmalaligned common atrioventricular canal defects. Several diagnostic tools or measurements have been advanced to accurately predict the inadequacy of one ventricle, of which the most useful is probably the atrioventricular valve index proposed by Cohen and Rychik and colleagues [18]. While abnormal development of the aortic outflow (aortic arch hypoplasia, coarctation) is a common accompaniment of unbalanced common atrioventricular canal defect with right ventricular dominance, the converse is not necessarily true, and one does not predictably observe pulmonary stenosis or hypoplasia in the left ventricular dominant form of unbalanced common atrioventricular canal defect.

Functionally Univentricular Heart in Heterotaxy Syndrome

Atriovisceral heterotaxy refers to those anatomic circumstances where failure of normal right-left differentiation results in ambiguities of visceral and atrial situs, together with a variety of characteristic anomalies of systemic and pulmonary venous connections, abnormalities of abdominal organs, and heart malformations, which fall into readily recognizable patterns. Becker and Anderson [19] provide the useful description: "a particular arrangement of the thoracoabdominal viscera characterized by isomerism of the paired organs such as the lungs and atria together with a tendency for the unpaired organs to be midline in position." They, therefore, refer to this family of anomalies as atrial isomerism. Others have emphasized that there are two basic subdivisions [20,21], associated on the one hand with absence of the spleen (asplenia, bilateral rightsidedness [21]), and on the other with multiple spleens, (polysplenia, bilateral left-sidedness [20]). Thus, the more commonly used terminology *asplenia* and *polysplenia syndrome*. The majority of heterotaxy syndrome patients have a functionally univentricular heart. In addition to anomalies of systemic and pulmonary venous return, the cardiac abnormalities are characterized by endocardial cushion defect (atrioventricular canal type common atrioventricular valve) and frequently pulmonary stenosis or atresia.

Of asplenia patients, more than half have functionally univentricular heart, and typically they have a single right ventricle (42%) with double-outlet right ventricle (82%), pulmonary stenosis or atresia (96%), bilateral superior vena cava (71%), and a form of common atrioventricular valve (93%). Systemic arterial outflow obstruction is rare. Total anomalous pulmonary venous connection is typically to an extracardiac vein (64%) (Figure 28.3) [22]. There are bilateral sinoatrial nodes. The coronary sinus is almost always absent. Bilateral hepatic veins connect isomerically to the atria. Pulmonary anatomy is typically bilateral trilobed lungs with bilateral epiarterial bronchi.

Fewer than one half of polysplenia syndrome patients have functionally univentricular heart, but of those with single ventricles, two thirds have single (dominant) right ventricle. Not infrequently, ventricular morphology is indeterminate, without there being a rudimentary chamber. Interruption of the inferior vena cava and azygous continuation is common (80%). Bilateral hepatic veins are frequently present. Anomalous pulmonary venous drainage is typically to the right atrium, though isomeric or ipsilateral pulmonary venous connections (not truly anomalous) are common. Ventriculoarterial connection is concordant or

DORV (30%). Pulmonary atresia is significantly less frequent than in asplenia. The sinoatrial node may be hypoplastic and misplaced or may be absent. Bilateral superior vena cavae are common, and a persistent left superior vena cava may drain to the coronary sinus. Pulmonary anatomy is typically bilateral bilobed lungs with bilateral hyparterial bronchi.

Natural History

The natural history of patients with functionally univentricular heart is determined by the adequacy, at any point in time, of systemic blood flow and pulmonary blood flow and the effect of the combined volume load on ventricular function. In the current era, it is challenging to determine the true natural history of these malformations because of the influence of surgical interventions. Since the 1950s, surgical interventions to augment pulmonary blood flow (aortopulmonary shunts) and to decrease pulmonary blood flow (pulmonary artery banding) have drastically altered the outlook for survival of patients with functionally univentricular heart.

Moodie *et al*. [23] did study a population of unoperated patients with single ventricle hearts and described mortality of 50% 14 years after diagnosis. Deaths were most commonly attributed to congestive heart failure (20%), arrhythmia (20%), or unidentified causes (10%). More recently, Franklin [24] studied survival *without definitive repair* in 191 patients presenting in infancy (first year of life) with DIV. Some of the patients had undergone palliative procedures, but none had undergone complete separation of the pulmonary and systemic circulations. Actuarial survival was 57% at 1 year, 43% at 5 years, and 42% at 10 years [24].

Certain anatomic substrates have important impacts on the natural history. Atresia of the left atrioventricular valve (mitral atresia or left-sided atrioventricular valve atresia with ventricular L-loop) often coexists with a restrictive interatrial communication. This combination, which results in pulmonary venous obstruction, frequently causes death owing to hypoxia and acidosis in the early days or weeks of life. Even when the interatrial communication is not restrictive at birth, there is a strong tendency for it to become restrictive over time.

One of the most important anatomic factors which impacts negatively on survival in patients with functionally univentricular heart is the presence or development of systemic ventricular outflow obstruction or subaortic stenosis, which occurs when the aorta arises from the rudimentary chamber. This includes patients with DILV and discordant ventriculoarterial connection, those with tricuspid atresia and discordant ventriculoarterial connection, and those with mitral atresia and concordant ventriculoarterial connection. Systemic ventricular outflow obstruction is generally caused by small size of the interventricular communication, which is the only pathway for blood flow into the rudimentary subaortic outlet chamber. In circumstances where the ventricular septal defect is small at birth, there is generally aortic hypoplasia, frequently with coarctation, and occasionally with interrupted aortic arch. Even when the ventricular septal defect is nonrestrictive at birth, it often significantly narrows over time, and subaortic obstruction then becomes apparent [25]. The tendency for subaortic obstruction to progress after some forms of palliation, notably pulmonary artery banding, has been well described [26]. More recently it has been clearly documented that any operative strategy that reduces the total volume work of a single ventricle heart is accompanied by geometric changes characterized by increased wall thickness and mass to volume ratio and diminution in the size of the bulboventricular foramen or subaortic ventricular septal defect, if present [27]. This can occur at any stage of palliation, or following a Fontan operation.

In tricuspid atresia, the natural history is quite variable, but it is predicted by the underlying pathophysiology as in all functionally univentricular hearts. Most patients with tricuspid atresia and normally related great arteries have some degree of obstruction to pulmonary blood flow. This generally progresses as the ventricular septal defect becomes more obstructive or infundibular obstruction increases, and as a result there is increasing cyanosis. Without surgical intervention, over 90% of patients will die by one year of age from complications of hypoxia. Patients with normal or increased pulmonary blood flow at birth will show early symptoms of congestive heart failure and may succumb to this in the first months of life. If they survive the period of increased pulmonary blood flow they may gradually develop intracardiac obstruction to pulmonary blood flow, but are otherwise at risk for the development of pulmonary vascular obstructive disease. In either case, a falsely reassuring period of clinical improvement may occur as their circulation becomes more balanced [28] before their course progresses to either cyanosis, pulmonary vascular obstructive disease, or ventricular dysfunction owing to chronic volume overload.

Patients with tricuspid atresia and ventriculoarterial discordance (associated TGA) have, in general, a worse prognosis. Unobstructed pulmonary blood flow results in congestive heart failure and death within the first year of life. Subaortic obstruction complicates the scenario, further shortening survival time. In the extreme case, there is ductal dependency of the systemic circulation in the newborn. The rare patient with tricuspid atresia and TGA who has no subaortic obstruction and some degree of pulmonary stenosis may survive for a few years without surgical intervention. As in all patients with functionally univentricular heart without definitive surgical intervention, the left ventricle in patients with tricuspid atresia will, over time, develop progressive dysfunction resulting from chronic volume overload and chronic hypoxia. Patients who survive beyond the first few years of life often develop severe left ventricular dysfunction with low ejection fraction and mitral regurgitation.

Finally, the discussion of the natural history of functionally univentricular heart is incomplete without consideration of the impact of anomalies of pulmonary venous connection. While total anomalous pulmonary venous connection in functionally univentricular heart occurs most commonly in the setting of heterotaxy syndrome (and then most commonly in asplenia patients), it can occur in any of the anatomies covered in this chapter, as well as in cases of hypoplastic left heart syndrome. The natural history without surgery depends on the adequacy of pulmonary blood flow, which is influenced both by the presence of pulmonary stenosis and by the degree of obstruction of the pulmonary venous connection. Early mortality is very high among infants with single ventricle and total anomalous pulmonary venous connection [29], and late death is a continuing risk.

Evolution of Surgery for Functionally Univentricular Hearts

The development in the 1940s of the Blalock-Taussig shunt [30] and the original description in 1952 of pulmonary artery banding [31] ushered in an era of palliation for selected patients with single ventricle hearts who suffered from either a shortage or an excess of pulmonary blood flow. Of course, these early palliative efforts were undertaken, not as elements of a planned staged approach to definitive reconstruction but rather in an effort to salvage fragile patients severely compromised by either cyanosis or congestive heart failure.

Septation of the Single Ventricle

The first instance of definitive therapy for a single ventricle by means of septation of the main chamber and complete separation of the pulmonary and systemic circulations occurred in 1956 at the Mayo Clinic. A patient believed preoperatively to have congenitally corrected TGA with ventricular septal defect, was found intraoperatively to have a single ventricle. Septation was performed, and the patient lived 6 months. According to Kirklin and Barratt-Boyes [32] the concept of septation lay dormant for several years, and was revisited later by the Mayo Clinic group and by others including in 1972 by Sakakibara and associates [33] and in 1973 Edie and associates [34]. Additional cases from the Mayo Clinic were reported by McGoon *et al.* [35]. These early efforts at septation all involved opening the ventricle. Doty and colleagues in 1979 [36] described the right atrial approach to septation. In general the surgical mortality associated with septation was high, heart block was a frequent complication, and less than one third of patients were said to enjoy satisfactory late results. Not surprisingly, enthusiasm for this form of treatment was limited, although at the time the alternatives were few. Among a few others, Kirklin and colleagues at the University of Alabama in Birmingham pursued efforts at septation (Figure 28.4) [37] and in 1982 published their experience, focusing on 16 patients with univentricular heart with left anterior subaortic outlet chamber, the anatomical arrangement they believed to be most satisfactorily suited for septation of the dominant ventricle [38]. Hospital mortality was 44%. Five of the seven patients with outlet foramen obstruction died despite surgical enlargement of the outlet foramen. Of the remaining patients with unobstructed outlet foramen, there were two hospital deaths (18%), both in patients with small ventricular size. Reviewing this experience, McKay and associates [38] reported that at intermediate follow-up the majority of survivors were

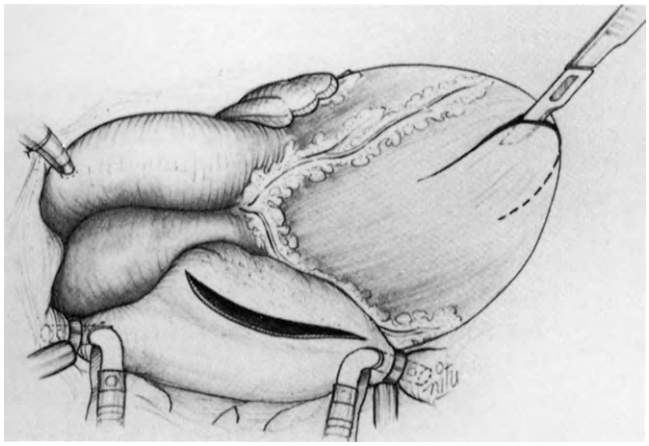

Figure 28.4 The positions of the atrial and ventricular incisions used in the combined approach for ventricular septation. (Reproduced with permission from Pacifico *et al.* [37].)

without symptoms, but the patients subjected to exercise testing performed well below normals for age and size. This important study identified the presence of outlet foramen obstruction, and small ventricular size, as incremental risk factors for hospital death. The authors drew the following inferences: that a shunt should be advised prior to septation in all patients with small heart size and pulmonary stenosis (either naturally occurring or secondary to pulmonary artery banding), regardless of their degree of cyanosis. This, they anticipated, would result in enlargement of the ventricular cavity and increase the probability of successful septation. For patients without pulmonary stenosis they suggested a protocol of septation early in life.

Despite such careful analyses, the morbidity and mortality associated with septation have remained high [39]. Frequently encountered complications include heart block requiring permanent pacemakers, late residual ventricular septal defect, atrioventricular valve incompetence requiring reoperation, and a high incidence of sudden death [40]. Careful selection of candidates excludes the majority of functional single ventricle patients from this form of definitive therapy. Important selection criteria include the anatomy and function of the atrioventricular valves and the presence or absence of pulmonary or subaortic stenosis. Atrioventricular valve repair, if necessary, is associated with increased rates of mortality. Pulmonary valve or subvalvar stenosis not amenable to direct relief requires an extracardiac conduit, which is also associated with increased morbidity and mortality [37].

As other forms of definitive surgical therapy for functional single ventricle have evolved, the application of septation became quite limited. Nonetheless, improvements in technique continued to be made. Importantly, Ebert in 1984 [41] proposed a two-staged approach to ventricular septation. He reported favorable results in five patients. At the first stage, a small patch was placed in the apex and a second patch between the atrioventricular and semilunar valves. The central section was left open. A pulmonary artery band was placed at this time if one had not been placed previously. Six to 18 months later the second stage of the repair was undertaken. This consisted of closure of the central portion of the ventricular septal defect with additional patch material. None of the patients acquired heart block in association with surgery. Ebert suggested that the procedure seemed to allow the apical and base patches to stiffen and heal to the endocardium, with fewer sutures required because the central area was open and no pressure differential existed across the patch. Despite Ebert's very encouraging initial report, subsequent applications of this innovative technique have been limited. Despite the relative rarity of ventricular septation as a primary approach to functionally univentricular heart, there continue to appear, from around the world, isolated reports of satisfactory functional status of patients subjected to septation with follow-up of one to three decades [42–44].

The Cavopulmonary Shunt

The superior vena cava to ipsilateral pulmonary artery anastomosis is generally known by the name Glenn shunt. In fact, the concept of the superior cavopulmonary anastomosis was developed concurrently and independently by several surgical teams. Years before the first clinical application of cavopulmonary shunting, several investigators studied the concept of the *dispensable right ventricle*. Rodbard and Wagner [45] in Chicago in 1949 experimentally anastomosed the right atrial appendage to the pulmonary artery and ligated the main pulmonary artery in dogs, demonstrating the feasibility of right ventricular exclusion. The first report of experimental cavopulmonary connection was published in 1950 in Italy by Carlo Carlon and coworkers of Padua [46] who advanced the notion that an "advantage would be received if the blood of the superior vena cava should reach the capillary region of the right lung by way of a convenient anastomosis between the great venous trunk and the arterial system of the right lung." The experimental canine preparation was an end-to-end anastomosis between the proximal end of the divided azygous vein and the right pulmonary artery with preatrial ligation of the superior vena cava. Carlon's first clinical experience was not reported until 1964. In the meantime, Glenn and colleagues at Yale published their first report of experimental cavopulmonary shunts in 1956—a large study of 59 operated dogs, with six long-term survivors [47]. The first clinical report by Glenn was published in 1958 [48]. It is following this report, and subsequent series by the same authors, that the superior cavopulmonary anastomosis has become widely known as the Glenn shunt. Interestingly

however, a fundamentally similar operation was at the same time being developed and evaluated in Budapest (and later North Carolina) by Frances Robicsek and associates [49], in Russia by Darbinian and Galankin [50] and by Meshalkin [51], in Italy by Carlon and others [46], and in the United States by Shumacher [52]. In retrospect, it appears likely that the first attempts at clinical cavopulmonary shunts were by Harris B Shumacher in 1954. His two young patients, one with truncus arteriosus and one with TGA, both had markedly elevated pulmonary vascular resistance and both died within hours of operation.

The Glenn shunt found a unique and important place in the management of cyanotic heart disease in general, and functionally univentricular hearts in particular, in that it differed in an important physiologic way from systemic to pulmonary artery shunts. The cavopulmonary anastomosis was capable of increasing pulmonary blood flow and thus systemic arterial saturation without increasing the volume load on the systemic ventricle. It also proved the feasibility of transpulmonary flow without complete dependence on a subpulmonary ventricle. During the 1960s and early 1970s, the classic Glenn shunt was used extensively with good results to palliate patients with tricuspid atresia and to a lesser extent other forms of functional single ventricle, although cyanosis eventually recurred in a high proportion of patients [53]. The unidirectional Glenn shunt was eventually modified by Dogliotti and colleagues [54], Haller *et al.* [55], and Azzolina and coworkers [56] to allow the flow of superior vena cava blood into both pulmonary arteries with an end-to-side superior vena cava to pulmonary artery anastomosis. This technique preserves the confluence and integrity of the central pulmonary arteries and eventually supplanted the classic Glenn anastomosis as preferred palliation for functional single ventricles. Currently, without particularly good reason, the bidirectional superior cavopulmonary anastomosis is generally and widely referred to as the bidirectional Glenn shunt.

Fontan's and Kreutzer's Operations

The first successful complete physiologic repair of tricuspid atresia, with separation of the pulmonary and systemic circulations, was accomplished in 1968 by Frances Fontan and colleagues and was reported in 1971 [57]. This followed the experimental work of Isaac Starr and colleagues [58] who had shown that functional destruction of a dog's right ventricle did not result in systemic venous hypertension, the previously described experiments in 1949 by Rodbard and Wagner [45] and by Warden, De Wall, and Varco in 1954 [52], which demonstrated the feasibility of bypassing the right ventricle by means of a right atrial to pulmonary artery anastomosis. Hurwitt and associates [59] reported an unsuccessful attempt to treat tricuspid atresia by right atrium to pulmonary artery anastomosis in 1955. Fontan's first corrective operation for tricuspid atresia involved the construction of a Glenn anastomosis and anastomosis of the right atrial appendage to the proximal end of the divided right pulmonary artery (Figure 28.5) [57]. In the subsequent two patients, an aortic homograft valved conduit was placed between the right atrium and the proximal right pulmonary artery (Figure 28.6) [57]. In all three patients, an additional homograft valve was placed at the junction of the inferior vena cava with the right atrium. The atrial septal defect was closed, and the main pulmonary artery was ligated or divided. The utilization of inflow and outflow valves, together with the strict inclusion criteria suggested by Choussat, Fontan, and colleagues [60], suggest a belief on their part that the right atrium of patients with tricuspid atresia could, to some extent, assume the pumping function of a subpulmonary ventricle.

Kreutzer in 1973 reported a modification of Fontan's operation in which the patient's own main pulmonary artery with its intact pulmonary valve was excised from

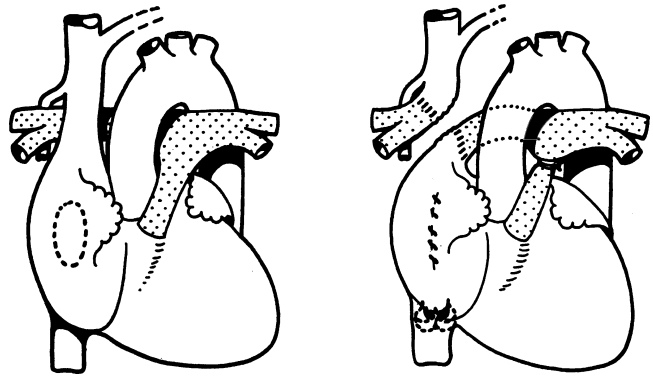

Figure 28.5 Artist's drawing of Fontan's original repair for tricuspid atresia type Ib. Case 1. (Reproduced with permission from Fontan *et al.* [57].)

the right ventricle and anastomosed to the right atrial appendage (Figure 28.7) [61]. The atrial septal defect and ventricular septal defect were closed. A Glenn anastomosis was not performed, and no inferior vena caval valve was used. At the 2009 meeting of the American Association for Thoracic Surgery, Kreutzer reported that one of his earliest patients was well 38 years after initial atriopulmonary anastomosis (and 3 years following conversion to total cavopulmonary connection [TCPC]) [62].

During the decade following Fontan and Kreutzer's pioneering work, a variety of modifications of their original operations were used to treat patients with tricuspid atresia. The value of maintaining the confluence of the pulmonary arteries became evident, and direct connection of the pulmonary arteries to the posterosuperior portion of the right atrium (as opposed to the right atrial appendage) emerged as the favored style of atrial pulmonary connection. Of course for tricuspid atresia, the operation was completed by closure of the atrial septal defect and of the main pulmonary artery. In most cases, the selection criteria espoused by Fontan's group were applied, so that patients did not undergo definitive operation until they were at least 4 years old, and often much older. Failure rates were high, and significant postoperative morbidity was common. In hopes of improving the hemodynamic status of these patients, several surgeons proposed the incorporation of the hypoplastic right ventricle into the pulmonary circulation, reasoning that the pump function contributed by a small right ventricle was better than none at all. In 1978, Bowman [63] introduced the use of porcine valved synthetic conduits to establish antegrade flow from the right atrium to the right ventricle and described significant subsequent increase in the volume of the right ventricular cavity. Others accomplished similar arrangements using homograft valved conduits. The operations for tricuspid atresia were completed by closure of both the atrial septal defect and the ventricular septal defect and relief of pulmonary stenosis if present. Recognizing the inherent long-term problems associated with valved conduits, Björk and colleagues [64] in 1979 described an anterior right atrium to right ventricle communication using as its inferior wall a flap of right atrial tissue, roofed over with autologous pericardium. The utility of these atrioventricular reconstructions was limited by the potential for sternal compression of the conduit or pathway constructed between the right atrium and the right ventricle. Efforts to document the utility of incorporation of the hypoplastic right ventricle into the pulmonary circulation yielded inconsistent results [65,66], though some authors, such as Ilbawi *et al.* [67] were convinced that incorporation of a right ventricle of greater than 30% normal size contributed to increased stroke volume, lower systemic venous pressure, and better systemic ventricular function.

As experience with modifications of Fontan's operation increased, there was considerable impetus to extend the concept of *right ventricular exclusion* beyond tricuspid atresia to other forms of functionally single ventricle. Yacoub and Radley-Smith [68] were among the first to use an atrial pulmonary connection (with valved conduit in their initial case) for correction of single ventricle. The challenge of applying the principles of Fontan's and Kreutzer's operations to single ventricle hearts with atrioventricular connections other than right atrioventricular valve atresia, eventually led numerous investigators to pursue technical solutions. Among the problems faced were the difficulty of reliably closing a patent right-sided atrioventricular valve (without creating heart block) in hearts with a dominant or single left ventricle and normal left-sided atrioventricular valve, and the even more vexing challenge of creating an unobstructed pathway for pulmonary venous return from the left atrium, through an atrial septal defect, and into the right-sided atrioventricular valve in hearts with left atrioventricular valve atresia. Initial efforts, which involved the placement of a large contoured patch over both the atrial septal defect and the opening of the right-sided atrioventricular valve, were met with high rates of failure as the patch was frequently displaced toward the atrial septal defect and atrioventricular valve (obstructing pulmonary venous inflow) by the higher pressure on the systemic venous right atrial side of the patch. To address these challenges, elaborate means of atrial partitioning were devised [69,70] to ensure unobstructed caval flow to the pulmonary arteries and unobstructed pulmonary venous flow to the functional atrioventricular valve(s) of the

systemic ventricle. Atrial partitioning was accomplished with either a pericardial or synthetic patch, a flap of atrial wall (reminiscent of Senning's operation for TGA), or even an intra-atrial tube graft.

By the middle of the 1980s, experience with modified Fontan operations for treatment of tricuspid atresia and other forms of functional single ventricle was becoming widespread. Several important lessons had been learned. Contrary to earlier notions, the pumping function of the right atrium was of little or no importance. Similarly, the notion that valves were required in the pathway between the caval veins and the pulmonary circulation had been dispelled. It was apparent that the principal determinants of success of a Fontan type connection were 1) unobstructed pathways with generous connections between the systemic veins and the pulmonary arteries; 2) preservation of the anatomic and functional integrity of the pulmonary vasculature (low pulmonary vascular resistance and minimal distortion); and 3) adequate function of the systemic ventricle. The feasibility of extracardiac TCPC in complex forms of heterotaxy syndrome with interrupted inferior vena cava and azygous or hemiazygous continuation of the inferior vena cava had been demonstrated by Kawashima and associates [71], who accomplished TCPC by means of anastomosis of the superior vena cava to the pulmonary arteries. This left only the return from the coronary circulation and the hepatic veins draining to the right atrium. At the 1988 meeting of the American Association for Thoracic Surgery, de Leval described elegant hydrodynamic studies, which led him and his colleagues to a modified approach to Fontan reconstructions that entailed exclusion of most or all of the right atrium from the systemic venous to pulmonary artery pathway [72]. The operation he described consisted of 1) end-to-side anastomosis of the superior vena cava to the undivided right pulmonary artery; 2) construction of a composite intra-atrial tunnel with use of the posterolateral wall of the right atrium; and 3) use of a prosthetic patch to channel the inferior vena cava to the enlarged orifice of the transected superior vena cava that is anastomosed to the main pulmonary artery. The operation, referred to as TCPC was touted as having the following advantages: 1) technical ease and reproducibility regardless of type of atrioventricular connection; 2) avoidance of injury to the atrioventricular node and minimizing the amount of atrial tissue subjected to elevated venous pressure in order to reduce the risk of early or late arrhythmias; and 3) reduction of turbulence with subsequent diminution of energy loss and lessened risk of thrombosis. As was the case two decades earlier with the evolution of the unidirectional cavopulmonary anastomosis, numerous surgical teams devised and described operations fundamentally similar to de Leval's TCPC roughly contemporaneously (Figure 28.8) [73,74].

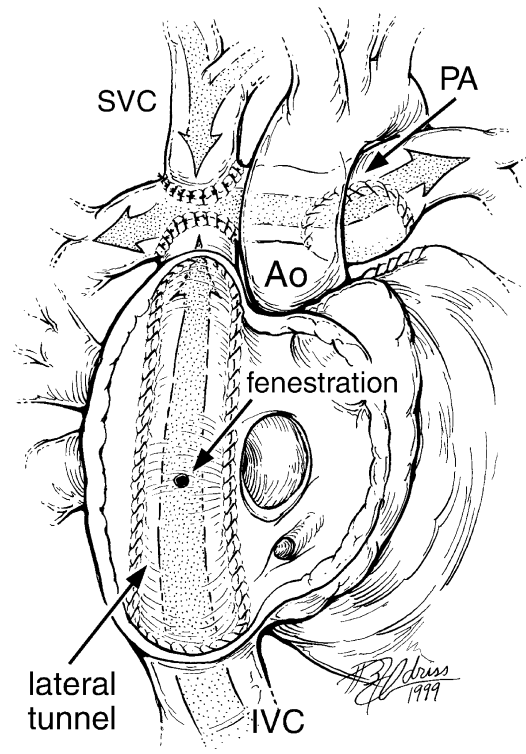

Figure 28.8 The lateral atrial tunnel type of total cavopulmonary connection. The lateral atrial tunnel is comprised of a gusset of polytetrafluoroethylene (PTFE) and of right atrial wall. In this instance, a single fenestration has been created in the polytetrafluoroethylene baffle. (Ao, aorta; IVC, inferior vena cava; PA, pulmonary artery; SVC, superior vena cava.) (Reproduced with permission from Backer *et al.* [74].)

de Leval's unique contribution was the analysis of in vitro studies, which demonstrated that the previously popular atrial pulmonary connection was a poor hydrodynamic design. These studies showed that the stream lines of superior and inferior vena caval blood collided within the atrial chamber, creating turbulence. Interestingly, the flow disturbances, demonstrated in the atrial cavity and at its inlets and outlet, were exaggerated by pulsation. While the technique presented by de Leval and associates at that time was essentially the lateral atrial tunnel combined with superior cavopulmonary connection, they also alluded to the possibility of interposition of a circumferential tube graft between the caval orifices as another means of TCPC. A fundamentally similar technique had already been described separately by Danielson and Norwood (personal communications) using an intra-atrial tube graft, and was proposed shortly thereafter by Marcelletti using an extracardiac tube graft [75]. de Leval, and the other early proponents of these techniques cited the theoretical advantages of having the entire right atrial wall at low pressure if a tube graft was used, and having a minimal amount of right

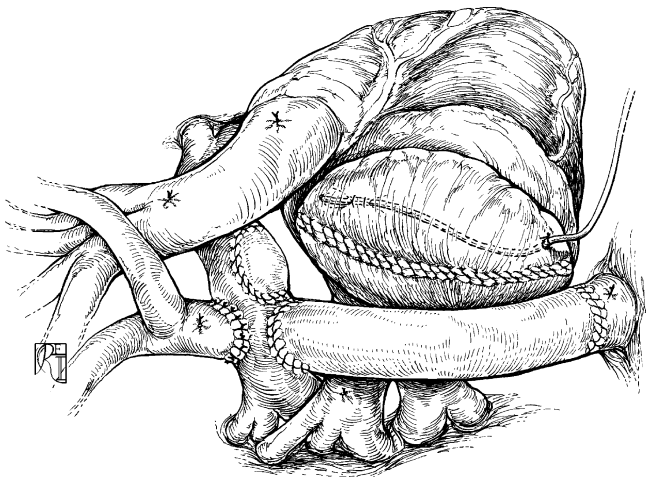

Figure 28.9 The total extracardiac conduit type of total cavopulmonary connection. In this instance, a right-sided superior cavopulmonary anastomosis is combined with the interposition of a polytetrafluoroethylene graft conduit between the divided inferior vena cava and the underside of the pulmonary artery confluence. atrial wall (the sinus venarum) at elevated central venous pressure when the lateral atrial tunnel was used.

For a period of time, the lateral atrial tunnel became the most widely used type of TCPC. However, over the latter half of the 1990s, the technique of using an extracardiac conduit to complete the TCPC (Figure 28.9) [76] met with increasing popularity [77,78]. In this operation, the divided superior vena cava is anastomosed to the ipsilateral pulmonary artery in end-to-side fashion. The inferior vena cava is transected and the cardiac end is oversewn. A conduit is interposed between the opened inferior vena cava and the underside of the pulmonary artery. Both homograft and prosthetic tube grafts (most often polytetrafluoroethylene [PTFE]) have been used to accomplish the so-called "extracardiac TCPC." The main theoretical advantages suggested by proponents of this method include the avoidance of atrial suture lines and the fact that none of the atrial wall is subjected to high venous pressures. An additional theoretical advantage rests in the possibility of accomplishing the extracardiac conduit Fontan procedure using normothermic or minimally hypothermic cardiopulmonary bypass without aortic cross-clamping in patients with a previously established superior cavopulmonary connection. In some instances, in fact, the conduit operation can be accomplished without the use of cardiopulmonary bypass [79]. The principle potential disadvantage, of course, is related to the use of a circumferential conduit without growth potential. Given this consideration, proponents of TCPC using a circumferential extracardiac conduit generally postpone the procedure until the patient has grown large enough to accept a conduit size not likely to be outgrown when full somatic growth is achieved.

Staging Fontan's Operation

Refinement of the technical aspects of modified Fontan operations led to a significant decrement in the overall mortality associated with these procedures. Nonetheless, nearly two decades after Fontan's pioneering work and despite concerted efforts to identify those factors that would allow Fontan operations to be undertaken with minimal risk, there persisted throughout the 1980s a troublesome degree of morbidity and early mortality following modified Fontan procedures. Too often, in carefully selected patients with adequate preoperative ventricular function and pulmonary vascular anatomy and resistance, the postoperative course was characterized by elevation of central venous pressure, tachycardia, sequestration of fluid in the pleural and peritoneal spaces, and hypotension, which was only transiently responsive to volume administration at the expense of further increases in venous pressure. Little improvement was seen with administration of inotropic agents and vasodilators and with external compressive devices to promote venous return while minimizing volume administration. Echocardiography frequently showed a strikingly high ventricular wall thickness to cavity volume ratio, regardless of the contractile state of the myocardium.

It became evident that the conversion from the unoperated or palliated state to the post-Fontan circulation was associated with rapid removal of a chronic volume load, but that regression of myocardial mass proceeds slowly. This results in a maladaptive response to removal of the ventricular volume load characterized by a markedly increased ventricular myocardial mass-to-volume ratio [27]. The persistence of increased muscle mass in the setting of acutely diminished ventricular volume results in increased ventricular wall thickness and decreased cavity dimensions. This significant change in mass-to-volume relationship of the ventricle, can result in significant alterations in both systolic and diastolic properties of the ventricle. This realization shed light on earlier observations that older age and increased ventricular mass (hypertrophy) were risk factors for mortality in association with the Fontan operation [80]. More importantly, it lead to the hypothesis that dividing Fontan's operation into two procedures could accomplish early reduction of the volume work of the single ventricle and might minimize the impact of changes in ventricular geometry on outcome and survival.

At the end of the decade of the 1980s and in the early 1990s, several groups investigated the merits of a staged

approach to Fontan's operation. For some, the protocol of performance of an early bidirectional superior caval pulmonary anastomosis followed later by a completion Fontan procedure was a pathway selected specifically for high-risk Fontan candidates [81], while others [82] pursued a two-staged approach to Fontan's operation for virtually all patients. They postulated that some of the morbidity and mortality associated with Fontan's operation would be eliminated by staging. As importantly, they suggested that the duration of the palliated state could be minimized and that the volume load on the single ventricle should be reduced as early in life as is practical. Thus in 1989, Norwood introduced the hemi-Fontan procedure, as the first step in a two-stage process of achieving TCPC. Obligating superior vena caval return to pass through the lungs before returning to the functional single ventricle, the hemi-Fontan operation is the physiologic equivalent of the bidirectional Glenn anastomosis. Because it is planned as an intermediate step before an anticipated completion Fontan procedure, it differs technically from a bidirectional Glenn anastomosis in ways that simplify the eventual completion Fontan. At the time of association of the pulmonary arteries with the superior vena cava, the natural connection of the right atrium with the superior vena cava is maintained, but the caval orifice is first enlarged (to be as large as the inferior vena caval right atrial connection) and then closed with a patch that is easily removed at the final stage. Other sources of pulmonary blood flow including systemic to pulmonary shunts and antegrade flow to the pulmonary arteries are eliminated. Pulmonary artery architecture is optimized by augmentation of the central confluence with homograft vascular patch material. Other potential hemodynamic burdens such as systemic ventricular outflow tract obstruction or atrioventricular valve regurgitation are addressed as part of the hemi-Fontan procedure. Bove and associates later modified Norwood's operative technique, avoiding an incision across the cavoatrial junction, with the theoretical goal of preserving the integrity of the sinoatrial node and its blood supply, with the hope that this would enhance the likelihood of preserving sinus rhythm [83].

For patients who have undergone a hemi-Fontan procedure, the final stage or completion Fontan procedure is technically very straightforward. The patch which had been used to occlude the opening of the right atrium into the superior vena cava is excised, and a lateral atrial tunnel is constructed, directing flow from the inferior vena cava to the previously created amalgamation of the superior vena cava with the pulmonary arteries. A majority of surgeons have persisted in using the technically more straightforward bidirectional Glenn anastomosis rather then the hemi-Fontan operation as the first of two stages. In these circumstances, the completion Fontan by lateral atrial tunnel requires re-establishment of the connection between the right atrium and the superior cavopulmonary amalgamation. Alternatively, after a bidirectional Glenn anastomosis, the completion Fontan may be easily accomplished using an extracardiac conduit.

The Incomplete Fontan Operation

Some of the same issues that are addressed by staging Fontan's operation led others to pursue the concept of a Fontan operation with deliberately incomplete atrial partitioning. One of the earliest and most enthusiastic proponents of this approach was Laks and colleagues [84] who advocated incorporation of an adjustable (snare controlled) atrial septal defect. While first applied with respect to the naturally occurring atrial septal defect at the time of atriopulmonary connection in hearts with atretic right-sided atrioventricular connection, this concept was subsequently applied to the more widely used TCPC. When constructing the lateral atrial tunnel, the suture line is interrupted on one edge of the tunnel patch. The subsequent gap at the edge of the patch may be enlarged by excision of a small amount of material, and this gap is then encircled with a snaring suture of polypropylene, both ends of which are brought out through the atrial wall and passed through a small piece of tubing, which is used as a tourniquet to adjust the size of the opening (Figure 28.10) [16]. The atrial septal defect may be closed after separation from bypass, or the tourniquet may be positioned under the linea alba at the lower end of the incision to be used at

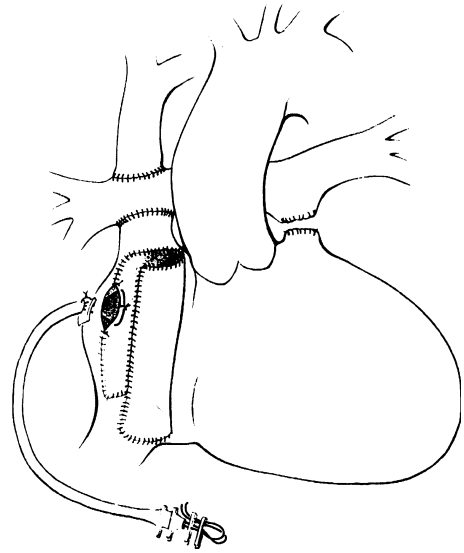

Figure 28.10 The lateral atrial tunnel type of Fontan connection with incomplete atrial partitioning (adjustable interatrial communication with snaring suture of polypropylene and exteriorized tourniquet) as advocated by Laks. (Reproduced with permission from Pearl *et al.* [16].)

a later time. The advantage claimed for the adjustable atrial septal defect is that it facilitates decompression of the systemic venous system and improves ventricular filling during an early postoperative course that may be characterized by transient elevation of pulmonary vascular resistance and altered ventricular function, but it can be closed following a period of recovery, thus eliminating the secondary problems associated with persistence of a right-to-left shunt.

Others have advocated simple fenestration of the prosthetic portion of the lateral atrial tunnel [85]. This is generally accomplished using the kind of aortic punch device that is used in aortocoronary bypass surgery. A simple round hole (of 4, 5, or 6 mm diameter depending on patient body size) is made in the synthetic patch. This is most easily accomplished when the lateral atrial tunnel is made of PTFE. Often the patient will undergo cardiac catheterization following complete recovery from the Fontan procedure, and the fenestration may be closed using a catheter-deployed device if satisfactory hemodynamics are observed during a period of trial occlusion of the fenestration with a balloon-tipped catheter [86]. Hemodynamic changes observed during fenestration occlusion most often include an increase in systemic venous pressure, increase in systemic arterial oxygen saturation, and slight decrease in measured cardiac output [87]. If the increase in systemic venous pressure or decrease in cardiac output is dramatic, then closure of the fenestration is not advisable. Early reports of the *fenestrated Fontan procedure* showed decreased operative mortality in high-risk patients. Fenestration has been applied for all Fontan patients by many surgical teams, as it also appears to be associated with a diminution of morbidity in the form of pleural effusions and ascites [88].

Surgical Methods

We routinely perform Fontan's operation in two stages. In the current era, most surgeons and centers do. The first stage has the important goal of reducing the volume load of the single ventricle, which in the unoperated or palliated state must pump blood to both the pulmonary and systemic vascular beds. This is accomplished by means of a superior cavopulmonary connection—either a bidirectional Glenn anastomosis or hemi-Fontan procedure. Many surgeons choose the bidirectional Glenn anastomosis because of technical simplicity, and because it can be performed on a beating heart with cardiopulmonary bypass or without cardiopulmonary bypass using a superior vena cava to right atrial shunt. In the latter case, the patient is dependent on preexisting antegrade pulmonary blood flow during construction of the superior vena cava to pulmonary artery anastomosis. Whether or not to completely eliminate other sources of pulmonary blood flow at the time of a bidirectional Glenn anastomosis is controversial. Proponents of maintaining an additional source of antegrade pulmonary blood flow claim higher systemic oxygen saturation and pulsatility of pulmonary blood flow as advantages. Proponents of eliminating all sources of pulmonary blood flow other than the cavopulmonary connection emphasize the important physiologic goal of minimizing the volume load on the ventricle, and cite higher superior vena cava pressures and a higher incidence of pleural effusions and chylothorax, as complications associated with failure to eliminate other sources.

We prefer the hemi-Fontan operation [89], because it does minimize the volume work of the systemic ventricle and because of its preparatory nature, which significantly simplifies the completion Fontan procedure. It is usually undertaken at 4–8 months of age but may be accomplished as soon as the pulmonary vasculature has matured sufficiently to allow superior vena caval blood to flow through the lungs without resulting in an undesirably high superior vena caval pressure. In practice, this is often true before 4 months of age (the author's earliest successful hemi-Fontan operation was performed at 9 weeks of age).

The Hemi-Fontan Procedure

The hemi-Fontan procedure is performed with the infant positioned supine. A radial or femoral artery line is inserted for monitoring pressure and blood gases. Central venous lines are not used. Surface cooling is begun following tracheal intubation. This includes the use of a cooling blanket beneath the patient, the application of ice bags to the head, and cooling of the operating room. The operative approach is by median sternotomy. Sufficient dissection to afford access to the aorta and the right atrium is accomplished before heparinization. Bypass is established with ascending aortic perfusion and drainage via a single cannula in the systemic venous atrium. All systemic to pulmonary artery shunts are occluded at initiation of bypass, and flow is adjusted to 150 mL/kg/min. The perfusate is gradually cooled to approximately 16 °C. During the cooling phase of cardiopulmonary bypass the remainder of the dissection is accomplished, with particular attention to freeing the pulmonary artery confluence behind the ascending aorta. When nasopharyngeal and esophageal temperatures have both reached 18 °C, the aortic cross-clamp is applied and circulation is temporarily discontinued. Blood is drained via the venous cannula into the cardiotomy reservoir, and the cannula is then removed. Cold crystalloid cardioplegia (30 mL/kg) is infused into the aortic root and is scavenged from the right atrium. An incision is made in the most superior portion of the right atrium and carried superiorly onto the medial aspect of the right superior vena cava (Figure 28.11) [89]. Through this incision the atrial septal defect is inspected, and if necessary it is enlarged. The

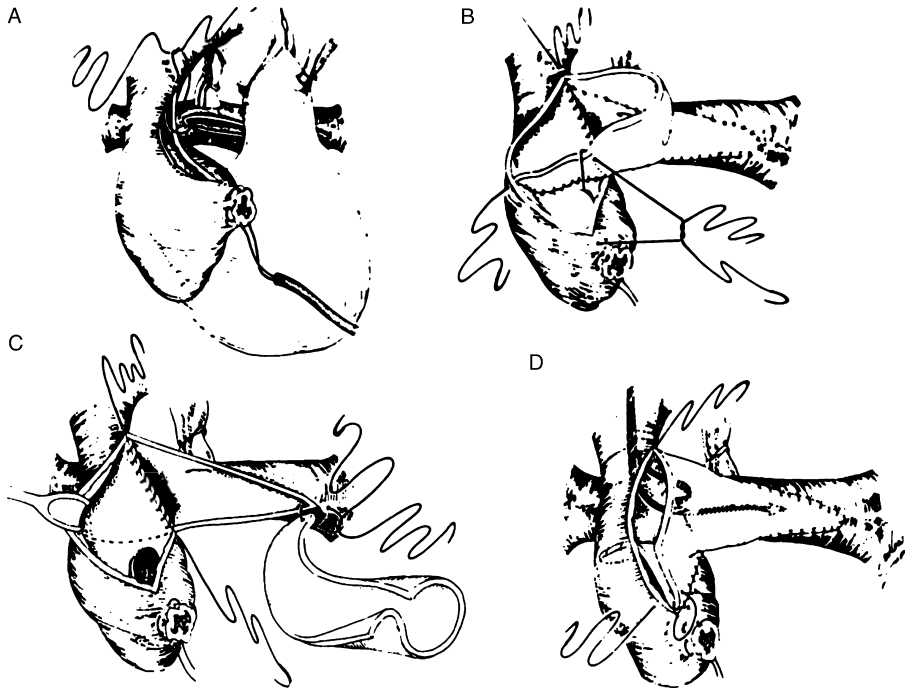

Figure 28.11 Artist's drawing of the hemi-Fontan procedure. **A,** The systemic-to-pulmonary artery shunt is occluded during the initial phase of cardiopulmonary bypass. During hypothermic circulatory arrest, the confluence of the pulmonary arteries is opened anteriorly. An incision is made in the superior portion of the right atrium and extended onto the medial aspect of the superior vena cava. The right pulmonary artery is anastomosed to the superior vena cava. **B,** A gusset of cryopreserved pulmonary artery homograft material is used for anterior augmentation of the confluence of the pulmonary arteries. **C,** This same homograft material is used to occlude the enlarged junction of the right atrium with the superior vena cava. **D,** The same homograft patch creates a roof over the patulous amalgamation of the superior vena cava with the pulmonary arteries. (Reproduced with permission from Norwood *et al.* [89].)

confluence of the right and left branch pulmonary arteries is opened anteriorly to a point just medial to the upper lobe branch on each side. In the absence of naturally occurring or surgically created pulmonary atresia, the main pulmonary artery is transected and oversewn proximally at the level of the pulmonary valve. (Simple ligation of the main pulmonary artery is ill advised, as it results in a cul-de-sac beyond the valve where stasis may predispose to thrombus formation). The posterior lip of the opened right superior vena cava is anastomosed in side-to-side fashion to the right pulmonary artery. If a left superior vena cava is present, it too is opened along its medial aspect, occluded at its cardiac end, and anastomosed in side-to-side fashion to the ipsilateral branch pulmonary artery. A single patch of cryopreserved pulmonary artery homograft tissue is used to augment the confluence of the pulmonary arteries anteriorly, to create a roof over each anastomosis of the vena cava(e) to the branch pulmonary arteries and to occlude the inflow of the right superior vena cava into the right atrium. The incision through, and subsequent patching of the junction of the right superior vena cava with the right atrium effectively enlarges this connection to a caliber equivalent to that of the junction of the inferior vena cava with the right atrium, but temporarily occludes this connection until it is reopened at the time of the completion Fontan procedure. Bypass is resumed and the cross-clamp is removed. In general the reconstruction can be accomplished during a period of hypothermic circulatory arrest of about 30 minutes duration.

During rewarming, the lungs are ventilated to minimize impedance to transpulmonary flow. After rewarming, separation from bypass is generally accomplished with minimal inotropic support. Following decannulation, catheters inserted through the cannulation purse string in the morphologic right atrium are used for infusions and to monitor cardiac filling pressure. Early in our experience we also placed catheters in the cavopulmonary amalgamation for pressure monitoring but no longer feel this is necessary. Sternal closure is accomplished routinely. Postoperative management includes judicious administration of fluids guided by cardiac filling pressures and early extubation, which can usually be accomplished 5–8 hours after completion of surgery. Diuretics are generally administered beginning on the first postoperative day. Hospitalization usually lasts a week or less. Facial swelling and irritability (which we suspect is attributable to headache from transiently

elevated venous pressure) often persist for a few days, and are more common in younger infants. Pleural effusion and chylothorax are extremely rare. Oxygen saturation in room air at discharge from the hospital is generally in the range of 80–84%.

Because it is intended specifically to be preparatory to an eventual completion Fontan procedure, concomitant procedures to address adverse hemodynamic circumstances should always be accomplished at the time of the hemi-Fontan procedure. Thus among 400 consecutive patients undergoing hemi-Fontan procedures by Norwood and Jacobs between May 1989 and August 1995 [90], 61 concomitant procedures were performed including atrial septectomy (17), relief of aortic arch obstruction (13), proximal main pulmonary artery to aortic anastomosis (6), repair or revision of previous repair of anomalous pulmonary venous connection (6), atrial ventricular valvuloplasty (6), and others (13). While the construction of a large side-to-side amalgamation of the superior vena cava and the confluence of the pulmonary arteries is facilitated by the absence of a drainage cannula from the superior vena cava, the same surgical result can be achieved using continuous cardiopulmonary bypass with venous drainage via the right atrium and via a small cannula placed high in the superior vena cava near its junction with the innominate vein if the surgeon wishes to avoid using hypothermic circulatory arrest.

The Completion Fontan Procedure

The completion Fontan procedure is usually performed 12–24 months after the hemi-Fontan operation. In theory, it should be undertaken whenever ventricular remodeling is complete and the mass to volume relationship of the systemic ventricle has normalized. Electively waiting longer than this prolongs the period during which systemic arterial oxygen saturation is at lower than normal levels and may increase the likelihood of the development of intrapulmonary shunting secondary to development of pulmonary arteriovenous fistulae. In practice, the completion Fontan by lateral atrial tunnel technique is generally undertaken when the patient is about 2 years old. If the plan for completion Fontan includes use of an extracardiac conduit, the procedure may be postponed to allow the patient to become somewhat larger and is usually undertaken at about 3 years of age.

Preparation and intraoperative monitoring are the same as for the hemi-Fontan procedure. Use of central venous lines is avoided in order to minimize the likelihood of thrombus formation within venous pathways. After repeat median sternotomy, minimal dissection is required to make preparations for cardiopulmonary bypass, which again is established with ascending aortic perfusion and drainage via a single cannula in the right atrium. Direct caval cannulation is avoided to minimize distortion and narrowing of these vessels, and caval tourniquets are unnecessary, eliminating the likelihood of caval or phrenic nerve injury. Bypass is established at flows of 120–150 mL/kg/min, and the patient is cooled until esophageal and nasopharyngeal temperatures reach 18 °C. During cooling, enough of the ascending aorta is mobilized to afford access for cross-clamping. The free wall of the right atrium is carefully dissected from the adjacent pericardium. When the desired temperature is reached, the aorta is cross-clamped and cold cardioplegic solution is infused. The venous cannula is removed. An incision is made in the free wall of the right atrium, parallel and slightly anterior to the sulcus terminalis. This incision extends inferiorly to the level of the Eustachian valve of the inferior vena cava and superiorly to within a few millimeters of the patched junction of the right atrium with the superior vena cava. The patch of homograft tissue that was previously placed to separate the right atrium from the confluence of the superior vena cava and pulmonary arteries is widely excised (Figure 28.12) [91]. Lateral tunnel cavopulmonary connection is performed using a gusset of PTFE. In our practice, this is generally trimmed from a 10 mm tube graft that has been split longitudinally. The gusset is sewn inferiorly around the opening of the inferior vena cava into the right atrium and along the interior atrial wall just posterior to the edge of the atrial septal defect. Superiorly the gusset is sewn to the edges of the opening of the right atrium into the superior vena cava and pulmonary arteries. The lateral tunnel is then completed by incorporating the anterior edge of the PTFE gusset in the closure of the atriotomy incision. Two important features of this type of lateral atrial tunnel Fontan are 1) insuring that the opening of the right atrium into the superior vena cava and pulmonary arteries is as large as the inferior vena caval opening; and 2) avoidance of suturing directly to the sulcus terminalis, which is believed to be important in the development of postoperative tachyarrhythmias. In most instances we choose to fenestrate the lateral tunnel and usually accomplish this by creating three separate holes in the PTFE gusset using a 2.5- or 2.7-mm punch device. Fenestrations of this size promote decompression of the venous pathway and enhance ventricular filling postoperatively, but generally go on to spontaneous closure, avoiding the need for devices in the venous pathway [92]. The completion Fontan procedure as described here can generally be completed with a period of hypothermic circulatory arrest of about 20 minutes duration.

As with the hemi-Fontan procedure, resumption of cardiopulmonary bypass is accompanied by ventilation of the lungs to optimize transpulmonary flow during rewarming. Low-dose inotropic support is used routinely, though it is often not necessary. Following decannulation, lines are inserted through the atrial purse string for infusion and

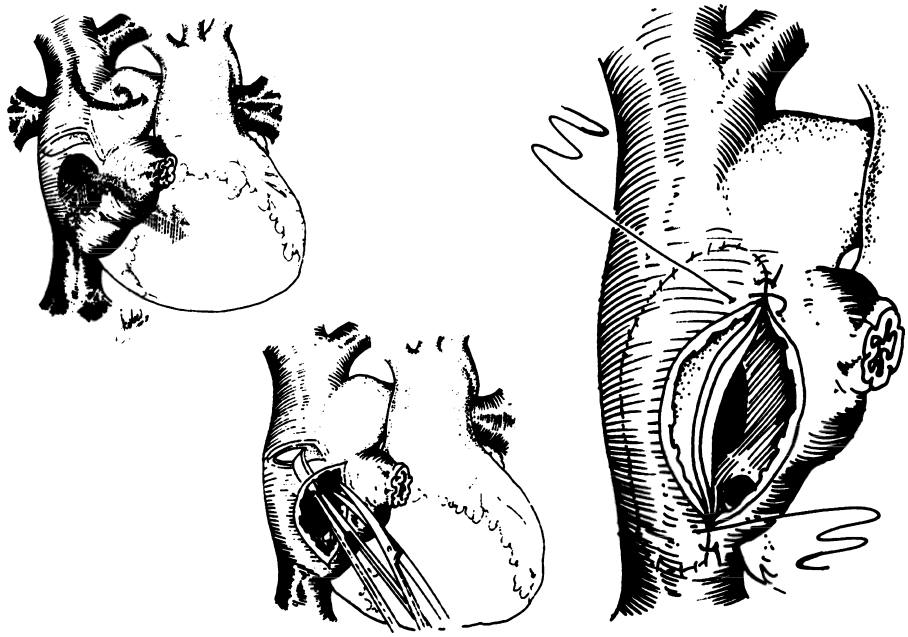

Figure 28.12 Completion of Fontan's procedure in a patient with previous hemi-Fontan operation. Through a lateral atriotomy incision, the homograft dam occluding the junction of the right atrium with the superior vena cava is excised widely. Atrial partitioning is accomplished using the lateral atrial tunnel technique. A gusset of polytetrafluoroethylene is used, with incorporation of the lateral edge of the polytetrafluoroethylene graft into the atriotomy closure. (Reproduced with permission from Jacobs *et al.* [91].)

monitoring of the cardiac filling pressure. We no longer monitor pressure in the cavopulmonary pathway, though we did so in earlier patients managed this way. One mediastinal chest tube is placed. The pleural spaces are opened to communicate with the pericardial space. Rather than inserting chest tubes in the pleural spaces at operation, we drain them later with 7 French polyvinyl catheters, only if significant pleural effusions occur. This method enhances early mobilization of the patient. Most patients can be extubated 5–8 hours after completion of surgery. We routinely administer baby aspirin, angiotensin converting enzyme inhibitors, and diuretics postoperatively. Intravenous inotropic support is generally continued for 2–3 days. The average duration of hospitalization using this scheme of management has been 10 days.

In certain patients, the extracardiac conduit type of completion Fontan is preferred. This is true when there is concern that an intracardiac lateral atrial tunnel may obstruct abnormal pathways of pulmonary venous drainage or when there are abnormalities of cardiac position and the ventricular apex is directed to the same side as the principle systemic venous connections. As mentioned, the operation may be performed at a slightly later age in order to optimize the size of the extracardiac conduit. Preparation and management of cardiopulmonary bypass are the same as for the lateral tunnel completion Fontan procedure. During the period of hypothermic circulatory arrest, the inferior vena cava is transected approximately 1 cm above the diaphragm and the cardiac end is oversewn. With the circulation arrested, a conduit of PTFE is anastomosed in end-to-end fashion to the inferior vena cava. The conduit is trimmed to an appropriate length and the superior end of the conduit is anastomosed to the pulmonary arteries. In patients with a prior bidirectional Glenn shunt, the anastomosis is performed between the conduit and the underside of the right pulmonary artery. The ideal alignment or offset between the anastomoses of the superior vena cava and the inferior caval conduit to the pulmonary artery are the subject of considerable controversy [93,94]. Many surgeons prefer to place the conduit-to-pulmonary artery anastomosis somewhat centrally, in the belief that this may increase the chances of achieving a favorable distribution of inferior vena cava blood flow to the right and left lungs. In patients with a prior hemi-Fontan, the superior end of the conduit may be anastomosed anteriorly to an opening created in the homograft roof over the amalgamation of the superior vena cava with the pulmonary arteries. As a general principle, most surgeons attempt to implant a conduit of such a size that it is unlikely that the patient will outgrow it. In practice, this translates into frequent use of conduits of 20–22 mm diameter, in patients with body weight of 10–15 kg. While such conduits certainly look large in children of this size, it is not clear that they are sufficiently large that they will not be associated with pres-

sure gradients or restriction of flow in adult size patients. On the other hand, there is evidence from computational flow dynamic modeling studies that 16 and 18 mm conduits are ideal for children 2–3 years old and that larger conduit sizes are associated with more stagnation volume in the lateral aspect of conduits larger than 20 mm and backflow in the expiratory phase of respiration at the lateral portion of conduits larger than 18 mm [95].

Numerous methods of fenestration of the extracardiac TCPC have been devised. In patients with a hemi-Fontan connection, a fenestration can be created in the patch which occludes the right atrium to superior vena caval junction. Alternatively, in any patient, fenestration may be accomplished by creation of a small window between the conduit and the adjacent wall of the right atrium by side-to-side anastomosis. Some authors have recommended the interposition of a small PTFE graft or shunt between the extracardiac conduit and the right atrium. This seems unnecessarily complicated. A very reliable and straightforward approach to fenestration of the extracardiac conduit type of Fontan connection involves suturing of the atrial orifice of the divided inferior vena cava to the leftward aspect of the conduit, in an end-to-side fashion. The circumferential suture line surrounds the fenestration, but remains away from the actual edge of the fenestration [96]. Following the extracardiac conduit completion Fontan procedure, postoperative monitoring and management are the same as described above for the lateral tunnel completion Fontan.

The techniques described above, including the conduct of bypass using a single cannula in the right-sided atrium and the use of hypothermic circulatory arrest to complete the TCPC, are elements of a strategy for Fontan operations that the author has used with considerable success. In fact, these techniques form the basis for a protocol associated with no mortality among 100 consecutive patients subjected to completion Fontan operations, including many with multiple risk factors [97]. It must be acknowledged, however, that a majority of surgeons currently perform the completion Fontan procedure using continuous cardiopulmonary bypass with mild or moderate hypothermia and that many reserve aortic cross-clamping for instances when associated repairs (such as valvuloplasty) are indicated [98]. Still others complete an extracardiac total cavopulmonary bypass without using bypass support, when technically feasible.

Results of Surgery

Mortality

Over the first two decades of the history of Fontan's operation and its modifications, the predominant influences on operative survival were appropriate patient selection and evolution and refinement of surgical techniques. It has become apparent that good health of the pulmonary vascular bed and satisfactory function of the systemic ventricle are essential ingredients for survival. Ventricular hypertrophy, pulmonary artery distortion, elevated pulmonary vascular resistance, atrioventricular valve regurgitation, and systemic ventricular outflow obstruction consistently emerged as incremental risk factors for suboptimal outcome. Early on, patients at both extremes of age seemed to be at higher risk with respect to operative mortality. Over time, the operations themselves became simpler rather than more complex, and eventually the TCPC (in one of a very few forms) could be applied more or less generically, usually without modifications necessitated by the details of atrioventricular and ventriculoarterial connections or ventricular morphology. In the last decade, the importance of patient selection has given way to the more powerful influence of patient preparation. Thus with more thoughtful palliation in neonates, and with staging procedures performed early in life to minimize the duration over which ventricular myocardium must adapt to excessive volume work, it has now become the case that most infants with functional single ventricles have a high likelihood of eventually undergoing a modified Fontan procedure with relatively low risk of operative mortality. These observations are born out by reports of steadily improving results of Fontan operations at many centers.

A 1996 report from the Mayo Clinic [99] compared the early morbidity and mortality as well as predictors of outcome for two consecutive cohorts of patients who underwent Fontan operations at that institution. The recent cohort of 339 patients (1987–1992) was compared with an earlier cohort of 500 patients (1973–1986). Overall mortality was considerably lower for the recent cohort (9% vs 16%, $p = 0.002$) despite increased anatomic complexity of patients. One year survival improved to 88% from 79%, and 5-year survival to 81% from 73%. The authors attributed the improved outcomes to patient selection, younger age at time of operation, and refinements in surgical technique and postoperative management.

A 1997 report from the Children's Hospital Boston reviewed their experience with the first 500 consecutive patients who underwent modified Fontan procedures there [100]. The incidence of early failure decreased from 27.1% in the first quartile to 7.5% in the last quartile. In a multivariate model, factors associated with an increased probability of early failure include a mean preoperative pulmonary artery pressure of 19 mmHg or more, younger age at operation, heterotaxy syndrome, a right-sided tricuspid valve as the only systemic atrioventricular valve, pulmonary artery distortion, an atrial pulmonary connection originating at the right atrial body or appendage, the absence of a baffle fenestration, and longer cardiopulmonary bypass time. An

increased probability of late failure was associated with the presence of a pacemaker before the Fontan operation. More recently the Children's Hospital Boston group reported the results of 220 patients who underwent lateral tunnel Fontan procedures with 10-year follow-up [101]. There were 12 early deaths, seven late deaths, four successful takedown operations, and four heart transplantations. Kaplan-Meier estimated survival was 93% at 5 years and 91% at 10 years, and freedom from failure was 90% at 5 years and 87% at 10 years. Freedom from new supraventricular tachyarrhythmia was 96% at 5 years and 91% at 10 years; freedom from new bradyrhythmia was 88% at 5 years and 79% at 10 years.

Similar improved outcomes have been reported by other institutions, paralleling the experience at those two very large centers. The impact of staging on the outcome of Fontan procedures is difficult to analyze, as most consecutive series are influenced by several additional factors that have contributed to reduced mortality. Jacobs and Norwood [91] in 1994 reported a significant improvement in survival with a two-staged approach to Fontan's operation (8% mortality for completion Fontan vs. 16% mortality for primary Fontan operation). While there are mortalities associated with the hemi-Fontan or bidirectional Glenn procedures, it is difficult to compare outcomes between groups that had early staging versus those with later primary Fontan operations, because information concerning nonsurgical mortality of single ventricle patients that occurs in the palliated or unoperated state is less readily available. Whether an early first-stage procedure (hemi-Fontan or bidirectional Glenn) selects out poorer candidates by means of operative mortality at that early stage, or alternatively enables more single ventricle patients to ultimately reach a Fontan completion, is debated. Increasing evidence suggests that the latter is true. In 1996 the author reported on 400 patients who had undergone hemi-Fontan operations at the Children's Hospital of Philadelphia between 1989 and 1995, revealing an overall mortality of 8%, which was reduced to 4% in the latter half of the series and 0% in the most recent quartile [90].

Contemporary results are represented by the authors' experience between 1996 and 2006, which includes 113 superior cavopulmonary anastomoses with three operative deaths and one late death and 100 completion Fontan procedures with no operative deaths and one late death. Each of the 100 Fontan procedures had been preceded by either a hemi-Fontan or bidirectional Glenn anastomosis. Eighty-four completion Fontans were of the lateral atrial tunnel type, and 16 were of the extracardiac conduit type. Patient age ranged from 1.5 to 15 years, with 98 patients less than 4 years old and median age 26 months [97].

As mentioned above, many surgeons perform Fontan's operation with bicaval cannulation and continuous cardiopulmonary bypass at mild to moderate hypothermia. Still others, in selected cases, accomplish completion Fontan procedures of the extracardiac conduit type without any extracorporeal bypass support. In the author's series, the hemi-Fontan procedure and all completion Fontan procedures were accomplished using hypothermic cardiopulmonary bypass and limited circulatory arrest as described above. This technique avoids potential problems of caval stenosis and phrenic nerve injury that may be related to cannulation, and minimizes the need for dissection and thus the potential for bleeding. Similar techniques used by Spray and associates at the Children's Hospital of Philadelphia [102] and by Mosca and Bove and associates at the University of Michigan [103] have yielded comparable results with operative mortality in the range of 1–2%. The report by Mosca and associates [103] of 100 consecutive Fontan operations for hypoplastic left heart syndrome revealed improved survival from 79% to 98% in consecutive cohorts and attributed much of the improvement in survival to evolution of the operative strategy from cardiopulmonary bypass and moderate systemic hypothermia in the earlier cohort, to profound hypothermia and circulatory arrest in the later cohort.

A more recent report from the same institution summarized their 15-year experience with 636 primary Fontan operations between 1992 and 2007 [104]. Total cavopulmonary connection was by lateral atrial tunnel in 92% and by extracardiac conduit in 8%. Hospital survival was 96%. Long-term survival was 97% at a mean follow-up of 50 months (range, 0–173 months). Ventricular anatomy and preoperative hemodynamics did not predict early or late survival. Longer aortic cross-clamp time was associated with decreased late survival ($p = 0.01$). Fontan takedown was required in 3%. The majority of recent cases were accomplished using continuous cardiopulmonary bypass support.

The progressive reduction of the operative mortality associated with modified Fontan procedures is clearly multifactorial. Clearer understanding of the fundamental physiologic and anatomic issues have led to refinements in operative technique, early neutralization of potential risk factors, widespread use of a staged approach, and selective application of the concept of fenestration or incomplete partitioning. While further reduction of operative mortality is important and may be anticipated in the future, major emphasis now must be placed on optimizing functional outcome and understanding and managing the late complications associated with Fontan operations and the unique circulatory physiology that results from them.

Late Considerations

In 1990, Kirklin and Blackstone and colleagues in collaboration with Professor Fontan [105] applied the meticulous

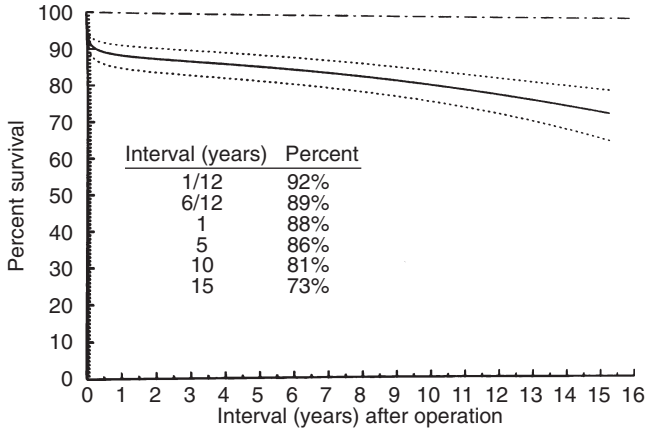

Figure 28.13 Fontan and Kirklin's predictive survival after a "perfect Fontan operation" performed under ideal circumstances. The multivariable risk factor equation for survival was derived from analysis of a heterogeneous group of patients (n = 334; deaths = 110) who underwent Fontan operations. To derive the survival curve shown in this figure, optimal values were entered for each of the risk factors. (Reproduced with permission from Fontan *et al.* [105].)

statistical methods that characterize their analyses of outcomes following cardiac surgery to a heterogenous group of patients undergoing an initially complete (nonstaged, nonfenestrated) Fontan operation. The hazard function for such patients had three phases: an early phase of about one year duration with rapidly declining risk of death, a relatively flat period of very low constant risk of death, and a gradually rising late phase of hazard, which becomes evident about 8 years after operation. They reasoned that many deaths after the Fontan operation may have been owing to circumstances that, based on lessons learned, could be avoided. To address the question of whether the persisting and rising hazard function for death years after the Fontan operation could be a result of these now avoidable circumstances, they undertook an analysis of survival under circumstances that could be considered ideal (Figure 28.13) [105]. Into the multivariable risk factor equation derived from the analysis of the above group of patients, they entered optimal values (within the realm of realism) for each of the risk factors. Under these ideal circumstances, the 15-year survival was predicted to be 73%, and the gradually rising late phase of hazard was still present (Figure 28.14) [105]. The only risk factor identified for the late phase of hazard was older age at operation. Is it then the case that the late phase of hazard for premature death is an inevitable accompaniment of the circulatory state after the Fontan operation? The answer is unknown. Many of the issues and events that complicate the course of survivors of Fontan operations are only now beginning to be understood.

Functional Status

Numerous studies of patients following Fontan-type repairs have found that resting cardiac indices were not different from those of healthy children. Some but not all achieve exercise cardiac indices similar to controls. The predominant mechanism for achieving high cardiac output during exercise is increased heart rate, with low-normal resting ejection fraction and smaller increments in ejection fraction with exercise than in normals. One recent study [106] demonstrated an inverse relationship between peak oxygen uptake and age at Fontan operation (particularly in patients with single ventricle of right ventricular morphology). Mahle and associates at the Children's Hospital of Philadelphia undertook an evaluation of the impact of early ventricular unloading on exercise performance in preadolescents with single ventricle and Fontan physiology [107]. Evaluating the exercise stress test results of 46 patients, they concluded that volume unloading at younger age was associated with increased aerobic capacity ($p = 0.003$). Patients who had reduction of ventricular volume work by hemi-Fontan or Fontan procedures before 2 years of age were compared with a group that had successful Fontan operations, but in whom the volume loaded state of the single ventricle had persisted for more than two years. The authors observed better peak exercise capacity in the group which had undergone early volume unloading. Recently, 147 patients (ages 7–18 years) at a median of 8.1 years after Fontan, were evaluated as part of the Pediatric Heart Network cross-sectional study of Fontan survivors. Findings included the observation that physical activity levels were reduced in this patient group, independent of exercise capacity, and were associated with lower perceived general health but not other aspects of functional status [108].

Neurologic Status

As operative survival has improved, emphasis has been appropriately placed on assessment of neurodevelopmental outcome. Uzark and colleagues [109] in San Diego tested 32 patients who had undergone the Fontan procedure and found, on average, normal developmental indices. Goldberg and colleagues [110] at the University of Michigan studied a group of 51 patients who had undergone Fontan operations. They undertook developmental testing, behavior evaluation, and central nervous system imaging. Most of the Fontan survivors evaluated in the study demonstrated intelligence scores within or above the normal range. These patients performed significantly better in areas of verbal intelligence than in nonverbal areas. The diagnosis of hypoplastic left heart syndrome and a history of perioperative seizures were independent risk factors for lower developmental scores. Nearly half the patients who underwent imaging of the central nervous system (magnetic resonance imaging [MRI] or computed tomography [CT]) were demonstrated to have acquired abnormalities, but the authors did not find that significant developmental abnormalities appeared to be related to evidence of central nervous systemic ischemia. An evaluation of 133 patients who had undergone Fontan procedures at Children's Hospital Boston in the 1970s and 1980s [111] revealed that most individual patients had cognitive outcomes and academic function within the normal range, but the performance of the cohort was lower than that of the general population. Importantly, in a review of 645 patients who underwent the Fontan procedures at the same institution, du Plessis and associates [112] found a 2.6% incidence of stroke following the Fontan operation. The risk period for stroke extended from the first postoperative day to 32 months after the Fontan procedure.

Thromboembolic Complications

Thromboembolic events account for significant morbidity and mortality following Fontan procedures. Retrospective studies have reported the incidence of thromboembolic events after Fontan operations ranging from 3% to 20% [113,114]. The time course of these events ranges from 24 hours after surgery to as late as 16 years (Figure 28.15) [115]. Efforts have been made to characterize abnormalities of coagulation that are associated with the post-Fontan state [116,117] but they are hampered in part by lack of age-specific controls. There is general agreement that ligation of the main pulmonary artery leaving a blind pouch or cul-de-sac distal to the pulmonic valve is a worrisome substrate for the occurrence of thromboembolism. Almost every other assertion with regard to thromboembolic events after Fontan's operation is the subject of controversy. As yet, there is a lack of evidence from randomized controlled

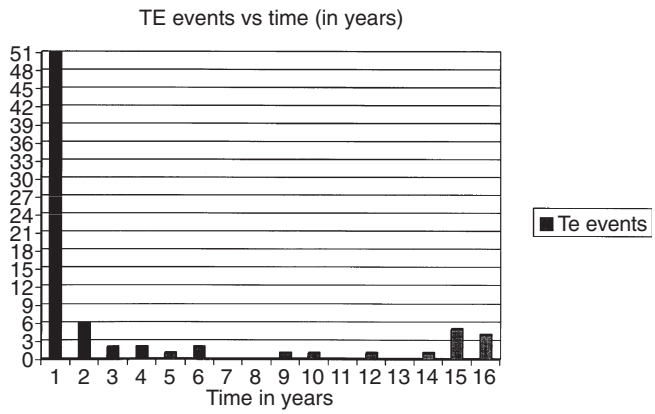

Figure 28.15 Graphic representation of the frequency, over time in years, of thromboembolic events occurring in patients who have undergone Fontan operations. These data are derived from a review by the author of the English language literature on the subject. (TE, thromboembolic.) (Reproduced with permission from Jacobs *et al.* [115].)

trials to support the use of any specific strategy for post-Fontan anticoagulation therapy. In the absence of any compelling evidence to support the routine use of warfarin therapy, the author gives aspirin (81 mg daily) to all Fontan patients beginning on postoperative day one and continuing indefinitely. This strategy combined with operative techniques described above, has resulted in freedom from clinically apparent thromboembolic complications [115]. A recent retrospective study from the University of Michigan found that anticoagulation with aspirin was associated with a statistically significantly decreased risk for cerebrovascular events in Fontan patients [118]. Notwithstanding the lack of evidence of a consistent benefit of warfarin therapy in patients who have undergone Fontan procedures, there are circumstances in which this type of more aggressive anticoagulation is probably warranted in individual patients. These certainly would include instances where there is evidence of pathway obstruction, low cardiac output, and chronic or recurrent arrhythmias [119].

Systemic Ventricular Outflow Tract Obstruction

Subaortic obstruction is a frequent accompaniment of single ventricle anatomy. It occurs most often when the aorta arises from an outlet chamber that is connected to the dominant ventricle by a bulboventricular foramen or ventricular septal defect. This connection may be restrictive of flow at birth, or may become obstructive after surgical procedures that reduce the volume work of the ventricle [27]. This phenomenon impacts on the management of patients with functional single ventricle at many stages. In neonates, significant systemic ventricular outflow obstruction is often associated with aortic arch hypoplasia. With

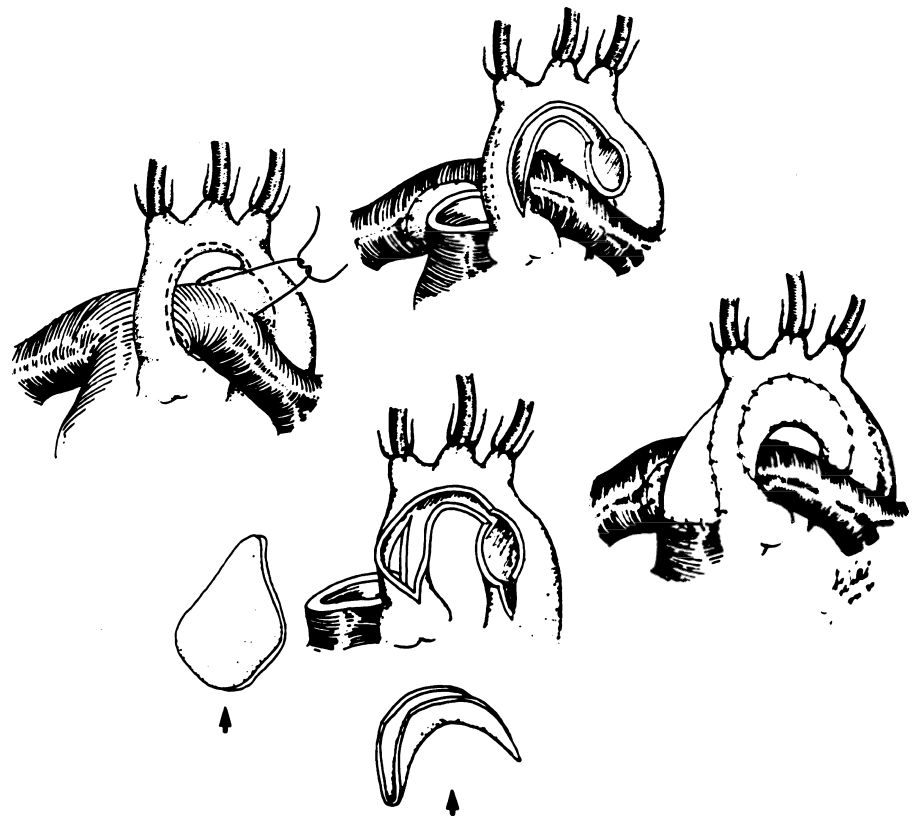

Figure 28.16 Artist's illustration of the surgical management of subaortic stenosis (systemic ventricular outflow tract obstruction) in a neonate with functional single ventricle. The case illustrated is of double-inlet left ventricle with L-transposition of the great arteries and significant aortic arch hypoplasia. Under hypothermic circulatory arrest, the aortic arch is augmented with a gusset of cryopreserved pulmonary artery homograft tissue. A separate homograft patch is used to augment the side-to-side amalgamation of the transected main pulmonary trunk with the ascending aorta. A systemic-to-pulmonary artery shunt is constructed (not shown in the illustration), completing a stage I Norwood palliative procedure. (Reproduced with permission from Jacobs *et al.* [122].)

parallel pulmonary and systemic circulations, and particularly when there is a patent arterial duct, it is difficult to quantitate subaortic obstruction. In the setting of ventriculoarterial discordance, the potential for development of systemic ventricular outflow obstruction must be presumed, even if it is not readily apparent. Thus it must be considered in planning initial palliation. For some time, it has been recognized that pulmonary artery banding is associated with a tendency for subaortic obstruction to progress [120]. Thus, this technically simple means of palliation must be considered carefully when there is anatomic substrate for systemic ventricular outflow obstruction. Appropriate alternatives are the performance of a stage 1 Norwood procedure or palliative arterial switch as the initial operation. Apical ventricular to aortic conduits or direct relief of subaortic obstruction are less desirable strategies. If systemic ventricular outflow obstruction is not addressed definitively at the time of initial palliation, it may progress with important consequences at any stage during the sequence of reconstructive procedures or may develop after a completed Fontan operation [121]. This fact, together with the known deleterious effects of systemic ventricular outflow obstruction and the associated secondary myocardial changes on the function of the single ventricle, suggests that an optimal strategy for dealing with subaortic obstruction in single ventricle hearts is simply to prevent it. Thus, if present in the neonate, subaortic stenosis is best managed by amalgamation of the proximal main pulmonary artery with the ascending aorta and relief of arch obstruction (Figure 28.16) [122–124]. Alternatively, the same goal can be achieved by a palliative arterial switch operation and arch repair (Figure 28.17) [125–127]. In hearts where subaortic obstruction was not important or apparent at initial presentation but where the potential for its development exists (i.e. ventriculoarterial discordance or subaortic conus), it is advisable to address the issue by means of a pulmonary artery to aortic anastomosis (Damus-Kaye-Stansel procedure) at the time of the hemi-Fontan or bidirectional Glenn anastomosis. If these guidelines are followed, only rarely will a direct ventricular approach to relief of subaortic stenosis be required, and the adverse impact of myocardial hypertrophy on outcome of Fontan's operation should be effectively neutralized by prevention.

Rhythm Disturbances

Both tachyarrhythmias and bradyrhythmias complicate the course and management of patients who undergo Fontan operations. Though not completely understood, they are thought to be consequences of 1) injury to the sinoatrial node or its blood supply, 2) extensive atrial incisions and

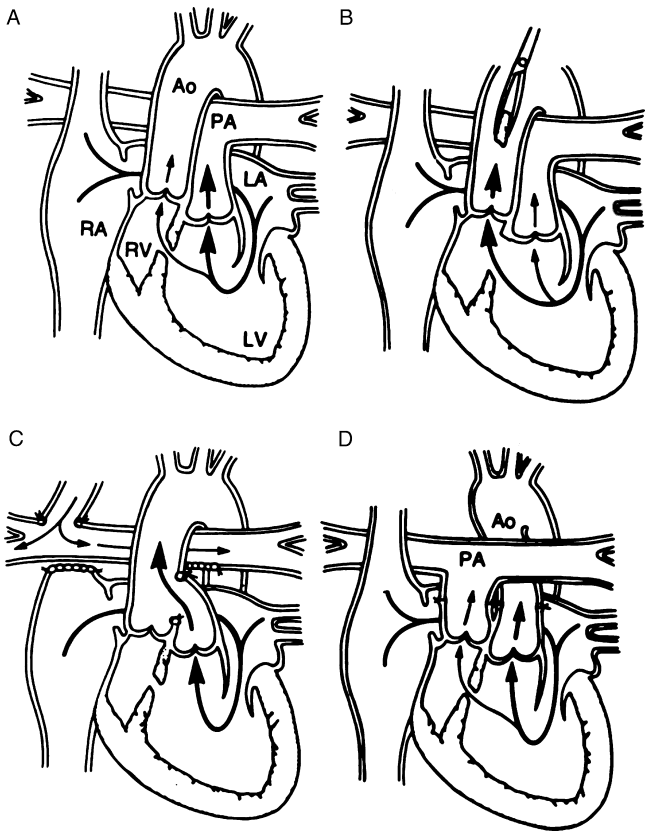

Figure 28.17 Methods of treatment of subaortic stenosis in hearts with functional single ventricle. **A,** Anatomy of type IIc tricuspid atresia with significant subaortic stenosis. **B,** Direct resection of myocardium with ventricular septal defect enlargement. **C,** Damus-Kaye-Stansel operation, main pulmonary artery-to-ascending aortic anastomosis. **D,** Palliative arterial switch operation. (Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.)

sutures lines, and 3) chronic exposure of atrial myocardium to elevated pressure. In some instances, they are directly related to the underlying anatomic substrate (as in hearts with atrioventricular discordance or heterotaxy with intrinsic abnormalities of the conduction system) or to hemodynamic factors such as atrioventricular valve regurgitation. Analysis of risk factors for the development of tachyarrhythmias after Fontan operations support these hypotheses. A study of nearly 500 patients who underwent modified Fontan operations at the Mayo Clinic between 1985 and 1993 [128] revealed the following risk factors for supraventricular tachyarrhythmias: atrioventricular valve regurgitation, abnormal atrioventricular valve, preoperative supraventricular tachyarrhythmias, and age at operation. The type of Fontan connection was not strongly predictive, though the frequency of supraventricular tachyarrhythmias was slightly lower in patients with an atrial pulmonary connection with lateral tunnel then those with TCPC. In a study from the Children's Hospital Boston of 334 early survivors of Fontan operations done between 1973 and 1991 [129], atrial flutter was identified in 54 patients (16%) at a mean 5.3 ± 4.7 years (range 0–19.7 years). Atrial flutter developed sooner and was more likely to occur in patients who were older at the time of Fontan operation. The presence of sinus node dysfunction was associated with a higher incidence of atrial flutter. While there was a lower prevalence of atrial flutter in patients with a TCPC, the follow-up for that group was shorter. Analysis of a smaller series of Fontan patients by Paul and associates [130] in Hannover, Germany also revealed a lower risk of supraventricular tachyarrhythmias with TCPC as compared with atrial pulmonary connection.

Strategies to minimize the risk of post-Fontan arrhythmias include technical modifications that minimize the likelihood of injury to the sinus node and its blood supply, minimization of atrial incisions and sutures line (particularly in the region of the sulcus terminalis), and early interventions against atrioventricular valve regurgitation. It is not yet absolutely clear whether the TCPC using lateral atrial tunnel technique is superior to atrial pulmonary connection with regard to the risk of arrhythmias, though increasing evidence suggests that this is the case. Proponents of the extracardiac conduit type of TCPC suggested the potential advantage of avoiding incisions and suture lines in the region of the sinus node and its blood supply and predicted a lower frequency of postoperative arrhythmias. However, at least one study comparing the incidence of early sinus node dysfunction between groups of Fontan patients who had either lateral atrial tunnel or extracardiac conduit types of completion Fontan procedures, found no discernible difference in the incidence of early postoperative sinus node dysfunction [131]. Options for management of recurrent or persistent postoperative arrhythmias following Fontan procedures include 1) pharmacologic antiarrhythmic therapy, 2) permanent pacing to address sinus node dysfunction and potentially minimize the likelihood of tachyarrhythmias, and 3) in selected instances conversion from atrial pulmonary connections to TCPC of the lateral tunnel or extracardiac Fontan type [132]. The most aggressive and most productive approach has combined conversion to TCPC, atrial reduction, modified maze-type procedure, and permanent pacing (Figure 28.18) [76, 133,134]. At the 2007 meeting of the Society of Thoracic Surgeons, Mavroudis *et al.* presented a series of 111 consecutive Fontan conversions with arrhythmia surgery and pacemaker therapy [135]. There were one early (0.9%) and six late deaths (5.4%); six patients required cardiac transplantation (5.4%). Two late deaths occurred after transplantation. Four risk factors for death or transplantation were identified: presence of a right or ambiguous ventricle, pre-

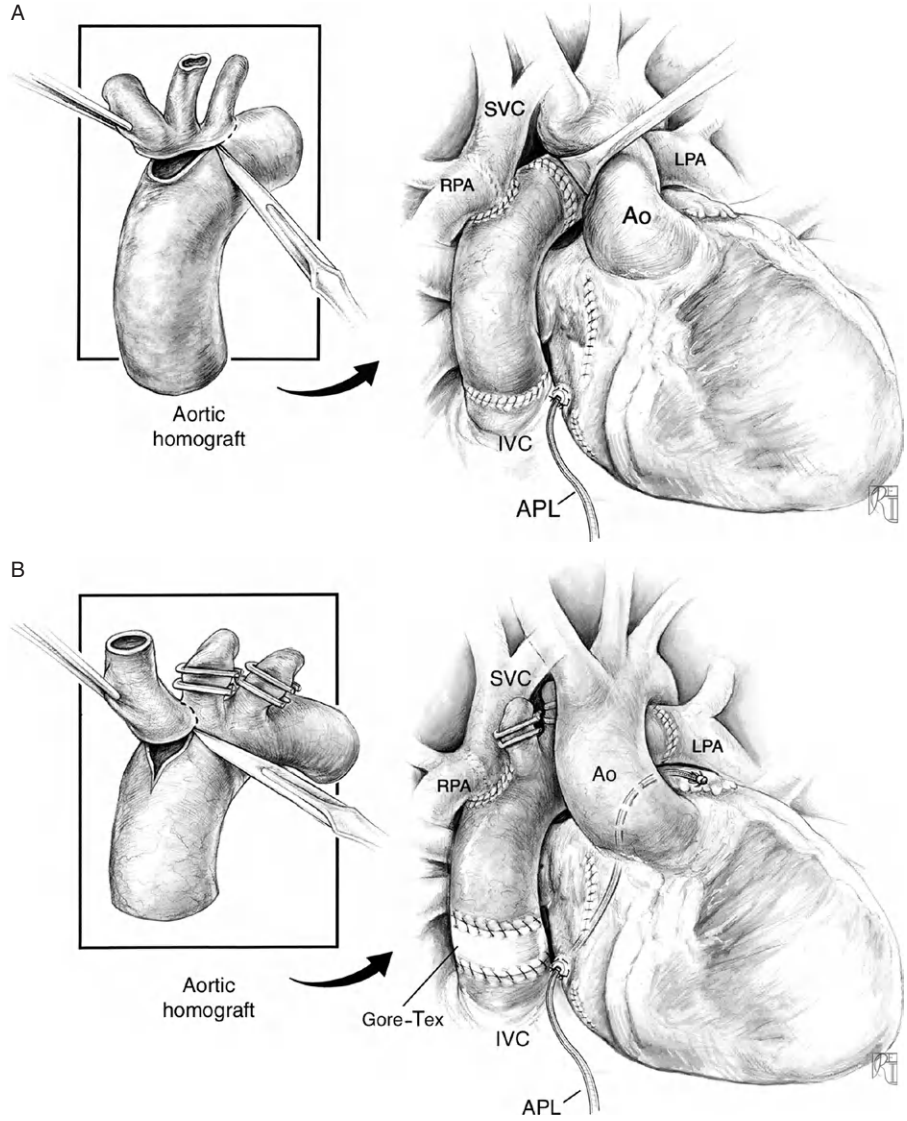

Figure 28.18 Original artist's drawing of a Fontan revision in an adult patient with double-inlet left ventricle who had undergone previous classic right-sided Glenn anastomosis and interposition of a valved conduit between the right atrium and left pulmonary artery. In addition to conduit obstruction, the patient developed right lung pulmonary arteriovenous fistulas and right pulmonary vein obstruction as a consequence of right atrial enlargement. The operative conversion results in total extracardiac cavopulmonary connection, using an aortic homograft conduit to connect the inferior vena cava and the Glenn anastomosis and the distal left pulmonary artery. (Mavroudis *et al.* currently recommend use of a polytetrafluoroethylene conduit in place of the aortic homograft conduit). The procedure described by Mavroudis and associates also includes a modified maze antiarrhythmic procedure, combined with permanent pacing. (Ao, aorta; APL, antitachycardia pacemaker lead; IVC, inferior vena cava; LPA, left pulmonary artery; RPA, right pulmonary artery; SVC, superior vena cava.) (Reproduced with permission from Mavroudis *et al.* [133].)

operative protein-losing enteropathy (PLE), preoperative moderate-to-severe atrioventricular valve regurgitation, and long (>239 minutes) cardiopulmonary bypass time. Evidence supported performance of biatrial maze procedures in patients with history of left atrial re-entry tachycardia or atrial fibrillation.

Protein-Losing Enteropathy

Protein-losing enteropathy is a syndrome characterized by excessive loss of serum proteins into the intestinal lumen. Manifestations include edema, immunodeficiency from hypogammaglobulinemia, malabsorption of fat, intestinal lymphocyte loss, hypercoagulopathy from loss of clotting factors, and electrolyte disorders including hypocalcemia and hypomagnesemia. Protein-losing enteropathy is known to occur with certain primary gastrointestinal disorders, abnormalities of gut lymphatic drainage, and certain cardiovascular disorders. After Fontan operations, the incidence of PLE has been estimated to be as high as 13.4% [136] though the prevalence in an international multicenter study was 3.7% [137]. The time to onset after Fontan operation is quite variable. Survival after the diagnosis of PLE is poor, with 50% of patients dying within 5 years of diagnosis and 80% within 10 years.

The pathophysiology of PLE is not clear. While Fontan patients share the common feature of elevated central venous pressure with other cardiac patients known to be at risk for PLE (constrictive pericarditis, tricuspid regurgitation, inferior vena caval obstruction), PLE has been known to occur in Fontan patients with generally very

satisfactory hemodynamics (low venous pressure) and is not an invariable accompaniment of failing Fontan circulation with markedly elevated venous pressure. A relationship between PLE and altered portal venous blood flow after the Fontan operation has also been proposed [138]. A general hypothesis holds that PLE after Fontan operation is related to low cardiac output and low flow states, which may result in increased mesenteric vascular resistance leading to altered intestinal mucosal function. A similar process with a break in mucosal integrity to protein loss can occur at the bronchial mucosal level, with leakage of proteinaceous material into the airways resulting in bronchial casts or plastic bronchitis. This rare complication also occurs in a small number of patients after the Fontan operation. While PLE is associated with a high rate of mortality, certain interventions appear to have merit in selected cases. All Fontan patients with PLE or plastic bronchitis should undergo full hemodynamic evaluation including catheterization. Adverse anatomic and hemodynamic factors including pathway obstruction, atrioventricular valve regurgitation, and systemic ventricular outflow obstruction must be addressed. Beyond this, fenestration of the atrial septum or venous pathway by surgical means [139] or catheter techniques [140] has been reported to result in resolution of some cases of PLE, though at the expense of arterial desaturation. When PLE has occurred in patients with significant sinus node dysfunction, pacing has reportedly been associated with improvement [141]. Medical therapy with either corticosteroids or heparin has been used with some success. Currently, there is cautious optimism that another form of medical therapy may benefit Fontan patients with PLE. The drug sildenafil, a phosphodiesterase 5 inhibitor, leads to increased cellular levels of cyclic guanosine monophosphate and causes vasodilation. Extensive experience has proven sildenafil to be effective treatment in children and adults with pulmonary hypertension. Although experience in the single ventricle population is limited, it has been postulated that sildenafil may lower pulmonary vascular resistance and improve forward flow through the pulmonary circuit, thus increasing cardiac output in Fontan patients. Thus far sildenafil has been shown to contribute to the resolution of PLE and plastic bronchitis in case reports and to improve exercise performance in patients after Fontan operation following a single dose [142]. Ultimately, in patients with PLE refractory to all of these measures, heart transplantation may represent the only therapeutic alternative.

Conclusion

For the vast majority of patients with functionally univentricular hearts, some modification of Fontan's operation represents, at the present time, the best form of surgical reconstruction. The role of septation is difficult to assess, particularly because it is applicable to a select minority of patients. The evolution over three decades from Fontan's and Kreutzer's initial corrective operations for tricuspid atresia to the current forms of surgical management has been associated with progressive decline in the risk of operative mortality. Though the body of knowledge concerning functionally univentricular heart patients and strategies for management culminating in a Fontan connection has become vast, many questions remain unanswered. Perhaps most important of these is the issue of whether or not the late phase risk of premature death after an "ideal Fontan operation" identified two decades ago by Fontan and Kirklin is in fact inevitable. Current research is focused on means of increasing the durability and extending the longevity of the Fontan circulation for patients with functionally univentricular hearts and physiology.

CHAPTER 29

Ebstein Anomaly

Morgan L. Brown and Joseph A. Dearani
Mayo Clinic, Rochester, MN, USA

Anatomy

Dr. Wilhelm Ebstein, a young Polish physician, described the cardiac findings of a 19-year-old man who had died of cyanotic heart disease in 1866 [1]. Ebstein described the characteristic anatomical findings in this anomaly, as well as the hemodynamic abnormalities, and correctly correlated them with the patient's signs and symptoms.

Ebstein anomaly is a malformation of the tricuspid valve and right ventricle that is characterized by a spectrum of several features (Table 29.1). Ebstein anomaly is a myopathy of the right ventricle that results in variable degrees of "failure of delamination" of the tricuspid valve leaflets from the underlying endocardium. The tricuspid leaflets are usually bizarre, dysplastic, and may be muscularized. The abnormal leaflets are often tethered by shortened chordae, and papillary muscle(s) may directly insert into the leading edge of the leaflet(s). Chordae may be few to absent, and leaflet fenestrations are common. As the severity of Ebstein anomaly increases, the fibrous transformation of leaflets from their muscular precursors remains incomplete, with the septal leaflet being the most severely involved (i.e., most nondelaminated) and the anterior leaflet being the least severely involved (i.e., most delaminated, having greatest mobility). This results in a downward displacement of the hinge point (functional annulus) of the posterior and septal leaflets in a spiral fashion below the true tricuspid annulus. There are varying degrees of delamination of all three leaflets, resulting in infinite variability from one patient to another. Although the anterior leaflet is most likely to have the greatest degree of delamination, it can also be severely deformed so that the only mobile leaflet tissue is displaced toward the right ventricular outflow tract. The malformed tricuspid valve is usually incompetent and rarely stenotic.

The atrialized right ventricle can vary in its thickness and in its ability to contract. Infrequently, it can have near normal thickness and show evidence of contraction by echocardiography or magnetic resonance imaging (MRI). More often, it is thinned, dyskinetic, and dilated. In general, the entire free wall of the right ventricle, both proximal and distal to the abnormal insertion of the tricuspid leaflets, including the infundibulum, is also dilated. Dilatation of the right ventricular free wall is associated not only with thinning of the wall, but also with an absolute decrease in the number of myocardial fibers [2]. The atrioventricular node is located at the apex of the triangle of Koch, and the conduction system is in its normal position. Atrial septal defect (ASD) is the most common associated anomaly and other cardiac defects (e.g., ventricular septal defect, patent ductus arteriosus, or pulmonary stenosis) anomalies may also be present.

In those congenital cardiac anomalies in which there is situs solitus and atrioventricular discordance with ventriculoarterial discordance (corrected transposition), Ebstein anomaly of the left-sided (systemic, morphologically tricuspid) atrioventricular valve may be present. The remainder of this chapter focuses on the classic right-sided Ebstein anomaly.

Physiology

Forward flow of blood through the right side of the heart is retarded because of the functional impairment of the right ventricle and the incompetence of the deformed tricuspid valve. Moreover, during contraction of the right atrium, the atrialized portion of the right ventricle that is in continuity with the right atrium, distends or acts as a passive reservoir, thus decreasing the volume of right ventricular blood ejected. During ventricular systole, the atrialized right ventricle contracts, creating a pressure wave that impedes venous filling of the right atrium, which is in the diastolic phase. In the majority of cases, there is a communication between the left and right atria, either because of

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

patency of the foramen ovale or a distinct secundum ASD. The shunt of blood through the septal opening is generally from right to left but may be bidirectional. The overall effect of these structural abnormalities on the right atrium is to produce gross dilatation, which may reach enormous proportions, even in infancy. This dilatation leads to further incompetence of the tricuspid valve and further widening of the interatrial communication.

As a consequence of atrial dilatation, atrial tachyarrhythmias are common. In addition, approximately 15% of patients will have one or more accessory conduction pathways associated with Wolff-Parkinson-White syndrome, and 1–2% of patients will have atrioventricular nodal reentrant tachycardia (AVNRT) [3,4]. In end-stage heart failure, ventricular arrhythmias may be present.

Table 29.1 Anatomical features of the spectrum of Ebstein anomaly.

Adherence of the tricuspid leaflets to the underlying myocardium (failure of delamination)
Downward (apical) displacement of the functional annulus (septal > posterior > anterior)
Dilation of the "atrialized" portion of the right ventricle with variable degrees of hypertrophy and thinning of the wall
Redundancy, fenestrations, and tethering of the anterior leaflet
Dilation of the right atrioventricular junction (true tricuspid annulus)

The Neonate

Presentation and Diagnosis

In the newborn period, any degree of tricuspid regurgitation is accentuated by the normally occurring elevated pulmonary arteriolar resistance. As a result, neonates with Ebstein anomaly may develop severe right-sided heart failure and cyanosis. Severe tricuspid regurgitation results in elevated right atrial pressures and may result in profound right-to-left atrial shunt across the patent foramen ovale. Low cardiac output may also result from paradoxical motion of the septum or malposition of the interventricular septum because of the enlarged right ventricle. If the neonate survives this critical period, the degree of cyanosis and of heart failure may diminish as fetal pulmonary hypertension regresses.

In the neonatal period, decreasing pulmonary vascular resistance with pulmonary vasodilators may be helpful to unload the right ventricle, promote antegrade blood flow into the lungs, and improve right ventricular function. In some cases, a large patent ductus arteriosus may allow a circular shunt, where blood flows from the aorta into the patent ductus arteriosus, to the right ventricle, to the right atrium, to the left atrium, and then to the left ventricle [5]. If this circular shunt occurs, administration of prostaglandins should be stopped to allow ductal closure.

Chest X-ray typically demonstrates profound cardiomegaly (Figure 29.1). Echocardiography remains the standard for establishing the diagnosis. The tricuspid valve should

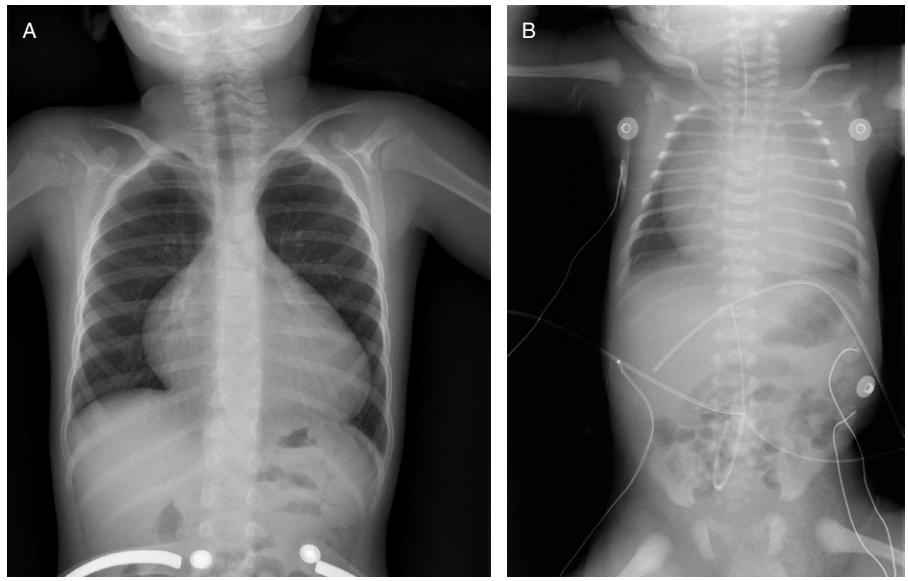

Figure 29.1 These two chest films demonstrate the characteristic cardiac silhouette in Ebstein anomaly and the extreme cardiac enlargement. **A,** Child age 4 years. This child had oxygen saturations between 50% and 90%, headaches, and episodes of supraventricular tachycardia. **B,** Neonate on the first day of life. This baby required immediate intubation, nitric oxide, and prostaglandin infusion to maintain adequate oxygenation.

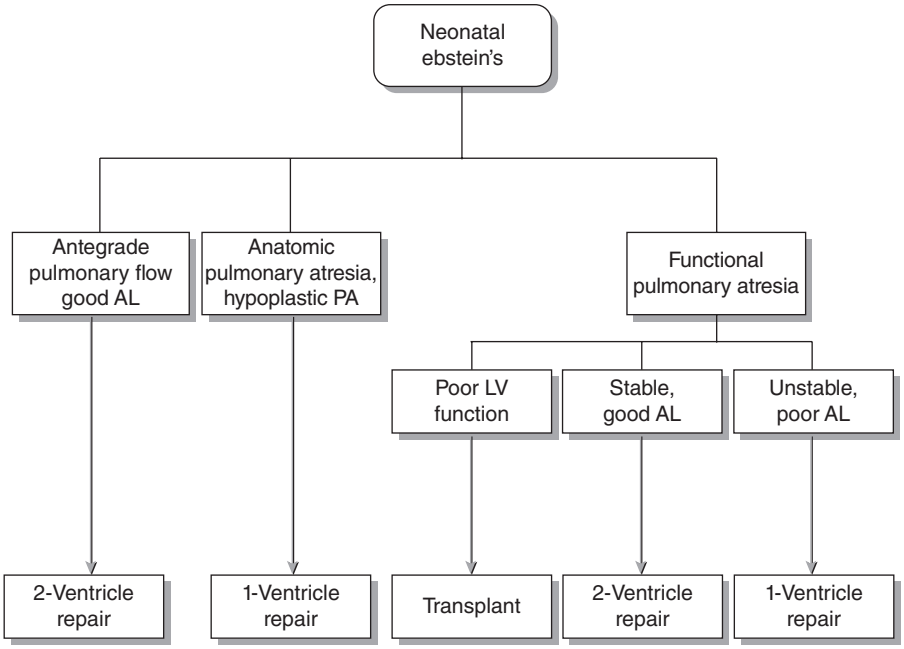

Figure 29.2 This simplified algorithm provides a guideline for decision-making with the symptomatic neonate with Ebstein anomaly. A good anterior leaflet for potential monocusp repair is large, sail-like, and mobile. (AL, anterior leaflet; LV, left ventricle; PA, pulmonary arteries.) (Reproduced with permission from Knott-Craig *et al.* [11].)

be thoroughly assessed, and the Great Ormond Street Ebstein Score (GOSE score) calculated [6]. The GOSE score, as described by Celermajer, is calculated in the four-chamber view to create a ratio of the combined areas of the right atrium and atrialized right ventricle compared to the functional right ventricle, left atrial, and the left ventricular areas.

It is important that the right ventricular outflow tract be completely visualized to ascertain whether there is "anatomic" or "functional" pulmonary atresia. Functional pulmonary atresia refers to a setting of severe tricuspid regurgitation and right ventricular dysfunction, with reduced or absent antegrade blood flow across a normal anatomic pulmonary valve. Any degree of anatomic right ventricular outflow tract obstruction (RVOTO; infundibulum, pulmonary valve, or branch pulmonary arteries) is a risk factor for both early and late mortality [7]. Differentiating functional from anatomic pulmonary atresia in the neonatal period may be difficult, and the administration of nitric oxide or sildenafil at the time of echocardiography may be useful to decrease pulmonary vascular resistance, allowing forward blood flow into the lungs in cases of functional pulmonary atresia.

Indications for Surgery

In neonates or infants who remain in congestive heart failure or profoundly cyanotic with appropriate medical therapy, surgery is required. Asymptomatic neonates who have a GOSE score of 3 or 4 or symptomatic neonates with a GOSE score of 3 or 4, mild cyanosis, a cardiothoracic ratio of more than 0.80, or severe tricuspid regurgitation are other indications for surgery [8]. There are three potential treatment pathways that can be considered in the neonate: the biventricular repair (Knott-Craig approach), single ventricle repair (i.e., right ventricular exclusion technique [Starnes approach]), or cardiac transplantation (Figure 29.2) [9–11].

Surgical Strategies

One approach to repair of neonatal or infant Ebstein anomaly is the biventricular strategy that has been described by Knott-Craig [8,10–12]. In this method, there is subtotal closure of the ASD and repair of the tricuspid valve. Multiple tricuspid valve repair methods have been described to improve the chance of successful valve competency, but they depend on having a mobilizable anterior leaflet. The Knott-Craig technique is generally a monocusp repair based on a satisfactory anterior leaflet (Figure 29.3) [12]. The incomplete closure of the ASD allows for right-to-left shunting that may be helpful in the early postoperative period when there is high risk of right ventricular dysfunction and elevated pulmonary vascular resistance. In order to reduce the heart size and allow for lung development, generous right atrial reduction is performed routinely.

Starnes has pioneered the right ventricular exclusion approach. In this univentricular strategy, the tricuspid

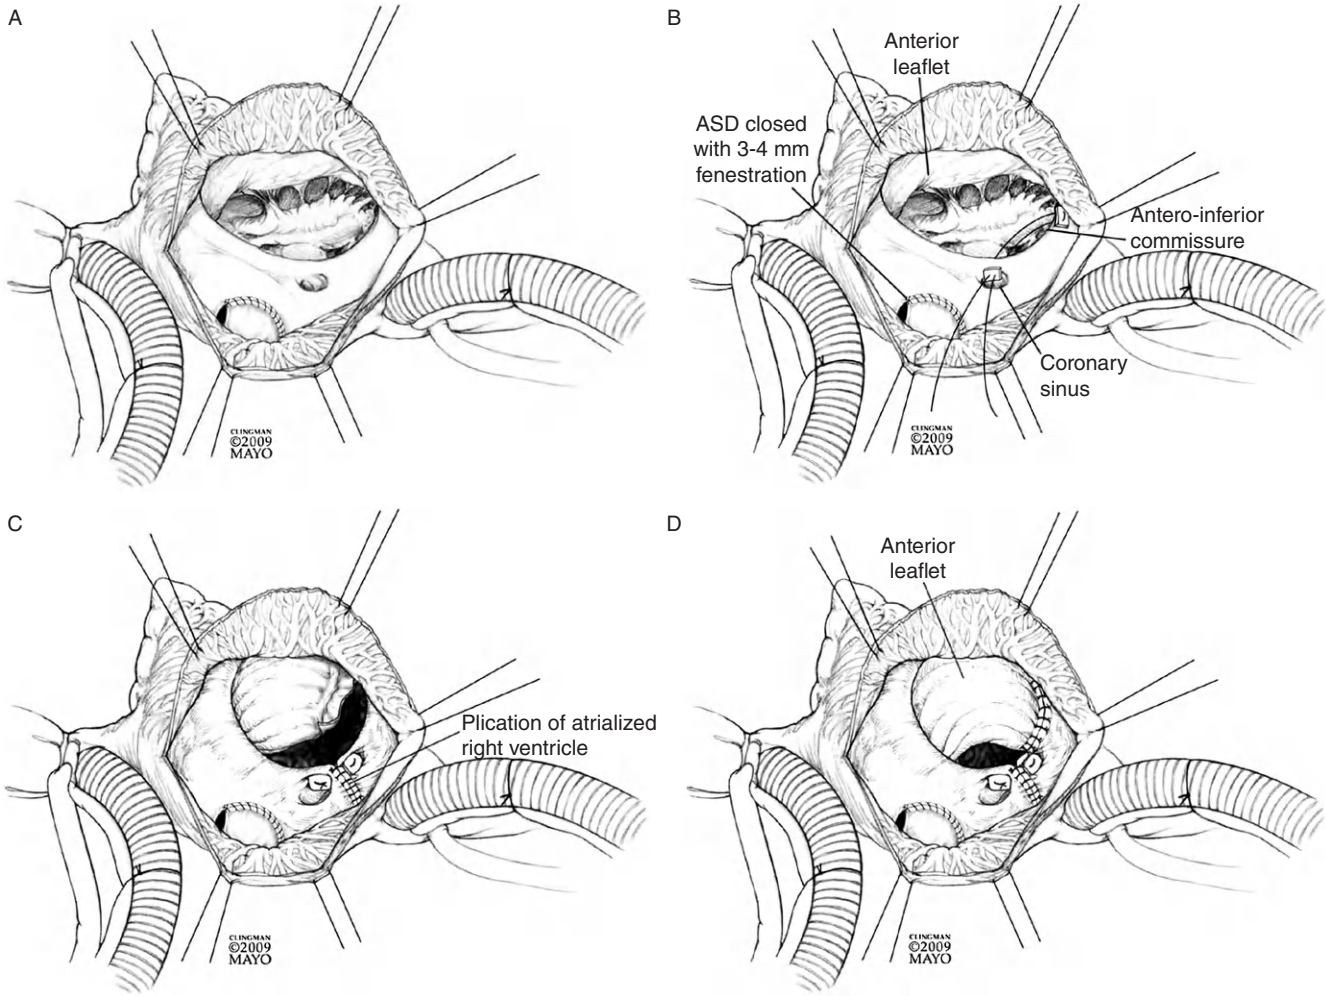

Figure 29.3 A, In the biventricular Knott-Craig repair [12], the tricuspid valve is repaired creating a monocusp valve. If the anterior leaflet leading edge is fused to the free wall of the right ventricle, it must be delaminated to allow for free movement of the anterior leaflet. A pledgeted suture may be placed through the dominant papillary muscle of the anterior leaflet and brought to the interventricular septum at the site of the laminated septal leaflet (Sebening stitch). This maneuver will maintain apposition of the free wall of the right ventricle and the anterior leaflet to the posterior aspect of the tricuspid annulus and may provide durability to the repair (not shown). **B,** When the annulus is very dilated (>20 mm), a pledgeted suture is placed at the antero-inferior commissure through the medial wall of the coronary sinus. This will reduce the size of the tricuspid valve annulus. **C,** The tricuspid valve orifice is reduced in size and the anterior leaflet is detached from its annulus. **D,** The anterior leaflet is rotated clockwise and reattached to create a monocusp repair. Plication of the atrialized right ventricle completes the tricuspid valve repair. A functional orifice of approximately 13 mm is generally considered adequate. The atrial septal defect has been subtotally closed, leaving a 3 mm residual defect or fenestration. (Copyright © 2009 Mayo Foundation for Medical Education and Research.)

valve orifice is patched closed, the interatrial communication is enlarged, and a systemic-to-pulmonary artery shunt is placed [13–16]. This approach is particularly appealing in those patients who have anatomic RVOTO or an abnormal anterior leaflet that would preclude a successful valve repair. Right ventricular decompression of thebesian venous drainage is facilitated by placing a small fenestration (4–5 mm punch) in the tricuspid valve patch (Figure 29.4) [15]. This also allows progressive involution of the enlarged, dysfunctional right ventricle, which is helpful in the long term while preparing for the eventual Fontan procedure. In patients who have a patent right ventricular outflow tract, a competent pulmonary valve is required to prevent blood from entering the right ventricle, resulting in distension. If an incompetent pulmonary valve is present, the main pulmonary artery should be ligated or oversewn. These maneuvers are important to avoid persistent dilatation of a poorly functioning right ventricle that can com-

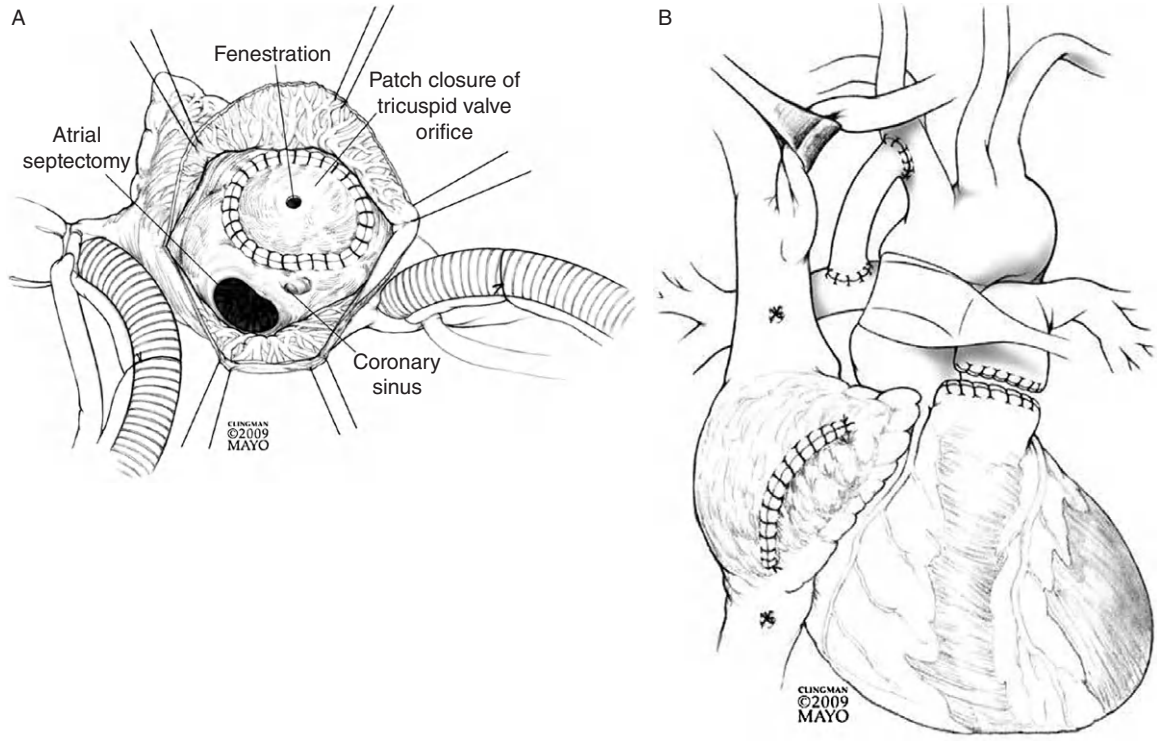

Figure 29.4 A, In the Starnes approach to neonatal Ebstein anomaly [15], fixed autologous pericardium is sewn to the anatomic annulus (at the atrioventricular groove) using a running suture. Careful examination of the surface of the right ventricular myocardium is needed to ensure no distortion of the right coronary artery. A 4-mm fenestration of the patch is performed, which allows for decompression of the right ventricle. **B,** If the pulmonary valve is competent, the pulmonary artery is divided and the valve is oversewn. If the pulmonary artery is small, a single hemoclip may be applied. Pulmonary blood flow is provided by a systemic to pulmonary artery shunt. In this illustration, a 3.5-mm Gore-Tex shunt connects the innominate artery to the right pulmonary artery. (Copyright © 2009 Mayo Foundation for Medical Education and Research.)

promise and impair left (systemic) ventricular function in the eventual Fontan circulation. Right atrial reduction is also routinely performed to allow space for the lung development.

Sano proposed a modification to the Starnes single ventricle approach. Total right ventricular exclusion is performed in which the free wall of the right ventricle is resected and closed primarily or with a polytetrafluoroethylene patch [17]. This procedure acts like a large right ventricular plication. This adaptation of the Starnes method may improve left ventricular filling, as well as provide decompression to the lungs and left ventricle.

In the most severe cases of Ebstein anomaly, heart transplantation remains an option, but is rarely necessary in the current era given the improved early results with the Knott-Craig and Starnes approaches. Limitations of heart transplantation include the scarcity of donor organs in the neonatal age group and the adverse effects of long-term immunosuppression and its associated complications in the transplant recipient. Finally, the development of smaller ventricular assist devices and advances in extracorporeal membrane oxygenation have provided mechanical support options in the perioperative period for the management of these challenging infants [18–20].

Children and Adults

Presentation and Diagnosis

In children, symptoms include fatigue, decreased exercise tolerance, dyspnea on exertion, and cyanosis. Palpitations because of paroxysmal atrial arrhythmias and premature ventricular beats are common and increase with age. A systolic murmur of tricuspid regurgitation may be heard along the left sternal border or may be absent. Low-intensity diastolic and presystolic murmurs, which result from anatomical or functional tricuspid stenosis (occurs rarely), may be present. There is wide splitting of both the first and second heart sounds. Atrial and ventricular filling sounds are relatively common and contribute to the cadence quality that is so often found in patients with Ebstein anomaly. The arterial and jugular venous pulse forms are usually normal. A large V wave may be seen in the jugular venous pulse. The liver may be palpably enlarged, but

ascites and peripheral edema are generally not common; when present, advanced right-sided heart failure is present.

The electrocardiogram is usually abnormal, but it is not diagnostic. Complete or incomplete right bundle branch block and right-axis deviation are typically present; atrial arrhythmias are common, particularly in older patients. On chest X-ray, the cardiac silhouette may vary from almost normal to the typical Ebstein configuration, which consists of a globular-shaped heart with a narrow waist (pedicle), similar to that seen with pericardial effusion. This appearance is produced by enlargement of the right atrium and displacement of the right ventricular outflow tract outward and upward. Vascularity of the pulmonary fields is either normal or decreased.

Echocardiography allows an accurate evaluation of the tricuspid leaflets and its subvalvar apparatus, the right atrium, the atrialized portion of the right ventricle, and the right and left ventricles (Table 29.2). Doppler echocardiography and color-flow imaging allow detection of an ASD and the direction of shunt flow. The principle echocardiographic characteristic that differentiates Ebstein anomaly from other forms of congenital tricuspid regurgitation is the degree of apical displacement of the septal leaflet at the crux of the heart ($\geq 0.8\,cm/m^2$; Plate 29.1, see plate section opposite p. 594) [21]. Other features that are usually present are fibrous and/or muscular attachments between the body of the tricuspid leaflet(s) and the underlying myocardium (i.e., failure of delamination). The most useful view for the surgeon is the four-chamber view. This outlines the degree of delamination (amount of attachments between the annulus and apex) of the anterior, inferior (to a lesser degree), and septal leaflets and indicates mobility of the leading edges. Echocardiographic factors that are favorable for valve repair include a large, mobile anterior leaflet with few free wall attachments and a free leading edge. Significant adherence of the edge or body of the leaflet to underlying endocardium (i.e., leaflet tethering) and tricuspid valve leaflet tissue present in the right ventricular outflow tract make successful valve repair more difficult. Any delamination of inferior leaflet tissue is helpful, and the more septal leaflet tissue present, the more likely a successful valve repair (especially a cone-type repair) can be realized. More recently, we have been using three-dimensional echocardiography to help delineate anatomic details of the abnormal tricuspid valve leaflets and the subvalvar apparatus. Further experience is required to determine the role of three-dimensional echocardiography in Ebstein anomaly.

MRI is being increasingly used in all types of patients with cardiac disease, including those with Ebstein anomaly. Quantitative assessment can be made of left and right ventricular size and function. Notably, however, there is little information available in the literature to guide therapy on the basis of this new imaging modality. We routinely perform MRI examination preoperatively and postoperatively to evaluate right ventricular size and function and also so that we can better understand what the other potential roles of MRI are in the evaluation of patients with Ebstein anomaly. At the present time, we prefer echocardiography for evaluation of tricuspid valve anatomy and MRI examination for assessment of right (and left) ventricular size and function.

Table 29.2 Echocardiographic information required by a surgeon. (AV, atrioventricular; RVOT, right ventricular outflow tract; RVOTO, right ventricular outflow tract obstruction.)

Echocardiographic variable	Description
Tricuspid valve regurgitation	Degree of tricuspid regurgitation Number of jets; location in relation to AV groove, and RVOT
Tricuspid valve leaflet anatomy	Degree of delamination – sites of adherence from AV groove to apex Fenestrations Status of leaflet edges and presence of linear attachment How much septal leaflet Unsupported segments
Tricuspid valve annulus dilatation	Size of annulus
Right ventricle and atrialized right ventricle	Size and function
Ventricular septum	Function, position, and motion
Left ventricular function	Size, function, and shape (D-shaped)
Right atrium	Size
Atrial septum	Presence of atrial septal defects and the shunt direction
Other cardiac anatomy	Rule out presence of RVOTO and left-sided valvular disease

In general, satisfactory anatomical and functional information can be obtained by echocardiography and MRI so that cardiac catheterization and angiography are usually not necessary. Hemodynamic catheterization may be occasionally required when there is left ventricular dysfunction in order to measure left- and right-sided pressures, especially if a bidirectional cavopulmonary shunt is being considered (see One-and-a-half ventricle approach), or in the case of a single ventricle pathway, before the modified Fontan procedure is performed.

Atrial and ventricular arrhythmias are common in patients with Ebstein anomaly; they often present therapeutic challenges and may experience sudden death, a common mode of late mortality. Twenty-four-hour ambulatory electrocardiographic monitoring is suggested for rhythm assessment in patients with palpitations or tachycardia. Invasive electrophysiologic study is performed for all patients with Ebstein anomaly who have pre-excitation on their electrocardiogram or who have a history of recurrent supraventricular tachycardia, undefined wide-complex tachycardia, or syncope as aspects of their clinical presentation [3,4].

Indications for Surgery

Although medical management, including diuretics and antiarrhythmic drugs, may be used to manage some of the symptoms of heart failure and arrhythmias, most patients eventually require surgery. Observation alone may be considered for asymptomatic patients with no right-to-left shunting, mild cardiomegaly, and normal exercise tolerance. Many patients in New York Heart Association (NYHA) classes I and II can be managed medically. Surgery is offered when symptoms or cyanosis are present, decreased exercise tolerance is noted on formal exercise testing, or if paradoxical embolism occurs. Surgery is also advised if there is progressive increase in heart size on chest X-ray, progressive right ventricular dilatation or reduction of systolic function by echocardiography, or appearance of atrial or ventricular arrhythmias. In borderline situations, the echocardiographic determination of high probability of tricuspid valve repair makes the decision to proceed with earlier surgery easier. When anatomy is appropriate for a cone repair, we are now advising surgery between 2 and 5 years of age, particularly when any degree of right ventricular dilatation is present. Once symptoms develop and patients progress to NYHA class III or IV, medical management has little to offer; surgery then becomes the only chance for improvement.

Surgical Strategies

A biventricular repair is possible for the vast majority of patients beyond the period of infancy. In some circumstances, a one-and-a-half ventricle (addition of a bidirectional cavopulmonary shunt) is advantageous when there is significant right ventricular dilatation or dysfunction, a leftward shift of the interventricular septum, or cyanosis. In addition, the bidirectional cavopulmonary shunt is helpful if the resultant tricuspid valve repair has a small effective orifice. Finally, the bidirectional cavopulmonary shunt may also reduce hemodynamic stress on a more complex (multiple suture lines) tricuspid valve repair, as the volume of the right ventricle can be reduced by 35–45%, depending on the patient's age. Cardiac transplantation is rarely indicated and is reserved for patients with severe biventricular dysfunction.

Our surgical management of patients with Ebstein anomaly consists of 1) closure of any atrial septal communications; 2) reconstruction of the tricuspid valve using the cone technique; 3) bioprosthetic tricuspid valve replacement when the valve cannot be successfully repaired; 4) selective plication of the atrialized right ventricle; 5) performance of any indicated antiarrhythmic procedures; 6) right reduction atrioplasty; 7) correction of associated anomalies; and 8) selective application of the bidirectional cavopulmonary shunt. Intraoperative transesophageal echocardiography is used in all cases.

Tricuspid Valve Repair

Reconstruction of the deformed tricuspid valve began in 1958 when Hunter and Lillehei attempted to create a competent valve by repositioning the displaced posterior and septal leaflets [22]. Although some good results have been reported with other early attempts at tricuspid valve repair [23,24], it has not been generally effective in establishing a competent valve in the moderate and severe forms of Ebstein anomaly, and heart block may be more frequent.

In 1972, David Danielson at the Mayo Clinic developed a repair based on the construction of a monocuspid valve by the use of the anterior leaflet of the tricuspid valve, which is usually enlarged in this anomaly; competency is obtained by coaptation of the anterior leaflet with the ventricular septum [25,26]. This repair also included posterior tricuspid annuloplasty; plication of the free wall of the atrialized right ventricle, bringing the functional tricuspid annulus up to the true annulus; and excision of redundant right atrial wall (right reduction atrioplasty). Although the basic principles of this original repair remain the same, we had subsequently incorporated various modifications in the repair because numerous anatomical variants of the anomaly have been encountered. One such modification is to repair the valve where it exists in the right ventricle (i.e., repairing the valve at the level of the displaced functional annulus) by bringing the papillary muscle(s), which are attached to the right ventricular free wall down to the ventricular septum, anchoring it with pledgeted sutures.

More recently, we have been using the cone reconstruction as described by da Silva and colleagues [27]. This technique is different from all previous valvuloplasty techniques in that it is closest to an "anatomic repair" (Figure 29.5) [28].

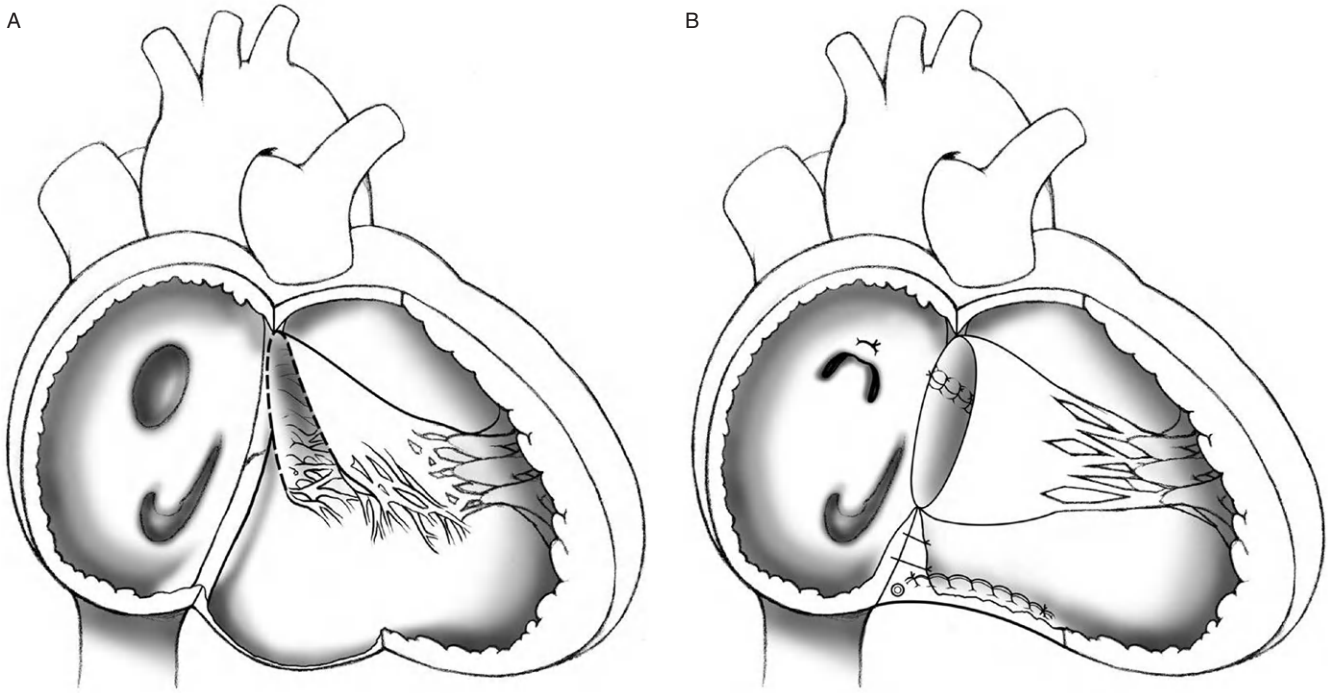

Figure 29.5 Cone reconstruction is a near anatomic repair. **A,** The marked displacement of the tricuspid valve is shown in a cross-sectional view of the right atrium and right ventricle. **B,** Following cone reconstruction, the reconstructed tricuspid valve forms a "cone" shape (i.e., 360 degrees of leaflet tissue), and the hinge point has been moved to the true tricuspid annulus. The atrialized right ventricle and true tricuspid valve annulus have been plicated to reduce the size of the tricuspid valve annulus. (Reproduced with permission from Dearani *et al.* [28]. Copyright © 2008 Mayo Foundation for Medical Education and Research.)

The end result of the cone reconstruction includes 360 degrees of tricuspid leaflet tissue surrounding the right atrioventricular junction. This allows leaflet tissue to coapt with leaflet tissue, similar to what occurs with normal tricuspid valve anatomy. In addition, the reconstructed tricuspid valve is reattached at the true tricuspid valve annulus (atrioventricular junction) so that the hinge point of the valve is now in a normal anatomical location. Thinned, transparent atrialized right ventricle is plicated so that any areas of right ventricular dyskinesis are eliminated. Right ventricular plication also helps reduce the size of the enlarged right ventricle, and it decreases tension on the numerous sutures required for the cone reconstruction. When somatic growth is complete, the final tricuspid repair is reinforced with a flexible annuloplasty band. Redundant right atrium is excised so the size of the right atrium is closer to normal. Since this technique can be applied to the wider variety of anatomical variations encountered with Ebstein anomaly, we have adopted this repair technique and have reported the details of the surgery (Figure 29.6) [28].

Relative contraindications to the cone reconstruction include the neonate, older age (>50 years), moderate pulmonary hypertension, significant left ventricular dysfunction (ejection fraction <30%), complete failure of delamination of septal and inferior leaflets with poor delamination of the anterior leaflet (i.e., <50% delamination of the anterior leaflet), severe right ventricular enlargement, and severe dilatation of the true tricuspid annulus (right atrioventricular junction).

Many others have reported their techniques and results of tricuspid repair for Ebstein anomaly in older children and adults, including Carpentier, Hetzer, Wu, Chen, and Quaegebeur [29–38]. Thus, tricuspid valve repair techniques continue to evolve to address the infinite anatomic variations present with this anomaly. Although each of the many described techniques provide value to the surgeon who is confronted with this anomaly, it is our belief that the cone reconstruction provides the most anatomic reconstruction and is preferred when the anatomy allows.

Tricuspid Valve Replacement

Prosthetic tricuspid valve replacement remains a good alternative for the treatment of Ebstein anomaly when valve repair is not feasible. Bioprosthetic (porcine) valve replacement, as opposed to mechanical valve replacement, is generally preferred because of relatively good durability of the porcine bioprosthesis in the tricuspid position and the lack of need for warfarin anticoagulation. While bioprosthetic valves do not have the thromboembolic complications of mechanical valves, they do have a limited

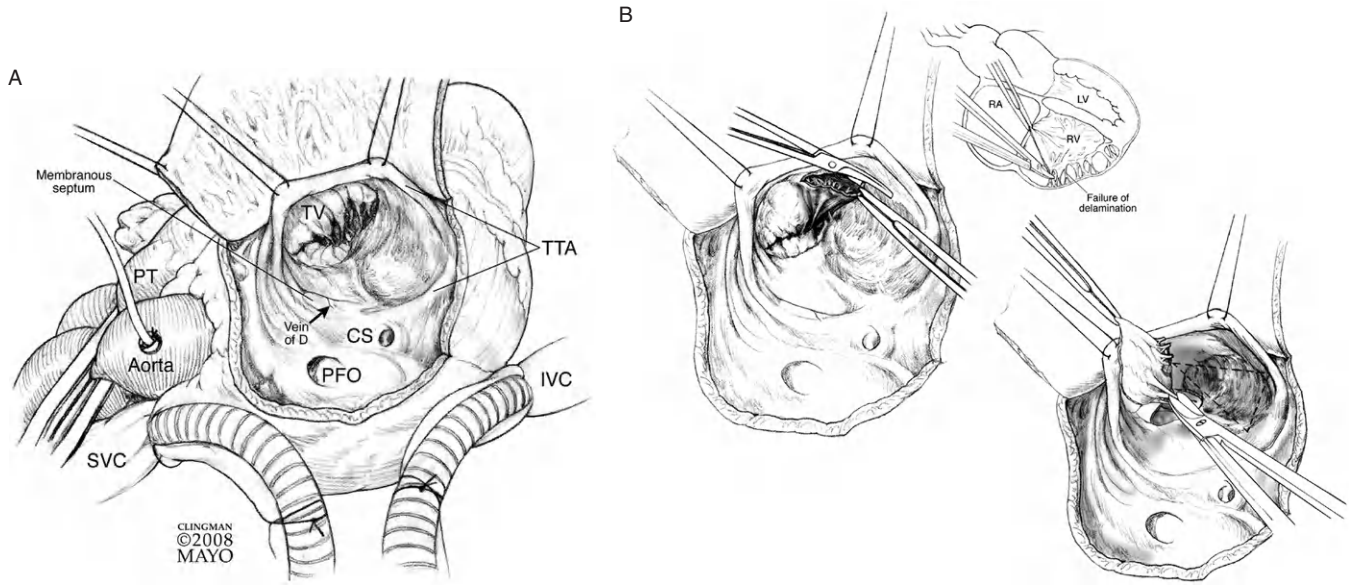

Figure 29.6 Cone reconstruction technique. **A,** Standard aortic cannulation and bicaval cannulation is performed. A right atriotomy is performed, parallel to the atrioventricular groove. Valve exposure is facilitated by stay sutures. The tricuspid valve anatomy is examined, and the atrialized right ventricle evaluated. The membranous septum and atrioventricular node are marked by a small vein (vein of D); fatty tissue is generally present in this area. **B,** The first incision is made in the anterior leaflet at 12:00; the incision is a few millimeters away from the true annulus. Using scissors, the incision is extended in a clockwise fashion, and it is common for there to be a true space between the anterior leaflet and the right ventricle in this region (i.e., a normally delaminated leaflet). It is also common for the anterior leaflet to be muscularized in this area adjacent to the annulus and for there to be degrees of failure of delamination (inset) of the medial aspect of the anterior leaflet and even more of failure of delamination of the inferior leaflet. Takedown of these fibrous and muscular attachments between the body of the leaflet(s) and the free wall of the right ventricle is called a *surgical delamination*. It is important for the surgical delamination process to include takedown of all attachments between the atrioventricular groove and leading edge of the leaflet(s), which is often close to the apex of the right ventricle. Care must be taken to keep all fibrous and occasionally muscular attachments of the leading edge of the leaflet(s) to the myocardium intact. The dotted triangle represents the atrialized right ventricle, which will be later plicated. **C,** The anterior leaflet should be examined to determine whether there are individual chordal attachments present, direct papillary muscle insertions into the leading edge, or whether the leading edge is attached directly (linear) to the myocardium. When a linear attachment is present (inset), fenestrations should be created in the distal aspect of the leaflet to create *neochordae*. This allows blood to enter the right ventricular cavity. Care must be taken not to injure the underlying thinned right ventricular myocardium when the surgical delamination process is being performed. **D,** To complete the cone reconstruction, after all tricuspid valve leaflets (anterior, septal, and inferior) are mobilized, the inferior leaflet (or most medial aspect of the anterior leaflet if no inferior leaflet is present) is rotated clockwise to meet the mobilized proximal edge of the septal leaflet. These two leaflets are approximated with interrupted fine monofilament sutures. This neotricuspid valve orifice is composed of 360 degrees of native tricuspid valve tissue. The more septal leaflet that is present, the easier and more successful this entire process is. Before reattachment of the neotricuspid valve to the true annulus, the atrialized right ventricle is examined and plicated as needed. **E,** To obliterate noncontractile, thinned portions of the atrialized right ventricle, an internal apex-to-base triangular plication of the atrialized right ventricle may be employed. We believe plication helps reduce tension on repair sutures at the level of the true annulus, helps reduce annular size, and eliminates paradoxical motion of the enlarged right ventricle. Monofilament 4-0 or 5-0 is started close to the apex of the right ventricle. This plication suture line is partial thickness and predominantly incorporates the endocardium. As the plication proceeds toward the atrioventricular groove (the base of the "triangular" plication), it is important to inspect and be sure that there is no compromise of the right coronary artery. **F,** The neotricuspid valve is reanchored at the true annulus. It is now our practice to reattach the septal leaflet to the ventricular septum just proximal (i.e., on the ventricular side of the true annulus) to the area of the conduction tissue and membranous septum. In older children and adults, the repair is completed with a flexible annuloplasty band to reinforce the neotricuspid valve annular reconstruction. We reinforce each end of the annuloplasty band with a mattress suture backed with felt pledgets; the inferior suture typically incorporates the orifice of the coronary sinus. This is particularly important when there has been a significant reduction in the size of the true annulus during the course of the neotricuspid valve reconstruction. (CS, coronary sinus; IVC, inferior vena cava; LV, left ventricle; PFO, patent foramen ovale; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; SVC superior vena cava; TTA, true tricuspid valve annulus.) Figure 29.6 (*Continued*)

durability, particularly in infants and young children. Bioprosthetic valves are also undesirable in the small patient, because reoperation may be required for replacement of the valve because of somatic growth as well as structural valve deterioration. Mechanical valves in the tricuspid position may be associated with a higher frequency of valve malfunction and thrombotic complications than mechanical valves in other cardiac positions [39], particularly when right ventricular function is poor.

When the tricuspid valve cannot be reconstructed and replacement is necessary, valve leaflet tissue toward the right ventricular outflow tract (which can cause RVOTO) is excised and the prosthetic valve (usually a porcine bioprosthesis) is inserted. It is important to anchor the prosthesis in the right atrium, opposed to the atrioventricular groove. The suture line is deviated to the atrial side of the atrioventricular node and membranous septum to avoid injury to the conduction mechanism (Figure 29.7) [40]. A small vein (vein of D) crossing the tricuspid annulus adjacent to the membranous septum typically marks the atrioventricular node. The coronary sinus can be left to drain into the right atrium if there is sufficient room between it

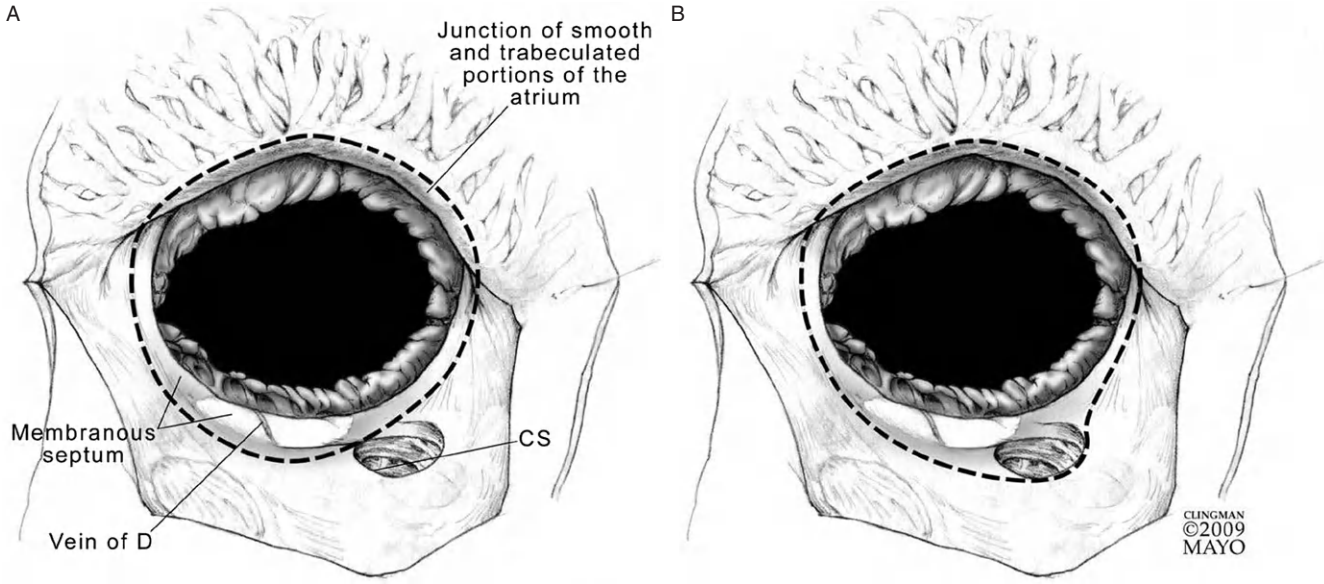

Figure 29.7 Diagram of technique for tricuspid valve replacement in Ebstein anomaly. The valve suture line is placed on the atrial side of the membranous septum and atrioventricular node to avoid injury to the conduction system. The suture line is also deviated cephalad to the tricuspid annulus posterolaterally when the tissues are thin to avoid injury to the right coronary artery. This results in the prosthesis being mounted in an intra-atrial position. **A,** When there is sufficient distance between the coronary sinus and the atrioventricular node, the coronary sinus is left draining normally into the right atrium. **B,** If the coronary sinus and the conduction tissue are in close proximity, the suture line is deviated further into the right atrium, leaving the coronary sinus to drain into the right ventricle. The sutures are tied with the heart perfused and beating to ensure that normal atrioventricular conduction is preserved. (CS, coronary sinus.) (Reproduced with permission from Dearani *et al.* [40]. Copyright © 2009 Mayo Foundation for Medical Education and Research.)

and the atrioventricular node; if the distance is short, the coronary sinus can be left to drain into the right ventricle so that heart block can be avoided. To avoid injury to the right coronary artery, the suture line is deviated toward the atrial side of the tricuspid valve annulus anteriorly and inferiorly where the smooth and trabeculated portions of the atrium meet each other. The struts of the porcine bioprosthesis are oriented so that they straddle the area of the membranous septum and conduction tissue. The valve sutures are tied with the heart beating (after intracardiac communications are closed) to detect any disturbances in atrioventricular conduction.

In our experience of more than 800 operations for Ebstein anomaly, we make every effort to repair rather than replace the tricuspid valve. Although our experience has demonstrated excellent durability of porcine bioprostheses in older children and adults [7,41], others have shown poor durability of bioprostheses in young patients (Figure 29.8) [7,42,43]. This decreased durability in young children is related to both increased calcification and rapid somatic growth, which results in patient prosthesis mismatch. In young children, we accept repairs that reduce the degree of tricuspid regurgitation to a moderate degree to avoid tricuspid valve replacement. In our experience, tricuspid

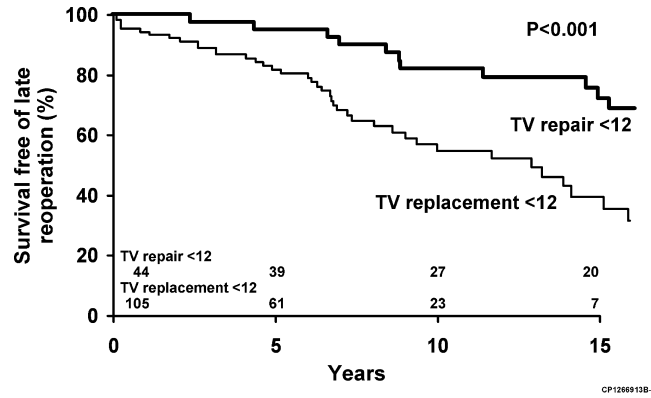

Figure 29.8 Patients less than 12 years of age were stratified into patients who had tricuspid valve repair or replacement. This cutoff was chosen because an adult-sized tricuspid valve prosthesis can generally be inserted into a 12-year-old patient with Ebstein anomaly. There was a significant advantage for young patients (<12 years) who had a tricuspid valve repair versus tricuspid valve replacement ($p < 0.001$). We prefer tricuspid valve repair whenever possible in all young patients with Ebstein anomaly. (Reproduced with permission from Brown *et al.* [7].)

bioprostheses in patients with Ebstein anomaly have greater durability in both pediatric and adult populations compared to bioprostheses in other cardiac positions and even when compared with bioprosthetic tricuspid valve replacement for other cardiac diagnoses [41]. We speculate that this favorable experience may be related to the large size of the bioprosthesis that can be implanted relative to patient somatic size and to the normal, low right ventricular systolic pressure after repair in patients with Ebstein anomaly. Both of these factors would tend to reduce turbulence and stress on the bioprosthesis. For this reason, in older adult patients (>50 years of age), we believe that a successful, durable tricuspid valve repair should have less than moderate tricuspid regurgitation; if this cannot be obtained, then we proceed with bioprosthetic replacement. For adult patients who are taking warfarin anticoagulation for other reasons and who want to potentially minimize the need for a subsequent reoperation for bioprosthetic deterioration, a mechanical valve can be considered. Mechanical valves should generally be avoided when there is significant right ventricular dysfunction since the discs may not open and close properly, resulting in a greater propensity for valve thrombosis even in the presence of therapeutic warfarin anticoagulation.

One-and-a-Half Ventricle Repair

The bidirectional cavopulmonary shunt is used selectively and more frequently in the current era. The bidirectional cavopulmonary shunt is helpful when the right ventricle is severely dilated or dysfunctional or if there is displacement of the interventricular septum toward the left ventricle (D-shaped left ventricle) [44]. This may also be advisable if there is preoperative arterial desaturation at rest or with exercise that suggests poor right ventricular function. Finally, a right-to-left atrial pressure ratio greater than 1.5 after separation from cardiopulmonary bypass also indicates poor right ventricular function and can be used as a guide for placement of a bidirectional cavopulmonary shunt [45]. The construction of a bidirectional cavopulmonary shunt may allow for less-than-perfect tricuspid valve repairs or more complex tricuspid valve repairs, since it will decrease the volume of blood traveling through the right ventricle and stress on the repair suture lines. The bidirectional cavopulmonary shunt should also be used if a tricuspid valve repair has resulted in an effective valve orifice that has mild to moderate stenosis (mean gradient >6–7 mmHg) or in more complex repairs with multiple suture lines. Finally, patients who receive a bidirectional cavopulmonary shunt may tolerate longer intervals between repeat tricuspid valve operations for progressive tricuspid regurgitation or failing tricuspid valve prostheses.

Since concomitant left ventricular dysfunction may be present when there is significant right ventricular dilatation and/or dysfunction, it is important to document by direct pressure measurements that the pulmonary arterial and left atrial pressures are low (which is usually the case); otherwise, the bidirectional cavopulmonary shunt will not be feasible. If the left ventricular end-diastolic pressure is less than 15 mmHg, the transpulmonary gradient is less than 10 mmHg, and the mean pulmonary arterial pressure is less than 18–20 mmHg, a bidirectional cavopulmonary shunt is permissible. Even in the presence of moderate left ventricular dysfunction (ejection fraction, 35–40%) it is usually feasible to perform a bidirectional cavopulmonary shunt in the setting of Ebstein anomaly. If the tricuspid valve requires replacement, the prosthesis should be downsized, since the amount of flow across the tricuspid orifice is reduced.

Chauvaud [30,31], Marianeschi [46], and Quiñonez [44] have proposed that the use of a bidirectional cavopulmonary shunt may decrease operative mortality and facilitate the postoperative management of patients with severe right ventricular dysfunction. The literature suggests that the frequency of bidirectional cavopulmonary shunt application in Ebstein anomaly is increasing; in a series of 150 patients in a European registry, almost 26% underwent a one-and-a-half ventricle repair [47]. However, late results of a bidirectional cavopulmonary shunt in patients in Ebstein anomaly are unknown.

Disadvantages of the bidirectional cavopulmonary shunt may include pulsations of the head and neck veins, facial swelling, and the development of arteriovenous fistulae in the pulmonary vasculature [48]. In addition, the placement of this shunt compromises access to the heart from the internal jugular approach for electrophysiologic studies and for pacemaker lead placement. The bidirectional cavopulmonary shunt is a promising application in the management of patients with Ebstein anomaly, particularly those with severe right ventricular dysfunction, but it should be reserved for selected patients mentioned above, until the late outcomes are well described.

The need to proceed to the Fontan procedure in the older child and adult with Ebstein anomaly is rarely, if ever indicated. While many have suggested the Fontan procedure in the child or adult with Ebstein anomaly and profound right ventricular dilatation and/or dysfunction, we have experienced poor outcome in those patients with a Fontan circulation who have two ventricles, one of which is enlarged and functions poorly – this is typically the case with Ebstein anomaly. In this most difficult group, we proceed with one-and-a-half ventricle repair, and rarely resort to transplantation.

Plication of the Atrialized Right Ventricle

Whether plication (or actual excision) of the atrialized right ventricle is necessary or desirable is controversial. Potential advantages include: 1) reduction in the size of the

nonfunctional portion of the right ventricle, improving transit of blood flow through the right heart; 2) reduction of compression of the left ventricle (pancake effect), improving left ventricular function; and 3) reduction of tension on the tricuspid valve repair suture lines (particularly the cone repair), providing more space for the lungs (especially important in infants). All internal forms of right ventricular plication by necessity interrupt some coronary arterial supply to right ventricular musculature, and many have the potential risk of kinking the right coronary artery, problems that may generate ventricular arrhythmias and compromise right and left ventricular function. The decision whether to plicate the atrialized right ventricle and how much to plicate are based on the anatomy encountered and the surgeon's personal philosophy. In our practice, we routinely plicate the atrialized right ventricle when it is noted to be thinned and dilated. We believe it is also important when a complex tricuspid valve repair, such as the cone repair, has been performed in order to reduce tension on the suture lines that may be present – this is more likely to occur when there is marked right ventricular and annular dilatation. It is important to emphasize that during the course of any ventricular plication technique, there should be frequent inspection of the right coronary artery and its major branches in order to minimize potential compromise of arterial blood supply to the right (and left) ventricle.

Right Reduction Atrioplasty and Surgical Treatment of Arrhythmias

A right reduction atrioplasty is performed routinely at the time of atriotomy closure because there is almost always significant right atrial dilatation. Special attention is Made to leave a small rim of tissue anterior to the crista terminalis for suture placement during the closure. In all circumstances of right atriotomy closure, we avoid placing suture lines in the crista terminalis, which can produce the substrate for atrial tachyarrhythmias [49,50].

Atrial fibrillation and atrial flutter are the most frequent atrial tachyarrhythmias that occur in Ebstein anomaly. For most patients, the lesion sets of a Cox III right-sided maze procedure have been successful [51]. With the availability of newer devices (radiofrequency ablation and cryoablation) the time taken to perform the complete biatrial Cox maze III procedure is shortened significantly. Consequently, we perform a biatrial maze procedure much more frequently at the present time for all diagnoses associated with atrial arrhythmias. This is particularly important if there is continuous atrial fibrillation, left atrial dilatation, or concomitant mitral regurgitation. It is our practice to follow the lesions in both atria that have been previously described [52,53]. In addition, if there is evidence of atrial flutter, we add a lesion to the right atrial isthmus (i.e., the posterolateral tricuspid annulus to the coronary sinus to the inferior vena cava). We make an effort to close the left atrial appendage as part of the maze procedure.

For patients with AVNRT who have had unsuccessful ablation in the electrophysiology lab preoperatively, perinodal cryoablation is performed after institution of cardiopulmonary bypass, right atriotomy, and closure of intracardiac septal defects. Multiple applications of the cryoprobe (freezes) are made around and within the coronary sinus and then carried anteriorly toward the proximal atrioventricular node until temporary complete heart block is noted, at which time rewarming is begun immediately. Normal atrioventricular conduction returns shortly thereafter. When indicated, supplemental freezes are made superior and anterior to the atrioventricular node and His bundle.

For patients with accessory conduction pathway (i.e., Wolff-Parkinson-White), mapping and ablation is performed preoperatively in all patients. Rarely is intraoperative mapping and ablation performed at the time of repair of Ebstein anomaly in the current era.

Heart Transplantation

Transplantation is an option in patients with Ebstein anomaly with severe biventricular dysfunction (i.e., a left ventricular ejection fraction <25%). In our experience, patients with severe right ventricular dysfunction and normal or mild to moderately depressed left ventricular function can be managed with a conventional two ventricle approach or a one-and-a-half ventricle approach (bidirectional cavopulmonary shunt with tricuspid repair or replacement) [54]. Other patients with Ebstein anomaly that should be considered for transplantation are those with significant left ventricular dilatation and dysfunction and those with severe mitral regurgitation with significant left ventricular dysfunction. Hemodynamic cardiac catheterization to ascertain left-sided filling pressures and pulmonary artery pressures is also helpful in this group of patients when trying to determine feasibility of conventional operation versus transplantation.

Postoperative Management

Postoperative care of the biventricular repair in a neonate can be challenging. Tolerance of early low peripheral oxygenation (from the subtotal ASD closure) is common, and inhaled nitric oxide may be necessary to decrease pulmonary vascular resistance and augment antegrade pulmonary flow. Delayed sternal closure is used liberally. Prophylactic use of a peritoneal dialysis catheter also may be used to ensure complete decompression of the abdomen and facilitate ventilation. As pulmonary pressures decrease, forward flow will gradually increase through the pulmonary valve, improving oxygenation.

Postoperative care of neonates with the single ventricular approach is similar to that of any shunt-palliated patient with a univentricular heart, as there should be a balance between optimizing systemic perfusion and obtaining adequate oxygenation. Delayed sternal closure and peritoneal drainage may also be beneficial. As with other patients with a shunt-dependent pulmonary circulation, careful surveillance is required between the first operation and second-stage procedure (bidirectional cavopulmonary shunt), which is usually performed at 4–6 months of age.

In children and adults, the postoperative period is generally straightforward when left ventricular function is normal and right ventricular dysfunction is not severe. Routinely, we separate from bypass using epinephrine and milrinone infusions. We are cautious in the administration of colloid and crystalloid and prefer a right atrial pressure of less than 10 mmHg. We maintain reasonably fast heart rates (100–120 beats/min) and use temporary atrial pacing to accomplish this if needed. Delayed sternal closure, especially in patients with severe dilatation and dysfunction of the right ventricle can be life saving. To decrease right ventricular afterload (i.e., decrease pulmonary arterial pressures), nitric oxide and mild hyperventilation may be helpful in some patients. Intra-aortic balloon placement should be considered in patients with concomitant severe left ventricular dysfunction or known elevation in pulmonary artery pressures (infrequent). Atrial and ventricular arrhythmias should be avoided or treated aggressively through the optimization of metabolic parameters and the use of amiodarone and/or lidocaine.

Medical therapy in patients who have undergone repair of Ebstein anomaly is dependent on the method of repair. In patients with tricuspid valve repair, afterload-reducing agents should be used to decrease right ventricular afterload as much as possible. Patients who receive a tricuspid valve replacement with a porcine valve are prescribed warfarin for 3 months postoperatively, followed by lifelong aspirin (81 mg). Because of the reduction of blood flow across the tricuspid valve in the one-and-a-half ventricular repair, if a patient receives tricuspid valve replacement and a bidirectional cavopulmonary shunt, anticoagulation with warfarin may extend up to 6 months or until all prosthetic valve leaflets are noted to be mobile on echocardiography [44]. If patients have any postoperative arrhythmias, amiodarone is used for a minimum of 3 months and then reassessed.

Risk Factors and Outcome

When the diagnosis of Ebstein anomaly is made prenatally or in the neonate, the prognosis is poor. Survival for patients diagnosed between birth and 2 years of age was only 68% in one series [14]. Important features to determine with echocardiography that predict outcome in neonates with Ebstein anomaly include assessing patency of the right ventricular outflow tract and the GOSE score [14]. Patients who have the most severe GOSE score (grades 3 and 4) have a very poor prognosis (Table 29.3) [13,55–57].

Table 29.3 Celermajer index and the estimated risk of mortality. (aRV, atrialized right ventricle; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.) (Reproduced with permission from Jaquiss *et al.* [56].)

GOSE score	Index RA + aRV / RV + LA + LV	Risk of mortality [55,57]
1	<0.5	0%
2	0.5–0.99	10%
3	1–1.49	44–100%
4	≥1.50	100%

Although early mortality for operation in the symptomatic neonate is high (biventricular repair is ~25%), the intermediate outcome with the biventricular approach appears to be promising. In 2007, Knott-Craig published his experience with 27 neonates and young infants [11]. These patients had concomitant anatomic or functional pulmonary atresia (n = 18), ventricular septal defect (n = 3), small left ventricle (n = 3), and hypoplastic branch pulmonary arteries (n = 3). Twenty-three patients (n = 25) received a biventricular repair with tricuspid valve repair, and two received valve replacement. Survival to hospital dismissal was 74%, and there were no late deaths (median follow-up, 5.4 years; maximum, 12 years). All patients were in functional NYHA class I. Although these early results for repair of Ebstein anomaly during the neonatal period are poor compared to many other neonatal anomalies corrected in the first month of life (e.g., arterial switch procedure, Norwood stage I, etc.), they have become a benchmark for this very difficult patient population.

The early results of the single ventricle pathway in neonates with Ebstein anomaly is similarly high (operative mortality, ~25%), but results continue to improve in the current era [13]. Of 16 neonates, two patients had tricuspid valve repair, one patient had heart transplant, 10 patients had a right ventricular exclusion procedure with a fenestrated tricuspid valve patch, and three patients had a right ventricular exclusion procedure with a nonfenestrated tricuspid valve patch. The operative survival was 80% (8 of 10) in patients with a fenestration and 33% in patients with no fenestration, leading the authors to recommend fenestration of the tricuspid valve patch. Among the nine hospital survivors of right ventricular exclusion, three underwent completion of the Fontan, and all nine have had a successful bidirectional cavopulmonary shunt (second stage).

In children and adults, the early and late (more than 25 years follow-up) results of our experience at the Mayo

Clinic have been reported [7,58,59]. In our experience with children (mean age, 7.1 ± 3.9 years) who underwent tricuspid valve repair, moderate or more tricuspid regurgitation on dismissal echocardiogram was the only risk factor for late reoperation [58]. Overall early mortality was 6% (3 of 52), but none since 1984. Overall survival was 90% at 10 years and 90% at 15 years. In our larger cohort of 539 children and adults who underwent operation for Ebstein anomaly, mitral regurgitation, RVOTO, higher hematocrit (cyanosis), greater than moderate right ventricular dysfunction, and moderate or greater left ventricular dysfunction were all independently associated with late mortality [7].

In 2007, Dr da Silva published his series of 40 patients who underwent the cone tricuspid valve repair technique [27]. Patient's average age was 16.8 ± 12.3 years, and after a mean follow-up of 4 years (range, 3 months to 12 years), only one patient died, and two patients required late tricuspid valve rerepair. The cone technique has the potential to cause tricuspid valve stenosis, although no patients in this initial cohort experienced this complication. Additional follow-up is required to determine if this method of repair has long term durability.

In a recent study of our patients at Mayo Clinic, the functional outcome after operation for Ebstein anomaly was good, and reported exercise tolerance was comparable to patients' peers [60]. In a small group who had exercise testing, there was improvement in the exercise tolerance after surgery, but this improvement was believed to be a result of the elimination of the right-to-left shunt at the atrial level rather than because of improvement in ventricular function [61,62]. Late reoperation, rehospitalization, and atrial tachyarrhythmias continued to be problematic, with a freedom from rehospitalization for cardiac causes including reoperation of 91%, 79%, 68%, 53%, and 35% at 1, 5, 10, 15, and 20 years, respectively [60]. Thus, further improvements in the durability of tricuspid valve repair and replacement, as well as improved control of atrial arrhythmias should be sought to improve the quality of life in patients with Ebstein anomaly.

CHAPTER 30

Left Ventricular Outflow Tract Obstruction

Introduction

Congenital left ventricular outflow tract obstruction (LVOTO) is defined as impedance to ventricular ejection at various levels from the left ventricle to the ascending aorta. It is caused by a relatively common group of anomalies representing approximately 3–10% of patients with congenital heart disease [1]. The obstruction most commonly occurs at the aortic valve, but it may also be subvalvar, supravalvar, or a combination of these three.

LVOTO may occur as part of a complex of congenital cardiac malformations such as Shone's complex or hypoplastic left heart complex (HLHC). In the neonate with critical aortic stenosis and left ventricular hypoplasia or with HLHC, the capacity of the left heart to adequately support the systemic circulation may be compromised. For some of these patients, survival may be higher with the Norwood operation rather than with a traditional two-ventricle approach. This discussion of LVOTO is limited to that without associated interrupted aortic arch, single ventricle, transposition of the great vessels, or other complex structural heart defects. Aortic atresia will likewise not be discussed.

The classification of LVOTO is based on the primary pathologic morphology. Valvar aortic stenosis is the most frequent form, occurring in 60–75% of cases [2,3]. Subvalvar and supravalvar aortic stenosis affect 15–20% and 5–10% of patients, respectively.

Valvar Aortic Stenosis

Aortic valve abnormalities represent one of the most common forms of congenital heart disease, at 3–6% of all congenital heart defects [4,5]. Valvar aortic stenosis is the most frequent primary lesion in children with LVOTO, accounting for nearly 75% of cases. Valvar aortic stenosis has a wide spectrum of anatomic and clinical variations [6]. In its most benign form, children with a bicuspid aortic valve and/or mild aortic stenosis will remain asymptomatic except for an incidental murmur found on routine physical examination. On the other hand, newborns with critical aortic stenosis and ductus-dependent systemic circulation will become severely ill when the ductus closes, manifesting systemic hypoperfusion, acute renal failure, and severe metabolic acidosis. Although less than 10% of children are first seen with signs of critical aortic stenosis [7], they represent a distinct and challenging group of patients, with unique pathophysiologic and therapeutic considerations.

Valvar aortic stenosis has clear gender predilection, with the incidence in males three to five times higher than in females. Many other cardiac anomalies are associated frequently with valvar aortic stenosis, including ventricular septal defect (VSD), patent ductus arteriosus (PDA), hypoplastic left ventricle, and coarctation of the aorta [2,3,7]. In the neonate, critical aortic stenosis may be associated with multiple left-sided obstructions and severe hypoplasia of the left heart structures, falling within the spectrum of hypoplastic left heart syndrome (HLHS). In the largest multicenter prospective study on critical aortic stenosis involving 320 neonates less than 30 days old at diagnosis, an initial Norwood operation was performed on 179 patients (56%) [8]. This demonstrates the high incidence of left heart hypoplasia when this lesion is diagnosed in early life.

Aortic Stenosis in the Neonate and Infant

Pathologic Anatomy

Reduced cross-sectional area in critically stenotic aortic valves is the result of abnormalities in the number and morphology of cusps and the development of valve commissures [5,9]. When seen in the neonate and infant, these valves are most frequently bicuspid, with thickened, dysmorphic leaflets, fused commissures, and an eccentric orifice. Less commonly, one finds unicuspid valves that may be commissural, with only a stenotic central orifice, or they may be unicommissural with a single eccentrically located commissure extending to the annulus and a lateral commissural attachment to the aortic wall. A tricuspid valve with three cusps and a stenotic central orifice is the least common form of valvar aortic stenosis. In older children, bicuspid valves are seen more commonly. These valves usually consist of a right and a left leaflet of unequal size, separated by the anterior and posterior commissures. The commissures usually have some degree of fusion, and there is limited mobility of the leaflets because of the straight rather than rounded shape of the commissural opening. Some valves appear to be bicuspid at first glance, but closer inspection reveals a tricuspid valve with one commissure rudimentary and fused, giving the impression of two leaflets.

Pathophysiology

LVOTO secondary to valvar aortic stenosis is usually compatible with life during fetal development. Increased left ventricular afterload, however, leads to myocardial hypertrophy with systolic and diastolic dysfunction [10]. In critical aortic stenosis, significant left ventricular dysfunction occurs with increased left atrial pressure, resulting in left-to-right shunt flow across the foramen ovale. Systemic perfusion is maintained via right ventricular ejection and the PDA. Left ventricular hypertrophy, intracavitary hypertension, and reduced coronary perfusion pressure together predispose the left ventricle to myocardial ischemia [11], which may lead to endocardial fibroelastosis [12]. In addition, severe obstruction causes reduced flow through the left heart during fetal development, which predisposes to hypoplasia of the left-sided structures such as the mitral valve, left ventricle, left ventricular outflow tract (LVOT), aortic valve, ascending aorta, and frequently the aortic arch [12].

The postnatal course depends on the severity of valvar obstruction, the degree of left ventricular dysfunction or hypoplasia, and in cases of critical stenosis, shunt flow at the atrial and ductal levels. Neonates and infants with mild to moderate forms of valvar aortic stenosis usually have a well developed left ventricle that is sufficient to support the systemic circulation. They remain clinically asymptomatic except for a systolic ejection murmur and evidence of progressive left ventricular hypertrophy. Occasionally, exercise intolerance may be present. More severe forms of valvar aortic stenosis cause increased ventricular afterload, resulting in increased ventricular wall tension and workload. This leads to myocardial hypertrophy and ventricular dysfunction. In addition, the pressure gradient across a stenotic valve causes a mismatch between coronary perfusion pressure and myocardial perfusion pressure. Consequently, myocardial ischemia, arrhythmia, and infarction are constant concerns in such situations. The subendocardial region is the area most vulnerable to ischemia, which may lead to endocardial fibroelastosis [13], a characteristic pathologic finding of valvar aortic stenosis. Patients with severe aortic stenosis manifest exertional chest pain, easy fatigability, and/or syncope.

In many neonates, the left heart is incapable of sustaining the systemic circulation, either because of severe LVOTO, severe left ventricular hypoplasia, and/or dysfunction [8]. Both systemic and coronary perfusions become dependent on the PDA. Typically, these patients have adequate peripheral perfusion with varying degrees of cyanosis, especially to the lower body, depending on the amount of flow through the native aortic valve. As the ductus begins to close soon after birth, however, these patients develop signs of cardiovascular collapse manifested by hypotension, acute renal failure, congestive heart failure, and metabolic acidosis.

Clinical Picture and Diagnosis

The timing of presentation is related to the severity of obstruction. Patients with mild aortic stenosis may remain essentially asymptomatic. As the degree of obstruction increases, exertional chest pain, easy fatigability, and syncope are manifest. Most patients with critical aortic stenosis who are not well compensated have obvious signs of cardiovascular compromise soon after birth. Only a small number of patients are first seen after 6 months of age. In these patients, a history of irritability, poor weight gain, and poor feeding is typical. However, these systems correlate poorly with the degree of obstruction.

Physical examination in patients with isolated aortic stenosis usually shows a normally developed, acyanotic child. Although the blood pressure is usually normal, a narrow pulse pressure and signs of reduced peripheral perfusion such as diminished peripheral pulses, pale cool skin, and slow capillary refill are found in more severe cases. A systolic ejection murmur may or may not be present, depending on the left ventricular function and the amount of blood flow across the stenotic valve. When present, it is best heard at the second intercostal space with good transmission to the neck apex. In very low output states, the murmur may be absent; as cardiac output and congestive heart failure improve, the murmur increases in intensity. A systolic thrill may be palpable along the right upper sternal

border, in the suprasternal notch or over the carotid arteries. An ejection click may be present and strongly suggests valvar, rather than supravalvar or subvalvar, obstruction. Lower body cyanosis may be present when there is significant right-to-left shunting through the PDA. When there is sufficient forward flow in the ascending aorta to sustain normal perfusion of the brachiocephalic vessels, differential cyanosis may be observed; the abdomen and lower extremities are perfused by desaturated blood from the PDA. Hepatomegaly suggests biventricular failure and may indicate a less favorable prognosis.

The electrocardiogram typically shows evidence of left ventricular, or biventricular, hypertrophy with or without a strain pattern. In mild cases, the electrocardiogram remains normal. However, correlation between the severity of the stenosis and the presence of electrocardiogram abnormalities is poor [14]. The chest radiograph is usually normal but may show an enlarged cardiac silhouette and evidence of pulmonary congestion in neonates with critical aortic stenosis.

Echocardiography and Doppler flow studies are extremely informative noninvasive studies that can greatly facilitate the management of congenital heart disease [15]. In addition to establishing the anatomic diagnosis, echocardiography can assess ventricular function, the presence or absence of endocardial fibroelastosis, as well as associated cardiac anomalies [12]. The severity of stenosis can be estimated by measuring the pressure gradient across the stenotic valve using Doppler studies, although such gradient may be greatly underestimated when there is ventricular dysfunction or a right-to-left shunt across the PDA. Echocardiography also defines the direction of flow across the PDA and in the ascending aorta. Such information helps to determine whether the left heart is capable of supporting the systemic circulation after biventricular repair. Prenatal diagnosis is also possible using fetal echocardiography [16].

Cardiac catheterization is performed as part of catheter-based therapeutic intervention or if there is uncertainty regarding the diagnosis or other associated anomalies. Direct measurements of left-sided and right-sided pressures, as well as the peak-to-peak systolic pressure gradient across the valve, can be taken to assess valve leaflet morphology, aortic annulus size, aortic and mitral valve competence, and ventricular performance.

Treatment

Indications for Intervention

For neonates and young infants, the development of congestive heart failure or the presence of ductal-dependant systemic circulation indicates the need for urgent intervention. Beyond the neonatal period, symptomatic valvar stenosis or a significant pressure gradient across the aortic valve (>50 mmHg) constitutes an indication for surgery. Generally, aortic valvotomy is preferred at the initial surgical intervention, with aortic valve repair or replacement strategies being reserved for future interventions.

Therapeutic strategy is based on assessment of the patient's clinical status and a complete understanding of the underlying anatomic defects. Because of the frequent association of critical valvar aortic stenosis and left heart hypoplasia, one of the key issues to be decided early on is whether the left-side structures are capable of sustaining systemic circulation. This distinction is essential in deciding whether to proceed with a Norwood-type single ventricle repair or cardiac transplantation instead of valvotomy or valve replacement procedures. Previous reports have described significantly worse results in those patients requiring a "crossover" between univentricular and biventricular strategies [17,18].

Despite numerous studies, preoperative assessment of left ventricular status as a predictor of surgical outcome is still controversial. Echocardiographic dimensions most commonly are used for such purposes. Unfavorable surgical outcome after biventricular repair has been associated with a small aortic valve, a small left ventricle, and a small mitral valve. In a retrospective study, Rhodes and associates proposed a scoring system to determine quantitatively the adequacy of the left ventricle based on the aortic root dimension indexed to the body surface area, the ratio of the long-axis dimension of the left ventricle to the long-axis dimension of the heart, and the indexed mitral valve area [19]. Others have suggested that the presence of predominant or total antegrade flow in the ascending and transverse aorta is associated with survival after two-ventricle repair [20]. However, surgical series of successful biventricular repair of HLHC and LVOTO have been reported when the above criteria would have predicted a univentricular approach [21–23]. Furthermore, the Rhodes score has been shown to lack discriminating power in neonates with multiple levels of left heart obstruction [18,22].

The Congenital Heart Surgeons' Society (CHSS) conducted a prospective multicenter study on management, outcomes, and risk factors in 320 neonates with critical aortic stenosis [8]. Of these, an initial biventricular repair consisting mainly of either surgical or balloon aortic valvotomy was performed in 116 patients, and an initial Norwood operation in 179 patients. Multiple management, survival, and risk factors were assessed for the biventricular and univentricular pathways. A multiple-regression equation was established to determine the 5-year survival benefit of Norwood versus biventricular repair for each patient. The factors found to be significant were the age of patient at entry, the size of the aortic valve at the sinuses, the grade of endocardial fibroelastosis, the diameter of the ascending aorta, the presence of moderate or severe tricuspid regurgitation, and the score of the left ventricular

length. Although the CHSS study is the most detailed and sophisticated analysis involving the largest-ever number of patients, the validity of this equation to determine the optimal surgical option for each patient remains to be tested in a prospective fashion.

More recently, the CHSS has reviewed a larger cohort with critical LVOTO, including the 320 neonates with critical aortic stenosis in the previously mentioned study [24]. This new analysis underscores the critical importance of deciding which patients are better suited for a univentricular and which patients for a two-ventricle approach. On the basis of that analysis, a univentricular-repair survival tool has been developed using separate risk factor analysis for death after intended univentricular or biventricular approach. This tool remains to be validated in a prospective trial.

Preintervention Management

Although relief of mechanical obstruction is the goal, therapeutic results can be improved greatly by aggressive resuscitation of the critically ill patient before invasive interventions. This usually requires endotracheal intubation and mechanical ventilation, inotropic support, and correction of fluid and electrolyte abnormalities. If signs of circulatory collapse develop with closure of the PDA, prostaglandin E1 infusion is invaluable for maintaining systemic perfusion and correcting metabolic acidosis. Using these measures, a patient's condition usually can be stabilized to allow time for proper preoperative studies and therapies that can be performed on an urgent rather than emergent basis.

Percutaneous Balloon Valvuloplasty

Percutaneous balloon valvuloplasty is considered by many the procedure of choice for relieving obstruction from valvar aortic stenosis [25–28]. Significant improvements have been made in both the technique and instrumentation since this procedure was first introduced in 1983 [29]. The CHSS evaluated the outcomes of surgical versus transcatheter balloon valvotomy in 110 neonates with critical aortic stenosis [30]. Although the transcatheter approach was associated with a greater percentage reduction in systolic gradients (65 ± 17% vs. 41 ± 32%) and lower residual median gradients (20 mm Hg, range, 0–85 mm Hg vs. 36 mm Hg, range, 10–85 mm Hg), there was a higher incidence of significant aortic regurgitation (18% vs. 3%). However, the two approaches did not differ significantly in regards to time-related survival (82% at 1 month and 72% at 5 years), as well as estimated freedom from reintervention (91% at 1 month and 48% at 5 years).

Vascular access is an important consideration for this procedure. The umbilical artery is the preferred site in neonates, whereas the femoral artery frequently is used in older patients. Axillary cannulation, as well as antegrade venous cannulation, have also been described [31]. However, severe aortic coarctation or interrupted aortic arch preclude the use of these routes. Carotid artery cannulation has been reported, including at the bedside, for relief of critical aortic valve stenosis, obviating the need to transport ill and hemodynamically unstable neonates to the cardiac catheterization laboratory [32]. A dysplastic valve with small annulus and aortic insufficiency are generally contraindications for balloon valvuloplasty.

Fetal Intervention

Balloon dilatation of the aortic valve has been described in fetal life. The objective is to limit postnatal left ventricular hypoplasia and dysfunction [33]. Although this approach is not yet considered standard of care, it may show promise in the future, allowing more patients with a borderline left ventricle to undergo a biventricular repair. In a report from Children's Hospital Boston, Tworetzky and associates performed balloon dilatation of the aortic valve in 20 fetuses at high risk for the development of HLHS by echocardiographic evaluation [34]. Technically successful procedures were those in which the guidewire was passed across the aortic valve, a 1 cm long balloon was inflated straddling the valve, and unambiguous improvement in aortic valve flow was confirmed by color Doppler imaging. There were 14 successful interventions, and these were associated with greater left-sided cardiac growth compared to unsuccessful cases. Technically unsuccessful cases shared several features, including suboptimal fetal positioning, the inability to manipulate the wire across the aortic valve, and a cannula angle that directed the wire either posterior or toward the ventricular septum instead of toward the aortic valve. In a separate report from Boston, a series of 22 fetuses diagnosed with critical aortic stenosis underwent aortic valvuloplasty [35]. Technical success increased significantly if maternal laparotomy was an option (83.3% vs. 20.0%), and laparotomy was performed in 66.6% of cases. Factors including gestational age, body mass index, or placental location were not associated with the need for laparotomy or the chances of technical success of the intervention. Postoperatively, three fetuses died, and two required preterm delivery.

Open Surgical Valvotomy and Open Surgical Valvuloplasty

Before the development of balloon valvuloplasty, a number of approaches had been employed successfully to perform surgical valvotomy. These procedures can be performed with or without cardiopulmonary bypass and with or without cardioplegia. Controversy continues concerning the advantages and disadvantages of different surgical approaches, and their use is based largely on individual preferences. Recently, some surgeons have advocated the use of a surgical aortic valvuloplasty, including commissurotomy, leaflet thinning, and excision of nodules and

tissue deposits that make the aortic valve leaflets bulky and immobile [36]. Our opinion is that the open surgical aortic valvuloplasty is far superior to the closed balloon valvotomy.

Open Valvotomy with Cardiopulmonary Bypass

Many surgeons prefer to perform open valvotomy during cardiopulmonary bypass, which offers the benefit and safety of controlled circulation (Figure 30.1) [37]. The aorta can be cross-clamped and the heart arrested using a single dose of cardioplegia solution. The aortic valve is exposed through a vertical aortotomy directed toward the noncoronary cusp. The major advantage of such an approach is that it allows a detailed inspection of the valvar anatomy and a precise valvotomy, which is critical to the success of the operation. Valvotomy should be carried out by dividing fused commissures to within 1–2 mm of the aortic wall. Because only a small increase in valve diameter is needed to gain a significant reduction in pressure gradient, it is recommended that the valvotomy be conservative in order to avoid creating aortic insufficiency. False raphes in a bicuspid aortic valve must not be incised for the same reason. In addition, the open technique allows the resection of nodules and mesenchymal tissue deposits on the valve leaflets and leaflet thinning under direct vision.

Open Valvotomy with Inflow Occlusion

Inflow occlusion offers rapid access to the aortic valve and direct visualization without cardiopulmonary bypass. The superior and inferior vena cavae are occluded with vascular clamps, and the heart is allowed to beat five to six times before the ascending aorta is cross-clamped. The aortic valve is exposed through a vertical aortotomy, and a conservative valvotomy is performed. Afterward, the heart is cleared of air by releasing the inferior vena caval clamp and filling the heart and the ascending aorta with blood. The

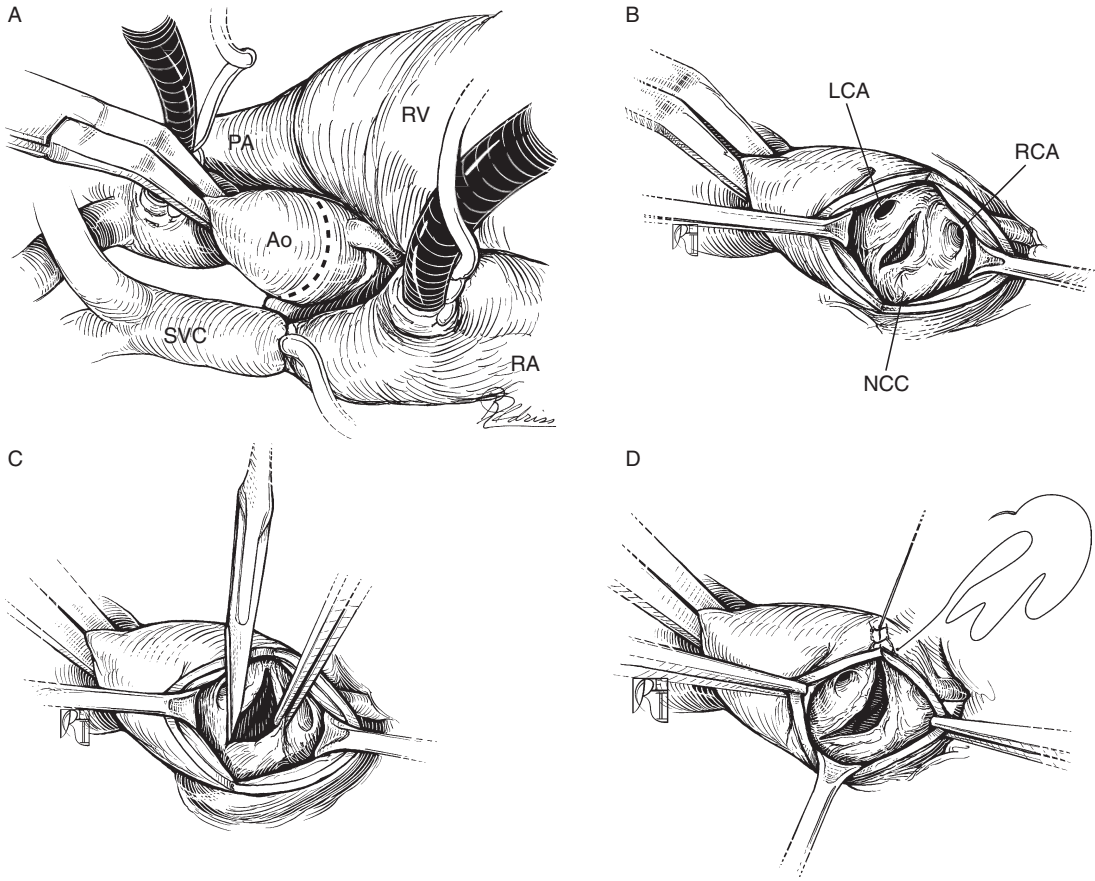

Figure 30.1 **A,** Initial surgical exposure for aortic valvotomy, which shows aortic cross-clamp, cardioplegia (not shown), and intended aortotomy site. **B,** Transverse aortotomy reveals a bicuspid aortic valve, which is fused at the commissures. **C,** Sharp aortic valvotomy is being performed to enlarge the left ventricular outflow tract. **D,** Valvotomy is completed and the aortotomy closure is commenced. Air maneuvers follow before cross-clamp is removed. (Ao, aorta; LCA, left coronary artery; NCC, noncoronary cusp; PA, pulmonary artery; RA, right atrium; RCA, right coronary artery; RV, right ventricle; SVC, superior vena cava.)

aortotomy is controlled with a side-biting clamp, and the cross-clamp is removed. The superior vena caval clamp is then released and the heart is resuscitated. This procedure is rarely used today because of the safety and utility of cardiopulmonary bypass and cardioplegia [38,39]. It is mentioned mostly for historical purposes.

Closed Valvotomy

Closed valvotomy is similar to balloon valvuloplasty in that the aortic valve opening is enlarged without direct visualization. This can be performed with or without cardiopulmonary bypass in a similar fashion. After a purse-string suture is placed around the left ventricular apex, a stab ventriculotomy is made in the middle of this purse string. Progressively larger Hegar dilators are inserted through the incision to enlarge the aortic valve opening to the desired diameter.

Aortic Valve Replacement

Aortic valve replacement using a pulmonary autograft with (Ross-Konno procedure) [40–42] or without aortoventriculoplasty (Ross procedure) [43–45] has been used successfully in infants who have critical aortic valve stenosis. In the Ross-Konno procedure, the LVOT is enlarged with either a synthetic patch, allograft aortic patch, or right ventricular infundibular free-wall muscular extension harvested in continuity with the autograft.

Univentricular Approach and the Norwood Operation

In patients with aortic valve stenosis that is not amenable to biventricular repair, the surgical options include staged surgical palliation and orthotopic heart transplantation. Given the limited availability of donor organs and the complications associated with long-term immunosuppression, staged surgical palliation is preferred rather than transplantation. The Norwood operation has significantly enhanced the survival of neonates with critical aortic stenosis with significant left ventricular hypoplasia.

Results

Preoperative discrimination between HLHS and isolated aortic valve stenosis has contributed to a significant reduction in operative mortality [19,46]. Although previous studies have described an operative mortality of 30–50% after aortic valvotomy in infants, more recent series [25–28,47,48] reported operative survival of 90% or higher. The major difference in the latter series is that the patients had a normal or near-normal left ventricular size. In one study, data analysis identified four morphologic variables that are predictive of death: a left ventricular long axis-to-heart long axis ratio of 0.8 or less, an indexed aortic root diameter of 3.5 cm/m^2 or less, an indexed mitral valve area of 4.75 cm/m^2 or less, and a left ventricular mass index of less than 35 g/m^2 [49]. The mortality rate was 100% in patients with two or more of these risk factors and 8% in patients with one or no risk factors. In the previously mentioned multicenter study on neonatal critical aortic stenosis, the 5-year survival after biventricular repair was 70% vs. 60% after the Norwood operation [8]. More important, the use of a regression equation would have provided survival benefit in favor of the Norwood operation in 50% of patients who had biventricular repair and in favor of biventricular repair in 20% of patients who had the Norwood operation. Of course, this regression equation remains to be tested in a prospective fashion as a decision-making tool.

Valvotomy for infants, whether balloon or surgical, should be considered a palliative procedure, because a large number of children eventually will require additional procedures for the aortic valve [50]. Recurrent aortic stenosis, stenosis with regurgitation, or isolated aortic regurgitation are common reasons for further interventions [51,52]. Repeat valvotomy is possible, although less effective in certain situations, and aortic valve replacement is eventually necessary.

Percutaneous Balloon Valvuloplasty

Since an initial report of successful balloon valvuloplasty for aortic valve stenosis in infancy, this modality has been used more frequently [53]. Balloon valvuloplasty during the first 60 days of life results in short-term relief of aortic stenosis in most patients. Although initially those with hypoplastic left heart structures may have worse subacute outcomes, this normalizes within 1 year [54]. Comparative studies concluded that balloon valvuloplasty and surgery for aortic stenosis provide equivalent relief as measured by ejection fraction improvement and left ventricular mass-to-volume ratio increase [55,56]. Early mortality and incidence of required additional aortic valve procedures were similar in both the balloon valvuloplasty and surgery patients [30,57]. Balloon valvuloplasty was associated with a higher incidence of important aortic regurgitation, while surgical patients had a higher incidence of residual stenosis. Long-term results are equally encouraging, with nearly two-thirds of patients being free from aortic valve surgery 10 years afterward [58], and most demonstrating catch-up growth of both the aortic valve and the left ventricle [59]. Fetal aortic valvuloplasty is demonstrating encouraging results, when technically successful. In one study, 26 out of 30 fetuses underwent a successful intrauterine angioplasty, with marked improvement in left heart physiology, including markers such as ejection fraction and antegrade flow in the transverse aortic arch [60].

Surgical Valvotomy and Surgical Valvuloplasty

Marked clinical improvement can be expected after successful valvotomy in the neonate [61–64]. This procedure,

as stated previously, should be regarded as palliative rather than curative. Most patients eventually will require reoperation because of progressive aortic insufficiency, aortic stenosis, or both [52,65]. However, current evidence indicates that aortic valve replacement can be safely delayed until implantation of an adult-sized prosthesis [66]. In a report from the German Pediatric Heart Institute, a retrospective review of the early and long-term results of primary surgical aortic valvotomy in 26 neonates and 8 infants was described [36]. The operative mortality was 6%, and the risk factors for early mortality were endocardial fibroelastosis, monocuspid aortic valve, and impaired left ventricular function. The mean follow-up was 115 ± 67 months, and no late mortalities were observed. The freedom from reintervention was 85.1 ± 6.9%, 78.0 ± 9.35%, and 53.5 ± 15.9% at 5, 10, and 15 years, respectively.

Although mortality as high as 30–50% had been reported after aortic valvotomy in infants, this has been attributed, at least in part, to inappropriate patient selection [49,67]. Better understanding of the disease process and improved distinction between HLHS and aortic stenosis with two well developed ventricles have improved results dramatically [19,47,48,64,68]. Operative mortalities approaching zero can be achieved in neonates with isolated critical aortic stenosis [66]. A recent study demonstrated a 30-day survival after surgical commissurotomy of 95% [69]. In another multicenter study, no significant difference in survival between open and closed valvotomy was observed (87% vs. 90%, respectively) [70]. The best results are observed in patients with isolated valvar aortic stenosis [47,63]. Despite reduced early postoperative mortality, surgical repair of congenital aortic stenosis is associated with significant long-term mortality. In one study, postoperative survival gradually decreased from 93% after 30 days to 76% after 25 years [71]. More recent literature suggests that late survival has improved dramatically [66]. Complex cardiac anomalies and endocardial fibroelastosis have been associated with increased operative mortality. The quality of life for long-term survivors of congenital aortic stenosis after treatment is comparable to that of the general population [72].

Aortic Stenosis in the Older Child

Pathologic Anatomy

Compared with patients who become symptomatic early on, aortic stenosis in older children usually manifests as milder forms of valvar obstruction. Although all anatomic variants are possible, more than three-fourths of patients have a bicuspid aortic valve [73]. The etiology of bicuspid aortic valve is not known, although a genetic influence has been suggested [74]. Severely dysmorphic valves and hypoplasia of the aortic annulus are uncommon in this age group.

Pathophysiology

The predominant pathophysiology in older children with aortic stenosis is similar to that in adults, namely increased left ventricular afterload. In compensation for such pressure overload, the left ventricular muscle undergoes concentric hypertrophy. This compensatory phase may progress for a long period without being clinically apparent. Eventually, symptoms develop as ventricular hypertrophy causes decreased ventricular compliance and increased left ventricular end-diastolic pressure. Increased ventricular muscle mass is associated with increased metabolic demand, but there is no accompanied increase in the number of coronary vessels. Myocardial perfusion pressure is also reduced because of the normal or reduced aortic pressure and elevated left ventricular end-diastolic pressure [11]. The end result is a noncompliant and hypertrophied left ventricle that is susceptible to ischemia, especially at the subendocardial layer. Symptoms of volume overload may also develop if the aortic valve becomes insufficient.

Clinical Picture and Diagnosis

In sharp contrast to neonatal critical aortic stenosis, most children who are more than 1 year of age when aortic stenosis is detected show normal growth and development [75]. Typically, these patients are brought to medical attention as a result of an asymptomatic murmur detected during routine medical examinations. Symptoms of aortic stenosis develop over time. Initially, symptoms may be present only during exercise when there is increased demand on cardiac output. As the child grows, the condition of the aortic valve remains the same or worsens, and the relative stenosis becomes more severe. Symptoms of congestive heart failure, syncope, and angina become more prominent and are present even at rest. The incidence of spontaneous bacterial endocarditis is estimated to be 3 per 1000 patient-years [76]. This incidence does not correlate with either the severity of stenosis or surgery [72]. The incidence of sudden death is also increased in children with aortic stenosis and is reported to be between 1.2% and 19% per patient-year. This usually occurs in patients with severe aortic stenosis, and ischemia-induced ventricular arrhythmia is thought to be the cause.

Physical examination is most often noteworthy for a prominent apical impulse, a parasternal thrill, and a crescendo-decrescendo systolic murmur. The murmur usually is associated with a pronounced systolic ejection click. A diastolic murmur of aortic insufficiency may be noted, as well.

The electrocardiogram in children with valvar aortic stenosis demonstrates left ventricular hypertrophy, which correlates reasonably well with the magnitude of the transvalvar gradient. T-wave inversion in lead V_6 is a particularly helpful indicator of severe LVOTO. However, the

correlation between the severity of aortic stenosis and the presence of electrocardiographic abnormalities is very poor [14]. Exercise electrocardiogram may further help to demonstrate physiologically important aortic stenosis as evidenced by ST segment depression and may help guide treatment strategies for patients with less well defined degrees of obstruction. Exercise tests for children with valvar aortic stenosis, in contradistinction to such examinations performed in adults with this lesion, can be performed with very low risk of untoward events.

Chest radiography findings in the child with aortic valve stenosis are often normal, although cardiomegaly or a subtle blunting of the left ventricular apex may be described. Post-stenotic dilation of the aortic root is uncommon until late childhood or early adolescence. Echocardiography and Doppler flow studies are highly reliable for valvar aortic stenosis in children and may reduce the necessity for cardiac catheterization. The correlation between the echo-Doppler and catheter measurement of cardiac gradient is usually good. Catheterization, if needed, most often is required for delineation of additional defects. In addition, therapeutic percutaneous balloon valvoplasty is being performed with encouraging results in this age group.

Treatment

Indications and Timing for Intervention

Any symptoms such as angina, syncope, or congestive heart failure with a hemodynamically significant aortic valve pressure gradient (peak-to-peak gradient >50 mmHg) constitutes an absolute indication for intervention. Severe valvar stenosis with a pressure gradient greater than 75 mmHg is also considered an indication for treatment, even without symptoms.

Mild-to-moderate stenosis (peak-to-peak gradient <40 mmHg) in asymptomatic patients is usually well tolerated. Although the nature of the disease is progressive in a large percentage of patients, it is usually safe to follow these patients with regular noninvasive studies, including electrocardiogram with exercise test and echocardiography. On average, the transvalvar gradient increases by 1 mmHg per year [77]. Echocardiographic evidence of progressive left ventricular hypertrophy, electrocardiographic evidence of left ventricular strain or ischemia, and the presence of ventricular arrhythmia are also strong indications for therapeutic intervention. Controversy exists as to the optimal treatment for asymptomatic patients with pressure gradients between 45 and 75 mmHg. Although each patient should be evaluated individually, evidence suggests that early intervention is beneficial in these patients.

Percutaneous Balloon Valvuloplasty

Percutaneous balloon valvuloplasty is often feasible in this age group. With advances in catheter techniques, balloon valvuloplasty is being applied to an increasing number of cases, even in patients who have undergone procedures for valvar aortic stenosis [78,79].

Surgical Valvotomy and Valvuloplasty

Aortic valvotomy is the standard treatment for congenital aortic stenosis for most children [61,80]. Surgical valvuloplasty is preferable to valve replacement in patients with nonregurgitant trileaflet valves [45]. In cases of recurrent valvar stenosis and regurgitation, extended aortic valvuloplasty has been described [81,82]. Aortic valve repair by multiple techniques, including pericardial leaflet extension, has been reported recently by multiple authors [83–86].

Cardiopulmonary bypass, moderate systemic hypothermia, and antegrade cold cardioplegia are used commonly for extended aortic valvuloplasty. Retrograde cardioplegia, given through the coronary sinus, may be desirable if significant aortic insufficiency is present. Exposure of the aortic valve is through a standard oblique aortotomy toward the noncoronary sinus of Valsalva. The aortic cusp is augmented by extending the commissurotomy incision into the aortic wall around the leaflet incision. The valve cusp attachment is mobilized at the commissures, and the aortic insertion of the rudimentary commissure is freed.

Most commonly, a bicuspid valve is present, with fused commissures that can be divided with a knife to within 1–2 mm of the aortic wall. Care must be taken to distinguish between true commissural fusion and a false raphe, which is frequently present in one of the bicuspid leaflets. It represents a rudimentary commissure but does not reach the wall of the aorta and offers no lateral support. An incision in a false raphe will cause valve incompetence and should be avoided. Congenitally stenotic tricuspid aortic valves are rare. Valve deformity and commissural fusion are usually present, which could make the distinction from a bicuspid valve difficult. When the diagnosis of a stenotic tricuspid aortic valve is uncertain, it should be treated as a bicuspid aortic valve to avoid creating valve insufficiency.

Unicuspid valves are less common in this age group. The technique of valvotomy is similar to that for neonates. Once again, a conservative valvotomy is advisable, because a small incision may reduce significantly the valvar stenosis, and valvar insufficiency is usually the cause of early valve replacement.

Aortic Valve Replacement in Children

It is estimated that within 10–20 years after initial valvotomy, 35% of children will require replacement of their aortic valves [47,71]. Under certain circumstances, repeat valvotomy can be performed if it is expected to relieve the stenosis, even though eventual valve replacement is

inevitable [81,87]. By delaying aortic valve replacement, it is possible to insert a larger size prosthesis and delay the need for anticoagulation and its attendant complications.

The selection of an optimal aortic prosthesis for the pediatric patient is difficult because of several limiting factors. All types of prosthetic valves have inherent drawbacks which are unique in young patients. Both porcine bioprostheses and allograft aortic valves are available in annular sizes suitable for smaller patients, but both valves suffer accelerated calcification and degeneration in the aortic position [88,89]. Such degeneration can lead to restenosis and regurgitation as early as 2 years after valve replacement. Consequently, the use of bioprosthetic and homograft aortic valves is severely limited by the prospect of frequent reoperations. The etiology of prosthetic valve degeneration in the pediatric population is unknown.

Mechanical prostheses do not suffer from limited durability [90]; however, the higher incidence of thromboembolic events associated with mechanical valve use necessitates long-term warfarin anticoagulation that is often poorly tolerated and difficult to monitor in young children.

A pulmonary autograft (Ross procedure) is another viable alternative for aortic valve replacement; this procedure was originally described by Donald Ross in 1967 [42–45,90,91]. The principle of this operation is to replace the aortic valve with the patient's own pulmonary valve, and a cryopreserved pulmonary allograft replaces the native pulmonary valve. The advantage of this operation is the placement of the patient's own pulmonary valve, which has the potential for growth, in the high-pressure aortic position to provide a durable valve, avoiding the potential for immunologic degeneration. The allograft valve, on the other hand, is placed in the low-pressure pulmonary position, which should be well tolerated even if the valve fails over time.

To perform the Ross procedure, cardiopulmonary bypass is established by aortic cannulation and bicaval venous drainage (Figure 30.2) [37]. Once cardioplegia is delivered, the aortic root is explored through a transverse incision. The technique we prefer is the root replacement. The aortic valve leaflets and sinuses are then removed, leaving only the aortic valve annulus. The coronary ostia, with a generous rim of aortic wall around them, are mobilized for coronary implantation. The pulmonary artery is opened transversely before its bifurcation, with great care taken not to damage the origin of the branch pulmonary arteries, and the pulmonary valve is inspected from above. If the pulmonary valve is acceptable, the main pulmonary artery is divided completely. With the guide of a right-angle clamp, a transverse incision is made in the anterior wall of the right ventricular outflow tract a few millimeters below the pulmonary valve. The critical part of valve harvesting is to leave an adequate cuff of right ventricular outflow tract muscle for suturing, without damaging the pulmonary valve, and to avoid injury to the first septal branch of the left anterior descending coronary artery. A shallower incision of the endocardial surface is made at the septum to avoid this pitfall. Once this pulmonary autograft is harvested, it is sutured to the aortic annulus using continuous or interrupted polypropylene suture. We prefer short, running sutures and a second adventitial layer over the posterior part of the circumference to decrease the risk of inaccessible hemorrhage. The coronary arteries are then implanted by continuous suture into circular openings made in the pulmonary arterial wall at the appropriate sites. Occasionally, in a small child or infant, the left coronary artery is harvested as a U-shaped button and implanted into a U-shaped defect in the pulmonary artery autograft wall. Its distal end thus becomes part of the distal aortic anastomosis. The distal pulmonary artery autograft-to-distal aorta anastomosis is then completed. A dose of cardioplegia solution is then given to assess the neoaortic valve function, to test the suture lines for leaks, and to make sure that the coronary arteries fill adequately. After reconstruction of the aorta, a cryopreserved valved pulmonary allograft is used to re-establish right ventricular-to-pulmonary artery continuity. This aortic root replacement represents the most popular surgical technique, and it can be used to deal with various aortic pathologies. Other surgical techniques of the pulmonary autograft procedure include the inclusion cylinder and scalloped subcoronary implantation, although they are technically more complicated and are less popular.

Dilatation of the pulmonary autograft is a major concern after root replacement using the Ross operation. There are some modified techniques associated with the Ross operation that may be used in order to prevent pulmonary autograft annular dilatation. Many groups have described wrapping the autograft with pericardium, Dacron, or Teflon felt at the annular level. However, none of these techniques provides support for the entire autograft with nondilatable material [92–94]. Ungerleider and colleagues have described the inclusion technique with a Dacron tube for the Ross operation [95]. However, this technique, which may limit the potential for autograft dilatation, is limited to the adult patient whose autograft growth is no longer necessary. Both techniques (conventional and inclusion) have been associated with excellent survival, as well as similar rates of long-term autograft failure, in recent reports. For root replacement, autograft dilatation was the main cause of failure. For the inclusion technique, autograft valve prolapse was the main cause of failure [96].

The technical challenge, and the potential for converting a single-valve disease into a two-valve problem, has created

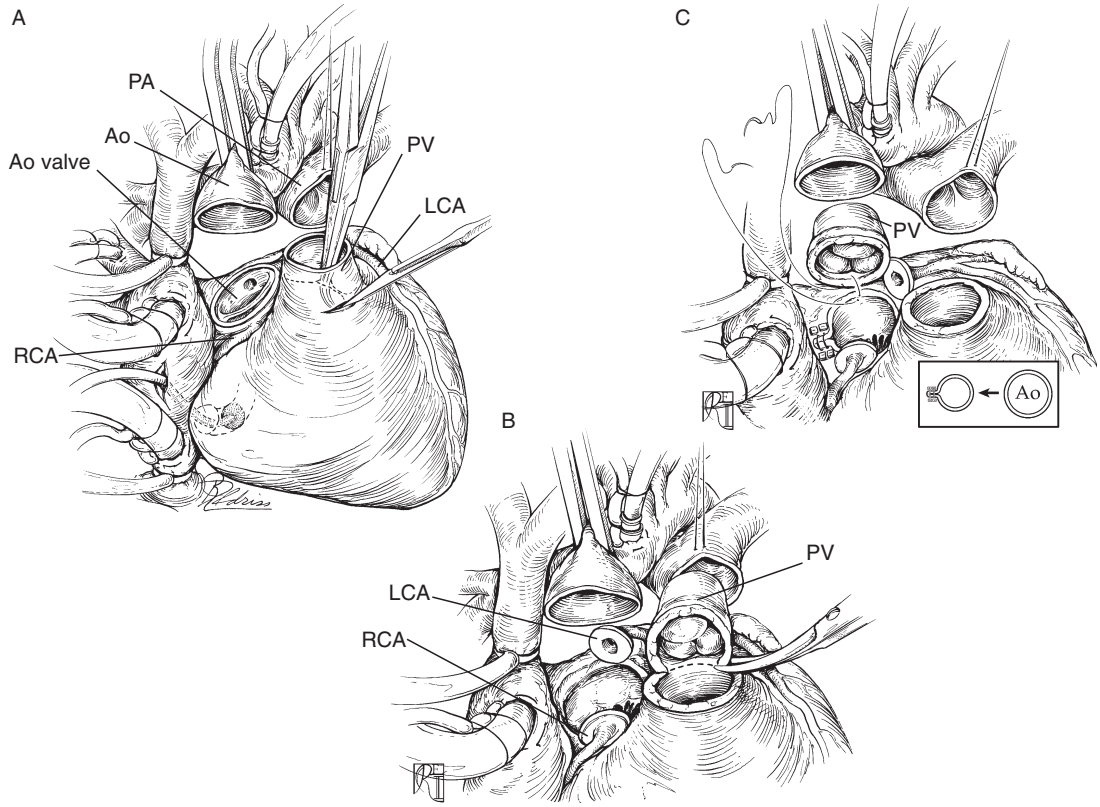

Figure 30.2 A, Conditions for the Ross procedure have been established by aortobicaval cardiopulmonary bypass, aortic cross-clamping, retrograde cardioplegia, and aortic resection. Shown here is the pulmonary autograft being harvested from the right ventricular outflow tract. The right-angle clamp ensures ventriculotomy below the pulmonary valve leaflets. Care is taken to avoid injury to the left coronary artery (LCA), the pulmonary valve structure, and the septal perforator coronary arteries. **B,** The pulmonary autograft harvest is being completed while the right and left coronary artery buttons have been formed and dissected for maximal mobilization. **C,** The pulmonary autograft is now being implanted in the left ventricular outflow tract using a running suture technique. Note that the aortic annulus has been made smaller by annular reduction using pledget-supported sutures. **D,** The neoaorta is shown in the act of reconstruction after implantation and left coronary artery anastomosis. The right coronary artery (RCA) is being anastomosed to the anterior facing sinus of Valsalva. **E,** The completed neoaortic reconstruction is shown after cross-clamp removal. The proximal homograft anastomosis has been completed and the distal connection to the confluence of pulmonary arteries is being performed. **F,** Completed Ross procedure is shown after separation from cardiopulmonary bypass. (Ao, aorta; PA, pulmonary artery; PV, pulmonary valve.)

a certain reservation toward the Ross operation as the procedure of choice in patients with valvar aortic stenosis. Although it has been shown to be safe and effective in relieving all types of LVOTO, there are concerns about the durability and the potential for growth of the pulmonary autograft in the aortic position and the fate of the pulmonary allograft in the pulmonary position [97]. However, full anticoagulation in the young child or infant, combined with the lack of growth potential of the traditional valve prostheses with the necessity of reoperation, are not small matters. This increasing appreciation of the lack of a better alternative has resulted in the renewed interest in pulmonary autograft in the pediatric population. Increasing experience with the Ross procedure has demonstrated that, although it may be the best possible alternative at present for most pediatric patients, it is far from ideal and has its own problems.

Some type of annulus enlargement procedure usually is required with aortic valve replacement using mechanical prostheses, bioprosthetic prostheses, or autografts in the use of a small aortic annulus. Annulus-valve size mismatch is a common problem in the pediatric population; even the smallest available prosthesis (about 16–17 mm) may not fit without enlarging the annulus. In addition, prostheses larger than 16–17 mm are preferable in order to avoid or delay the need for valve replacement as these patients grow. An aortic–mitral annulus enlarging procedure (Manouguian or Nicks procedure) can be used to

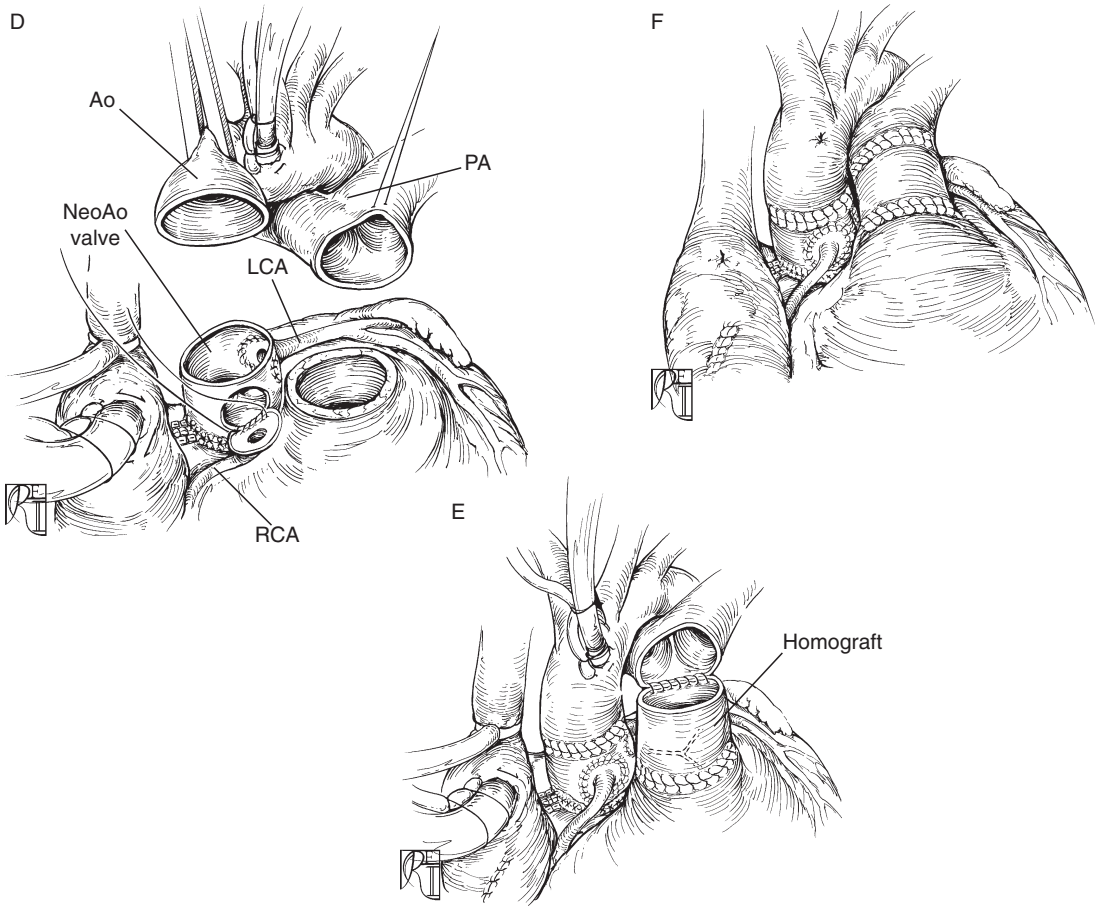

Figure 30.2 (*Continued*)

enlarge the aortic annulus [98,99]. Alternatively, a Konno-Rastan procedure (Figure 30.3) [37,100,101] is used commonly for annulus enlargement and has an acceptable early survival rate of 84% [98,102]. The classic Konno-Rastan procedure will enlarge the entire LVOT in addition to the aortic annulus. The modified Konno-Rastan procedure (Figure 30.4) [37] will limit the enlargement of the LVOT, exclusive of the aortic valve annulus. When significant enlargement of the LVOT is required, avoiding a prosthetic valve, a more complex anterior enlargement is useful. Combining the classic Konno-Rastan aortoventriculoplasty with the Ross procedure (Ross-Konno procedure) will relieve all subaortic, as well as valvar, stenosis (Figure 30.5) [37,41,103,104]. The Ross procedure part is essentially similar to that described earlier. The ascending aorta is transected transversely, and the aortic leaflets are resected down to the aortic annulus. A longitudinal incision is made in the aortic root toward the commissure between the left and right coronary sinuses. Anteriorly, this incision is extended in an oblique fashion into the RVOT. Posteriorly, the interventricular septum is incised leftward to avoid the conduction system, thereby enlarging the LVOT. The incision is augmented to the desired size using an appropriately shaped Gore-Tex or Dacron patch. This allows implantation of the larger pulmonary autograft and relieves the LVOTO. The pulmonary autograft is then sutured into the enlarged LVOT as in the standard Ross procedure. The incision in the RVOT is then repaired with a prosthetic patch or bovine pericardium. In smaller children or in infants, the interventricular septum can be enlarged by using the muscle cuff of the pulmonary autograft, harvested with extra length anteriorly, although some authors caution against this practice due to residual left-to-right shunts and aneurysm formation into the RVOT [85,105]. To avoid this problem, the Ross-Konno procedure can be accomplished by excision of the small aortic annulus or a large part of it. This will result in interruption of the circular collar of the LVOT [85]. This maneuver will enlarge the LVOT and obviate the need for a large incision into the interventricular septum and RVOT (Figure 30.6) [85]. Alternatively, Mavroudis and associates [85] described a modified Ross-Konno procedure, which combines aortic

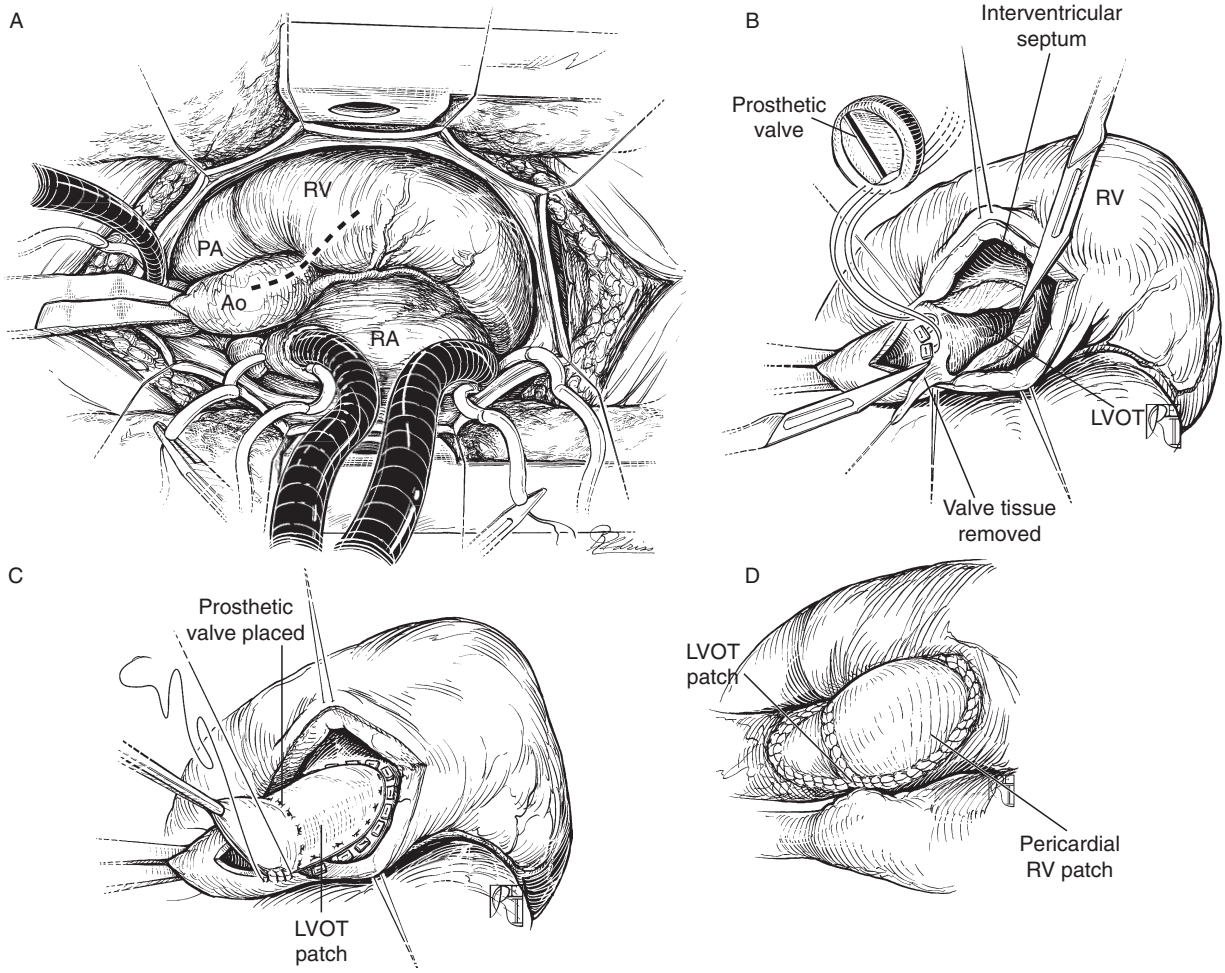

Figure 30.3 A, Operative conditions established to perform the classic Konno-Rastan operation, which involves aortic cross-clamping, cardioplegia (not shown), and the incision for aortoseptoplasty (dotted line). **B,** After the aorta is incised through the right ventricle (RV) and into the interventricular septum, the prosthetic valve can be implanted along the posterior aortic annulus. **C,** The anterior left ventricular outflow tract (LVOT) reconstruction is performed by augmenting the interventricular septum, attaching the prosthetic valve to the patch, and augmenting the ascending aorta as noted. **D,** Shown is the external reconstruction, noting the pericardial right ventricular outflow tract patch which was used to augment the subpulmonic area. annulus resection with an incision in the left ventricular free wall. This procedure has been associated with excellent outcomes without the attendant risk of complete heart block (Figure 30.7) [85].

Results

Balloon Valvuloplasty

Data suggest that the success rate of balloon valvuloplasty, with regard to relief of the transvalvar gradient, is comparable to that of surgical valvotomy [106,107]. Repeat balloon valvuloplasty is also possible in this age group, with good palliative results [107–109]. However, this is necessary in a minority of patients [58]. Although balloon valvuloplasty does incur a higher rate of aortic insufficiency than open surgical valvotomy, this appears to be less problematic in older children compared with neonates [58,108,110]. Furthermore, the excellent surgical results of the Ross operation are preserved in the context of initial balloon valvuloplasty [111].

Open Valvuloplasty and Valve Repair

Open surgical valvotomy remains the standard of care for isolated aortic stenosis in children. Recent literature demonstrates a low operative mortality (<5%) and excellent 10-year freedom from recurrent aortic stenosis or insufficiency (83% and 95%, respectively) [112]. The mortality of valvoplasty, however, is significantly higher if there is

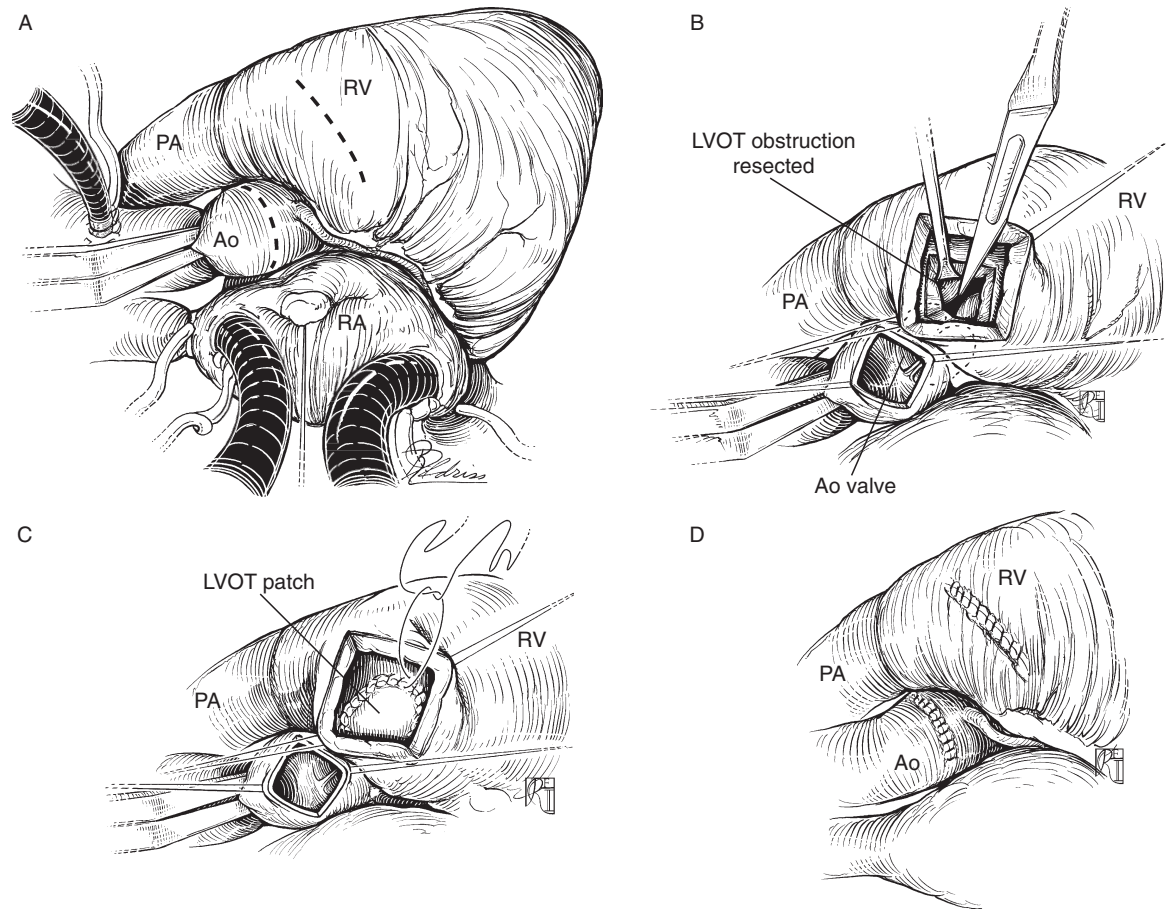

Figure 30.4 A, Operative conditions as indicated by aortic cross-clamp, cardioplegia administration (not shown), and right ventriculotomy site (dotted lines) in preparation for a modified Konno-Rastan procedure. **B,** The aortic valve is identified through the aortotomy. Shown here is sharp excision of the interventricular septum below the aortic valve annulus and away from the atrioventricular node. **C,** The subaortic left ventricular outflow tract (LVOT) is augmented by a patch which effectively closes the created ventricular septal defect. **D,** Completed right ventricular and aortic closures after the operation. significant valvar regurgitation or if the valve is nontricuspid [45]. Under the latter circumstances, aortic valve replacement is preferable. The overall survival of reoperation in congenital aortic stenosis is reported to be 88.6% after 10 years [87]. Long-term results have been published, suggesting good survival (73% at 37 years), but a marked increase in the rate of intervention/death after approximately 15 years [113]. Aortic valve repair can be performed in some patients after previous balloon valvuloplasty with good intermediate-term results [114]: mean peak gradient of 32 mmHg and no more than mild regurgitation at follow-up after 22 months. Furthermore, recent results with pediatric aortic valve repair have been promising [115]. Alsoufi and associates reported their short-term and midterm results of aortic valve repair by cusp extension with autologous pericardium in 22 children who were 5–18 years of age [83]. Among these patients, 16 had previous surgical or percutaneous intervention and 10 had a bicuspid aortic valve. The median follow-up was 1.7 years and ranged from 1 month to 5 years. Follow-up was 100% complete. No early or late mortality was observed, and the 5-year freedom from valve replacement was 75%. Although the overall cohort experienced a progression of their peak aortic gradients, those who had initial postoperative peak gradients less than 30 mmHg had stabilization of their gradients compared with those who had greater postoperative gradients.

Aortic Valve Replacement

Good clinical results, simplicity of performance, as well as the repeatability and safety of the technique, have made aortic valve replacement an important option in children. One recent report followed 45 children over the age of 1

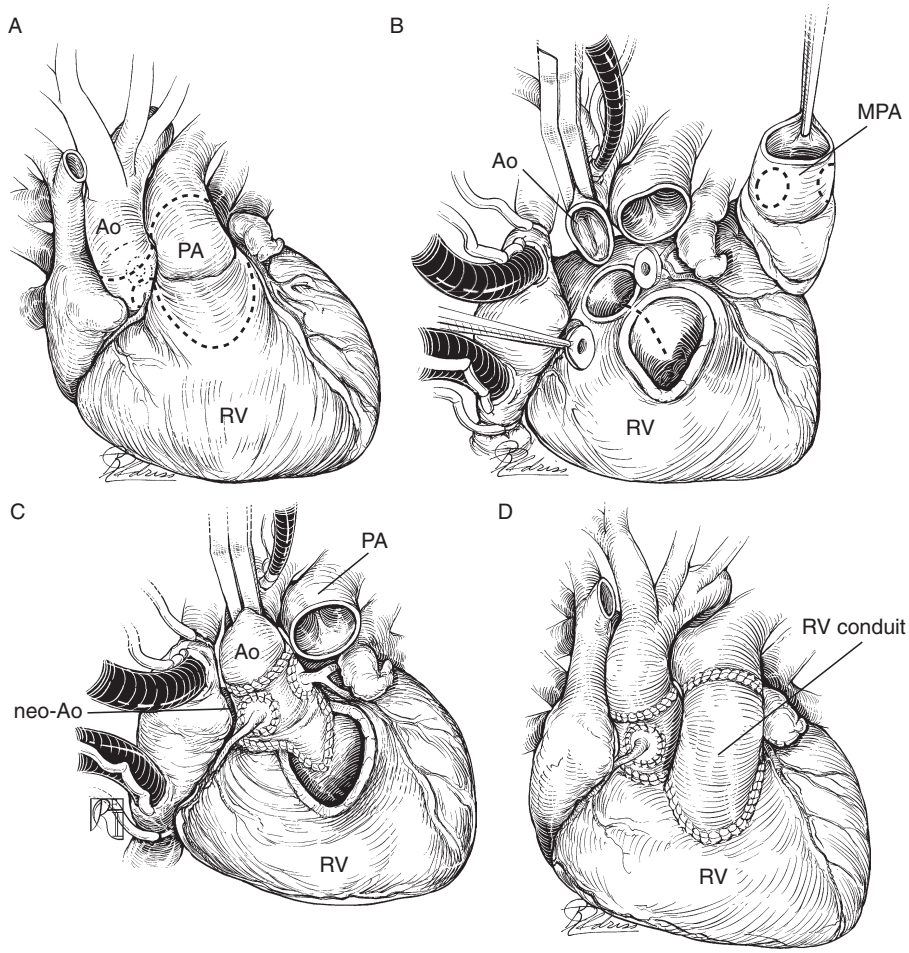

Figure 30.5 A, Intended incision and excision boundaries en route to the Ross-Konno procedure. **B,** After aortic cross-clamping, antegrade and retrograde cardioplegic arrest, aortic resection, coronary mobilization, and main pulmonary artery harvest, the interventricular septal incision is noted by the dotted line. The pulmonary autograft was harvested, with an extra portion of right ventricle to be used for the ventriculoseptoplasty part of this operation. **C,** The neoaortic left ventricular outflow reconstruction is shown using the pulmonary autograft extension into the interventricular septum ("apron extension"). **D,** The completed Ross–Konno procedure is shown after separation from cardiopulmonary bypass. (Ao, aorta, aortic; MAP, main pulmonary artery; PA, pulmonary artery; RV, right ventricle.)

year undergoing aortic valve replacement with bileaflet mechanical prostheses for an average of 9 years [116]. Over half of the patients required concomitant root enlargement procedures. Fifteen year results were excellent: survival was 92% and valve-related event-free survival was 86%. Another study confirmed the current low perioperative mortality in older patients (0%), and the normalization of left ventricular function and size [117]. However, it should be noted that at least one study showed a lower risk of complications (bleeding, thrombosis, infection) and an increased durability amongst biological valves [118].

Ross and Ross-Konno Procedure

It has been shown that the Ross procedure provides optimal hemodynamic performance with associated low valve-related complication rates, when compared with bioprosthetic and mechanical valves [119]. The Ross procedure is also associated with the regression of left ventricular dilatation and hypertrophy, and survival after pulmonary autograft replacement of the aortic valve is significantly better than with other types of valve replacement [120]. In addition, quality of life as reflected by the need for reoperation favors the Ross procedure, which has a freedom from reoperation of 87% after 9 years of follow-up [121]. A more recent study demonstrated improved results, with overall survival and freedom from reoperation of either the homograft or the autograft of 96.7% and 66.2%, respectively, at 10 years. Freedom from reoperation of the left ventricular outflow tract was 60.5% at 10 years [122].

Data on short-term and midterm follow-up of patients undergoing the pulmonary autograft procedure, including

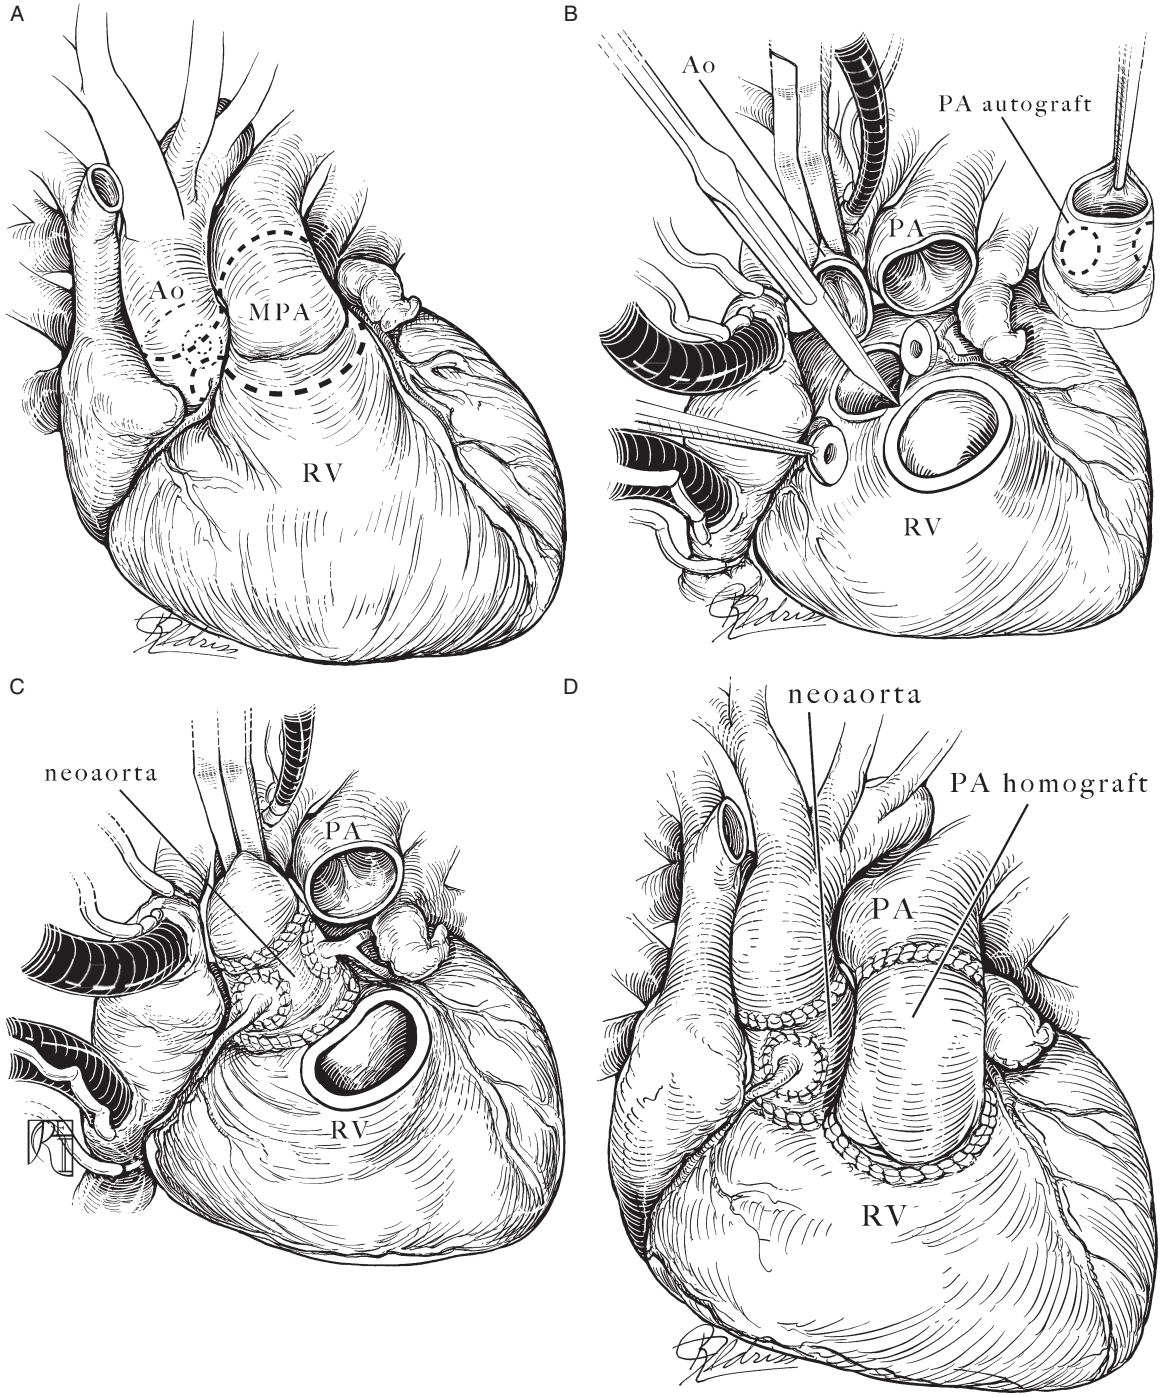

Figure 30.6 A, The intended incision and excision boundaries en route to the Ross–Konno procedure. Note that unlike Figure 30.5, no free right ventricular wall apron is included in the autograft harvest. **B,** After aortic cross-clamping, antegrade and retrograde cardioplegic arrest, aortic resection, coronary mobilization, and autograft harvest, the left ventricular outflow tract is enlarged by a localized linear incision without entry into the right ventricular cavity. **C,** The neoaortic left ventricular outflow reconstruction is shown. The right ventricular outflow is preserved without a septal incision and without the moiety that is required for the "apron extension" shown in Figure 30.5. **D,** The completed Ross–Konno procedure is shown after separation from cardiopulmonary bypass. (Ao, aorta; MPA, main pulmonary artery; PA, pulmonary artery; RV, right ventricle.) (Reproduced with permission from Mavroudis *et al.* [85].)

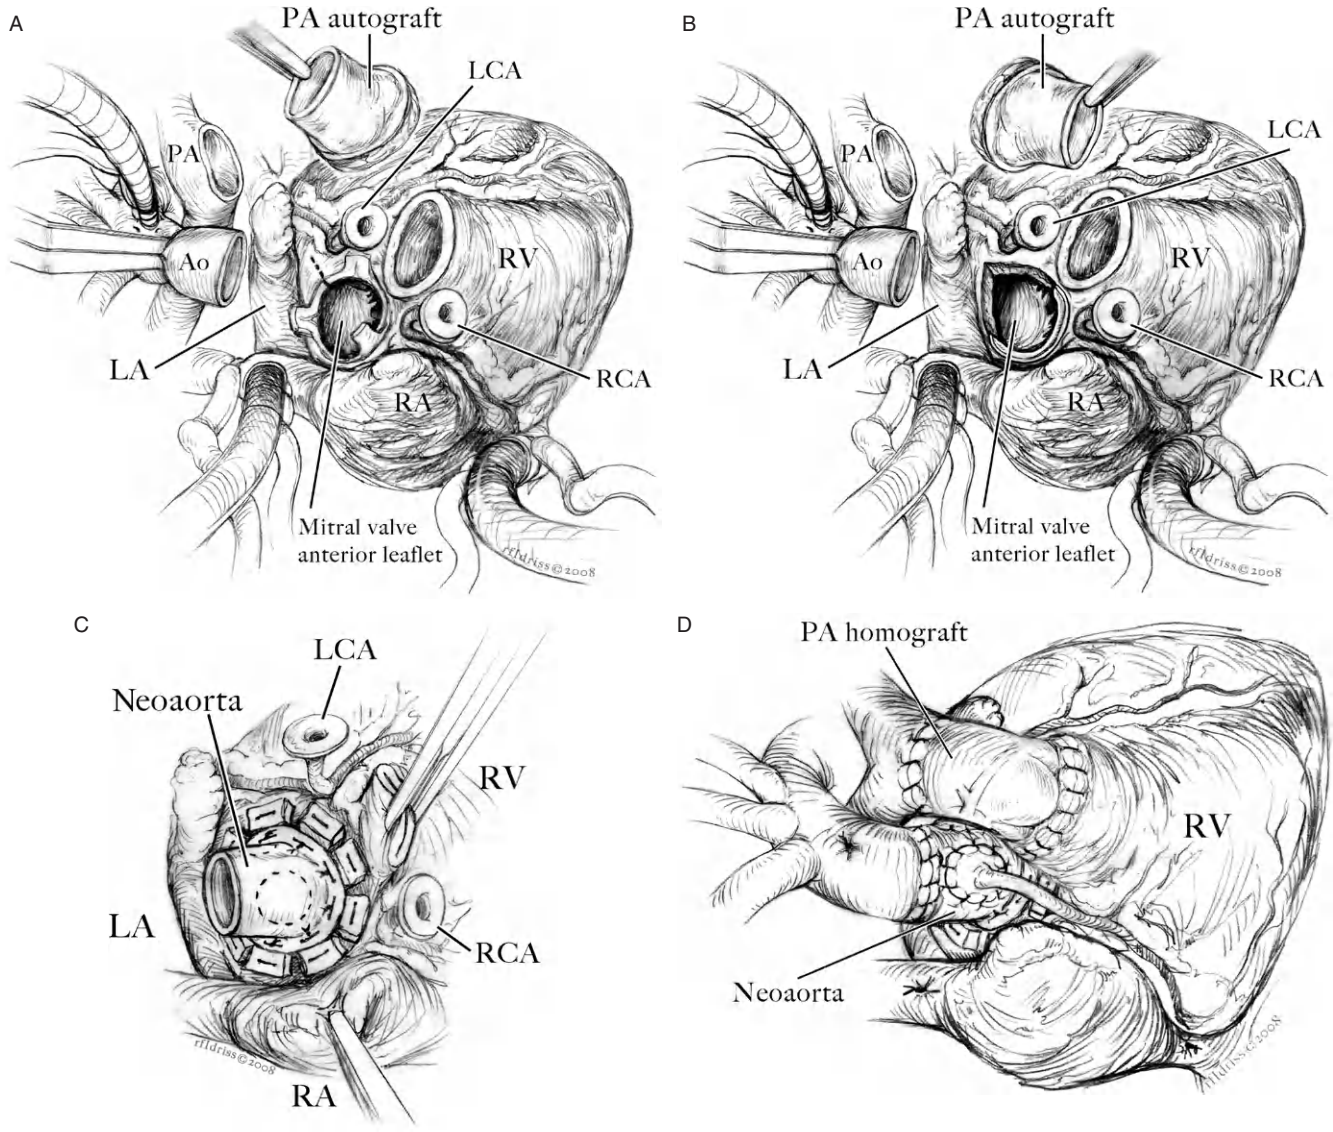

Figure 30.7 Completed modified Ross–Konno operation. **A,** The patient has been placed on aortobicaval cardiopulmonary bypass and the maneuvers involving aortic cross clamping, coronary artery mobilization, and autograft harvest from the right ventricular outflow tract are depicted. The dotted line, posterior to the course of the left main coronary artery, represents the lateral left ventricular free wall incision that will be used to enlarge the left ventricular outflow tract, which will accommodate the pulmonary autograft implantation. Careful dissection and attention to the details of anatomy to avoid injury to the pulmonary autograft, the coronary arteries and the surrounding structures is required. We employ antegrade and retrograde cold blood cardioplegia augmented by topical iced saline administered every 20 minutes for myocardial preservation. **B,** The result of circumferential resection of the aortic valve and annulus demonstrates the enlarged left ventricular outflow tract. The annulus of the aortic valve, especially when small, serves as a restrictive fibrous skeleton, which maintains the diminutive size of the left ventricular outflow. When this fibrous skeleton is resected, the remaining muscle can stretch to accommodate the larger pulmonary autograft. The small incision at the left ventricular free wall can further open the left ventricular outflow tract in order to implant the larger pulmonary autograft. **C,** The pulmonary autograft implantation technique is depicted after annular resection and the left free wall enlarging incision. Ordinarily, a double running suture technique is used for implantation; however, the muscular neck of the left ventricular outflow tract will not hold sutures as well as the previously resected annular ring. Individual interrupted pledgeted sutures help to provide the stability that the implantation procedure requires to sustain systemic pressure. **D,** The rest of the neoaortic reconstruction and the pulmonary homograft are shown after separation from cardiopulmonary bypass. (Ao, aorta; LA, left atrium; LCA, left coronary artery; PA, pulmonary artery; RCA, right coronary artery; RA, right atrium; RV, right ventricle.) (Reproduced with permission from Mavroudis *et al.* [85].)

those with complex LVOTO, suggest that it can provide an effective means of relieving any such obstruction with a low mortality and low valve-related morbidity. The long-term results of the pulmonary autograft procedure for aortic valve disease from the original series by Ross *et al*. reported 10-year and 20-year survival of 85% and 61%, respectively [123]. Freedom from autograft replacement was 88% and 75%, while freedom from pulmonary allograft replacement was 89% and 80%, respectively. Assessment of the pulmonary autograft in children further suggested its growth potential, which is believed to be secondary to passive dilation during the early postoperative period followed by normal active growth [124,125]. The pulmonary allograft in the pulmonary position also promises to be more durable than an aortic homograft in the same position [126]. A more recent study demonstrated a hospital and 5-year survival of 100% and 98%, respectively [127]. Minimal morbidity was noted, and length of hospital stay was, on average, 6 days. Eleven percent of patients required a right ventricular to pulmonary artery conduit exchange. Freedom from significant neoaortic insufficiency at 6 years was 97%. Autograft reoperation rate secondary to aortic insufficiency or root dilation was 0%. Similarly positive results have been reported by other authors [128]. More recently, concerns have been raised that the neoaortic root growth may actually be out of proportion to somatic growth, resulting in neoaortic insufficiency [129]. Routine use of annuloplasty does not appear to reduce the rate of insufficiency [130].

The experience reported in the literature with the Ross-Konno procedure is much less than with the Ross procedure alone. However, relief of LVOTO is usually very effective [131,132]. In addition, aggressive resection of endocardial fibroelastosis and hypertrophic myocardium can be achieved with this exposure. This, in turn, results in improvement of the left ventricular stroke volume and diastolic function. Reddy and associates reported their experience with the Ross-Konno procedure in 11 patients, with median age of 12 months (range 4 days to 17 years) [41]. All patients had evidence of annular hypoplasia, and diffuse subaortic stenosis was present in five patients. The aortic root was replaced with a pulmonary autograft, and LVOT enlargement was performed using a Dacron patch (n = 2), allograft aortic patch (n = 2), or a right ventricular infundibular free wall muscular extension harvested in continuity with the autograft (n = 7). One patient died 14 days after operation. The median follow-up was 8.5 months, and there were no late deaths or reoperations.

Subvalvar Aortic Stenosis

Subvalvar aortic stenosis is defined as obstruction of the LVOT below the level of the aortic valve. This lesion has an incidence of 0.25 for every 1000 live births, and it accounts for 15–20% of all cases of LVOTO [133]. The most common form of subvalvar stenosis is a fixed obstruction due to abnormally present fibromuscular structures in the LVOT. This form is rarely apparent clinically during the first year of life, except when it is associated with other types of complex cardiac congenital lesions. Hypertrophic cardiomyopathy, which usually causes dynamic obstruction of left ventricular ejection, is much less frequently seen in the pediatric population. Other rare causes of clinically significant subvalvar stenosis include abnormal mitral valve attachments and other uncommon space-occupying lesions in the left ventricular outflow tract.

Fixed Subvalvar Stenosis and Fibromuscular Obstruction

Pathologic Anatomy

Traditionally, fixed subvalvar aortic stenosis has been classified as either discrete or diffuse, although there is probably a continuous spectrum of anatomic presentations. The discrete form of subvalvar stenosis, which represents about 70% of cases, is characterized by a thin, fibromuscular diaphragm found along the space between the base of the anterior mitral leaflet and the bottom of the aortic valve leaflets [134]. This diaphragm typically forms a crescentic or circular extension from the area of aortic-mitral fibrous continuity toward the interventricular septum. Some reports have further classified discrete subaortic stenosis into two distinct anatomic subtypes, membranous and fibromuscular [135]. On the other end of the spectrum is the diffuse form of subvalvar stenosis that is associated with a long tunnel type of fibromuscular ridge extending towards the apex of the left ventricle; about 12% of cases belong to this category [134]. In some patients, it may be difficult to distinguish diffuse subvalvar stenosis from hypertrophic cardiomyopathy.

The aortic annulus in these patients may be reduced in size but the aortic valve usually has normal trileaflet morphology. However, valvar aortic stenosis with associated left ventricular hypertrophy may also be present [136]. Subvalvar aortic stenosis may also be observed in the context of aortic valve insufficiency [137]. Turbulent flow created by the fixed anatomic obstruction is believed to be responsible for gradual thickening of the aortic valve leaflets which may, in turn, contribute to the development of aortic valve insufficiency [134,138].

Subaortic stenosis may be the result of additional structural abnormalities, including abnormal mitral valve position [139], accessory mitral valve tissue [140], anomalous insertion of mitral papillary muscles [141], anomalous muscle bundles within the LVOT [142], or posterior deviation of the infundibular septum without a ventricular septal defect [143]. Associated cardiovascular lesions in the context of subvalvar aortic stenosis are more frequent than

in valvar stenosis and are found in up to 65% of cases [144,145]. Coarctation of the aorta, interrupted aortic arch, ventricular septal defect, and atrioventricular canal defects are commonly identified. Subvalvar aortic stenosis may also be a component of the Shone's complex of multilevel left-sided obstruction [146] and the hypoplastic left heart complex [23,147]. The combination of subaortic stenosis, VSD, and double-chambered right ventricle has also been described [148].

Pathophysiology

Subvalvar aortic stenosis is similar to valvar aortic stenosis in regards to pathophysiology as both lesions are associated with left ventricular pressure overload, concentric ventricular hypertrophy, and myocardial hypoperfusion [11]. For patients with similar degrees of obstruction, subvalvar stenosis is associated with more profound ventricular dysfunction compared with valvar stenosis [149]. Turbulence and jet lesions may damage aortic valve leaflets and render them susceptible to regurgitation and infections. Thick fibrous tissue may develop on the left ventricular surface of the aortic valve leaflets, a process which may deform the valve and thereby exacerbate aortic insufficiency [150].

Although the precise etiology for obstructive fibromuscular tissue in the LVOT is unknown, it is believed that anatomic or physiologic substrates for this lesion are present from birth. A discrete form of obstruction from below the level of the aortic valve develops over time as a result of abnormal contractile motion or abnormal growth and hypertrophy. In addition, the fibrous tissue which coats and tethers the leaflets of the aortic valve may impair its mobility and function, thereby contributing to the LVOTO [150]. Cape, Sigfusson, and coworkers' studies [151,152] postulated a multifactorial etiology for subaortic stenosis that included morphological abnormalities such as steepened aortoseptal angle [153], septal shear stress elevation, genetic predisposition, and cellular proliferation in response to shear stress. Septal shear stress responded markedly to changes in aortoseptal angle (from 103 dynes/cm^2 for a 150-degree angle to 150 dynes/cm^2 for a 120-degree angle) [151]. The presence and location of a ventricular septal defect enhanced this response; reduction in the distance between the ventricular septal defect and aortic annulus caused further increases in septal shear stress. Stress level increases were consistent with cellular flow studies showing growth factor stimulation and cellular proliferation. Echocardiographic studies in patients with fixed subaortic stenosis and intact ventricular septum suggest that, in addition to a steepened aortoseptal angle, these patients also have a significantly wider mitral-aortic separation, a marked aortic valve dextroposition, an increased left ventricular wall thickness, an increased septal thickness, and a smaller LVOT width [133]. A steepened aortoseptal angle has recently been shown to be a risk factor for the development of discrete subaortic stenosis in the adult population [154].

Clinical Picture and Diagnosis

Unlike that of valvar aortic stenosis, discrete subvalvar aortic stenosis rarely is seen as an isolated lesion in neonates and infants before 1 year of age. The progressive nature of this lesion with regard to the degree of obstruction and the development of aortic insufficiency is well documented [144,155]. Contrary to the discrete form of subaortic stenosis, the tunnel type of obstruction often is seen as a component of a complex lesion.

Children with subvalvar aortic stenosis are often found to have a systolic ejection murmur typically seen in patients with LVOTO. A diastolic murmur of aortic insufficiency is heard with increasing frequency as its prevalence increases with age. Although it is possible for the diagnosis to be made during infancy, clinically significant subvalvar aortic stenosis requiring surgery is rarely seen before a few years of age, and the incidence is highest during adolescence. Patients with subvalvar aortic stenosis most commonly show signs and symptoms of ventricular dysfunction or aortic insufficiency. Diminished exercise tolerance is a frequent finding, whereas angina and syncope are relatively uncommon.

Evidence of left ventricular hypertrophy is the most common electrocardiographic abnormality, seen in up to 85% of all children with subvalvar stenosis [155]. It is possible, however, to find normal electrocardiographic study results in patients with severe obstruction. The chest radiograph may show a mild degree of cardiomegaly, similar to that seen in patients with valvar aortic stenosis.

Echocardiography has changed significantly the approach to diagnosing complex congenital cardiac lesions. The combination of M-mode and two-dimensional echocardiography gives both anatomic measurements as well as direct visualization of the narrowed subvalvar LVOT. Continuous-wave Doppler provides estimation of the pressure gradient across the obstruction, while color Doppler study detects aortic insufficiency. With its superior ability to detect and distinguish various forms of obstructive lesions of the LVOT, echocardiography is the diagnostic method of choice.

Combined left and right heart catheterization is recommended to assess for associated cardiac anomalies, which are present in a large percentage of patients. In addition, the severity of obstruction cannot be determined accurately based on echocardiographic evaluation alone, and Doppler study may sometimes overestimate the gradient across a lesion. Cardiac catheterization provides direct measurements of peak-to-peak pressure gradient, as well as a visual road map of the lesion.

Treatment

Indications for Intervention

Surgery is indicated for any patient with symptoms attributable to subaortic stenosis, including shortness of breath, angina, syncope, or diminished exercise tolerance. In addition, evidence of progressive decompensation based on serial noninvasive studies is also an indication for surgery. In asymptomatic patients with discrete subaortic stenosis, a gradient above 30 mmHg constitutes an indication for surgery. Patients with gradients less than 30 mmHg and no significant left ventricular hypertrophy may be followed, but must be monitored for evidence of disease progression, particularly in the first years of life [156]. For asymptomatic patients with tunnel-type obstructions, a gradient higher than 50 mmHg is used. The presence of aortic insufficiency, even with a lesser gradient, is also considered an indication for surgery. Because of the progressive nature of the disease and concerns about damage to the aortic valve, some surgeons advocate surgery for subvalvar aortic stenosis at the time of diagnosis [157].

Subaortic Fibromuscular Obstruction

Subvalvar fibromuscular resection with septal myectomy is the standard surgical treatment for this form of disease. This can be achieved almost always through an aortotomy using sharp dissection. The membrane or ridge may be a complete ring or be crescent shaped, and is removed along with the appropriate amount of underlying septal muscle without creating a ventricular septal defect. Care must be taken to avoid injury to the adjacent structures, such as the mitral and aortic valves, as well as the conduction system.

In older patients with discrete subaortic fibromuscular obstruction, it is sometimes possible to enucleate the lesion by peeling away the fibrous ring from the underlying muscle, the aortic valve, or the anterior leaflet of the mitral valve, depending on the actual situation. However, it is generally recommended that myectomy be performed at the time of ring resection in order to reduce the risk of recurrence [158].

Significant reduction of left ventricle-to-aorta pressure gradient is expected after resection of subaortic fibromuscular obstruction [158]. Darcin and colleagues reported a reduction of the mean systolic gradient from 59.23 ± 35.38 mmHg preoperatively to 9.47 ± 9.91 mmHg postoperatively, with no early or late postoperative mortality [1]. Surgical intervention has also been associated with a reduced incidence of infective endocarditis [159]. It is important to have frequent and careful follow-up evaluation after surgery for subaortic stenosis, because the course of the disease is unpredictable at the time of operation, and recurrence of stenosis and progression of aortic insufficiency have been reported in as high as 55% of cases [138]. Surgery for fixed subaortic stenosis has been associated with geometric remodeling and normalization of the steepened aortoseptal angle in patients up to 10 years of age [133].

Diffuse Subaortic Stenosis

Treatment for the diffuse tunnel form of subaortic stenosis is more difficult, and the selection of procedure is dependent largely on the adequacy of the aortic valve annulus and associated lesions. When there is a well-developed aortic valve of adequate size, a septal ventriculoplasty (modified Konno-Rastan procedure) is the preferred option (Figure 30.4) [37,160,161]. The interventricular septum is exposed through an incision made in the pulmonary infundibulum. The septum is opened longitudinally in a slightly oblique fashion going from right to left, extending to just below the commissure between the left and right coronary cusps. Thickened septal muscle is then resected and the ventricular septal defect is closed using a piece of synthetic or pericardial patch to enlarge the LVOT. The right ventriculotomy can be closed primarily or with a patch. Satisfactory reduction of the LVOT gradient from 50 to 3 mmHg, and a relatively low operative mortality rate (6.2% at 2 years) have been reported [161].

If the aortic valve is damaged as a result of the subaortic stenosis, or if there is concomitant valvar hypoplasia, then an aortoventriculoplasty (classic Konno-Rastan procedure) is needed to relieve obstruction at both levels (Figure 30.3) [37,100,101]. This is similar to septal ventriculoplasty, except that the incision in the interventricular septum is extended upstream through the aortic annulus, and the aortic valve is replaced with a prosthetic valve or aortic allograft. Alternatively, root replacement with pulmonary autograft may be performed (Ross-Konno procedure) [41]. Tabatabaie and associates reported their experience with the classic Konno-Rastan procedure in diffuse subaortic stenosis [162]. Their series included 26 patients with a mean age of 12.8 ± 7 years. The mean peak systolic gradient decreased from 91.3 ± 39.3 to 28.1 ± 17.7 mmHg following surgery, the observed 30-day mortality was 11.5% (three patients), and there were no late mortalities among the 23 other patients.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy, also known as idiopathic hypertrophic subaortic stenosis (IHSS), is a form of ventricular outflow tract obstruction characterized by asymmetric ventricular septal hypertrophy. The histologic hallmark of this disease is the presence of disorganized and bizarrely shaped hypertrophied myocytes. As its name implies, this condition has no known cause and it appears to follow an autosomal dominant transmission. The patient is usually asymptomatic until the second or third decade of life and the condition rarely is seen in the pediatric population.

Obstruction arising from hypertrophic cardiomyopathy can occur along the entire length of the ventricular septum. It can result from the increased bulk of the septum as a form of fixed stenosis, or in the form of dynamic obstruction as seen in systolic anterior motion of the anterior leaflet of the mitral valve. When, in rare instances, infants with hypertrophic cardiomyopathy become symptomatic, the clinical course is atypical compared with that of older patients. The diagnosis is more difficult to make, and progressive congestive heart failure, rather than sudden death, is the most common cause of demise. Risk factors associated with mortality in symptomatic pediatric patients with hypertrophic cardiomyopathy include a family history of sudden death, the presence of septal hypertrophy measuring 30 mm or greater, and a history of ventricular tachycardia and syncope [163]. Medical management includes β blockade, calcium-channel blockade, and dual-chamber ventricular pacing. A subset of patients with suspected isolated dynamic LVOTO may have isolated or concomitant fixed obstruction, and careful two-dimensional and Doppler echocardiography are needed to identify this group of patients [164]. Surgical experience in the pediatric population has been limited, but septal myectomy is safe and effective in reducing ventricular outflow obstruction. In more severe cases, a Konno-Rastan procedure may also be performed [132]. Minakata and colleagues reported their experience with septal myectomy in 56 pediatric patients with obstructive hypertrophic cardiomyopathy [165]. The mean age at the time of surgery was 11 ± 5.6 years, with a range from 2 months to 20 years. Following surgery, the mean LVOT gradient decreased from 103 ± 34 to 16 ± 12 mmHg, and there were no early deaths. Survival estimates at 5 and 10 years were 97% and 93%, respectively.

Supravalvar Aortic Stenosis

Congenital supravalvar aortic stenosis is a complex anatomical anomaly of the entire aortic root characterized by narrowing of the aortic lumen commencing immediately above the aortic valve. This represents the least common form of LVOTO and occurs in about 5–10% of patients with LVOTO [2,3] Supravalvar aortic stenosis is often part of Williams' syndrome and can also be seen in conjunction with diffuse hypoplasia of the ascending aorta, distal arterial branches, and even of the branched pulmonary arteries [166].

Pathologic Features

Great Arteries

Supravalvar aortic stenosis is broadly categorized as diffuse in 23% of cases or localized in 77% [167,168]. The main feature of this form of LVOTO is severe thickening of the sinotubular ridge creating the characteristic hourglass appearance of the ascending aorta. This results in severe crowding of the aortic root exit, a limited space for the aortic valve leaflet expansion in systole and severe hypertension of the aortic root. On histology, the sinotubular ridge shows intimal hyperplasia, medial dysplasia and thickening with areas of necrosis and calcification. There are also areas of randomly arranged smooth muscle cells, decreased collagen content, and increased collagen deposition. Similar histological changes affecting the aorta may involve the pulmonary arterial tree, but to a much lesser degree [169,170].

Coronary Arteries

The systolic hypertension of the aortic root proximal to the obstruction exposes the coronary arteries to high pressure. Therefore, coronary artery abnormalities are frequently associated with supravalvar aortic stenosis. To varying degrees, intimal hyperplasia, fibrosis, dysplasia, disruption, and loss of internal elastic membrane with indistinct intimal-medial junction, medial hypertrophy, and adventitial fibroelastosis have been found in pathology specimens [167,168,170]. Morphologically, the coronary artery disease is more severe proximally. The coronary arteries are often markedly dilated and tortuous secondary to their exposition to a constantly very high systolic pressure proximal to the sinotubular junction [171]. High systolic pressures can also induce focal dissections and accelerated atherosclerosis of the coronary arteries. The proliferative process causing thickening of the sinotubular ridge can also extend and narrow the coronary ostia, most often the ostium of the left coronary sinus [172]. Also, the free edges of the aortic valve cusps can abnormally adhere to the intimal shelf present at the sinotubular junction. This obstructs flow to the sinuses of Valsalva and consequently entry of blood in the coronary arteries.

Valvar Abnormalities

In most cases, the aortic valve annulus is of normal size and the aortic valve leaflets are not fused and are morphologically normal. However, one should not consider abnormalities of the aortic valve to be uncommon in patients with supravalvar aortic stenosis as they are seen in 30–45% of operative or autopsy cases [168,173–175]. Thickening of the aortic cusps and aortic insufficiency due to the high systolic pressure proximal to the sinotubular junction are the most commonly described abnormalities. In most patients, they are of mild or moderate severity. These findings often will persist after relief of the supravalvar stenosis and in some surgical series, 17–40% of patients operated on for supravalvar stenosis will require reoperation for persistent stenosis [175–177]. Concomitant untreated aortic valve disease has been identified as a risk factor for reoperation and mortality. Also, as mentioned previously, the thickened aortic valve cusps tend to adhere to the

dysplastic sinotubular junction and this may isolate the coronary arteries from the aortic lumen [168,178]. In addition, supravalvar aortic stenosis can be associated with abnormalities of the mitral valve and of its apparatus; mainly fibrous thickening of the mitral leaflets and chordae tendinea [179].

Myocardial Pathology

Left ventricular hypertrophy is common with this form of LVOTO owing to the elevated pressure load on the left ventricular myocardium. The combination of this increased myocardial metabolic demand with the possible limitation of coronary blood flow secondary to the previously described anatomical abnormalities of the coronary arteries can lead to ischemic myocardial damage, which often develops during early childhood and accelerates with age [175].

Pathophysiology and Natural History

The basic pathophysiology of supravalvar aortic stenosis is similar to other forms of LVOTO. Indeed, it causes left ventricular hypertension and secondary concentric left ventricular hypertrophy and myocardial hypoperfusion. However, unlike in other forms of LVOTO, the coronary arteries are exposed to elevated systolic pressure and the coronary blood flow can be limited as described previously owing to accelerated coronary artery sclerosis. This creates the perfect substrate for myocardial hypoperfusion, ventricular fibrillation, and sudden death. Also, this form of LVOTO is often associated with involvement of the pulmonary arteries, aortic arch, and its branches. This complicates the clinical picture and the treatment. Indeed, in the diffuse form of supravalvar aortic stenosis, involvement of the main pulmonary artery and its branches, either in the form of discreet focal stenosis or, more commonly, diffuse hypoplasia, can complicate surgical intervention [180]. As mentioned before, the supravalvar form is the least common of the various types of LVOTO. Genders are equally affected. Studies show a tendency for a severe and rapid progression of supravalvar stenosis, more so than for other forms of LVOTO. On the other hand, spontaneous regression of the peripheral pulmonary stenosis is also possible [181,182]. Sudden death is also frequent if patients are left untreated due to the above-mentioned combination of left ventricular hypertrophy and premature coronary artery disease [168,175].

Clinical Picture and Diagnosis

Congenital supravalvar aortic stenosis can occur as an isolated defect or as a dominantly inherited familial arteriopathy [168]. The association of supravalvar aortic stenosis with elfin-like facies and mental retardation is known as Williams-Beuren syndrome. The Williams-Beuren syndrome is a genomic disorder (prevalence: 1/7500 to 1/20 000) caused by a hemizygous contiguous gene deletion on chromosome 7q11.23 [183]. It affects the elastin gene. Whereas supravalvar aortic stenosis associated with Williams-Beuren syndrome is associated with a complete deletion of this elastin gene and probably a disruption of adjacent genes, cases of familial non-Williams supravalvar aortic stenosis seem to result from a loss-of-function or point mutation of this same elastin gene [184–186]. The male to female ratio is 1.4:1 and patients may be seen as early as the neonatal period or in adulthood. Normally, cardiac symptoms only appear in the late stage of the syndrome [166,187–190]. Obstructive symptoms such as diminished exercise tolerance, syncope, and angina typically form the clinical picture. Systolic and diastolic murmurs may be present and may help in the diagnosis of the anomaly if the other features of Williams syndrome are not present. Signs of left ventricular hypertrophy may be noted on electrocardiography and echocardiography. Evidence of myocardial ischemia and subsequent cardiomegaly and congestive heart failure occurs progressively over time, even during childhood.

In terms of diagnostic studies, the electrocardiography may reveal signs of left ventricular hypertrophy and, if there is limited coronary flow, left ventricular strain. An echocardiography will provide the diagnosis and will delineate reliably the structural anatomy of the LVOT and other valvar abnormalities. It will also allow measurement of the gradient across the LVOT. Similar observations can be made with magnetic resonance imaging. This modality, however, will add information regarding the distal aortic arch and the great vessels that cannot be obtained from an echocardiography study. Cardiac catheterization may also be useful to better examine the status of the coronary arteries and measure precisely a pressure gradient across the LVOT. While performing coronary angiography in these patients, great care should be taken, especially if there is evidence that coronary blood flow is limited, as there is a risk of ventricular fibrillation.

Treatment

Medical and Interventional Management

Although balloon dilation has been reported anecdotally, it has not been accepted as a standard treatment for supravalvar aortic stenosis in most centers [191,192]. One exception is stenosis of the distal pulmonary arterial tree which can be amenable to balloon dilatation with or without stenting. In terms of medical management, agents reducing afterload may possibly reduce coronary perfusion in the context of a hypertrophied myocardium and should not be routinely used [193,194].

Indications for Surgery

As with other forms of LVOTO, the indication for surgery is based on the severity of the symptoms of obstruction. A LVOT gradient of 40–50 mmHg in the context of an important narrowing at the sinotubular junction is an indication to proceed with surgery. In cases where the gradient is less than 30–40 mmHg and there is no left ventricular hypertrophy, it is acceptable to follow the patients clinically and repeat biannual echocardiographic studies. However, considering the progressive nature of this disease, and in order to avoid the detrimental effect of continuously high pressures on the left ventricle, aortic valve, and coronary arteries, earlier surgical treatment may also be indicated.

Surgical Management

Surgical treatment needs to be tailored to the anatomical derangement of individual patients. Relief of all stenotic segments, restoration of normal aortic root geometry, and allowance for growth are principles determining the surgical technique chosen.

Localized Supravalvar Aortic Stenosis

In rare cases, a discrete supravalvar aortic stenosis consists only of a membrane, or localized ring, near or at the sinotubular junction. In such cases, complete excision of the stenotic segment completed by patch closure of the aortic root can be performed with satisfactory results [195]. Most commonly, however, extensive thickening of the aortic wall prevents simple local excision. A longitudinal incision in the ascending aorta across the stenosis and into the noncoronary sinus is used instead. Additionally, an endarterectomy procedure can be performed to excise a stenotic intimal ridge. The longitudinal aortotomy is closed using a teardrop-shaped single-sinus Dacron or polytetrafluoroethylene patch to create an aortoplasty including the entire stenotic segment as far in the aortic arch as is necessary [175,176]. This technique of patch enlargement was first independently reported by McGoon, Starr, and their associates in 1961 [196].

In 1976, Doty and coworkers introduced an extended aortoplasty that involves the creation of an inverted Y-shaped incision across the constricting segment and into the right and noncoronary sinuses of Valsalva (Figure 30.8) [37,197]. This operation provides a more symmetric reconstruction of the aortic root. Even if it may be difficult to achieve completely accurate restoration of the dimensions at the sinotubular junction in comparison with the aortic annulus, excellent hemodynamic results have been reported with this inverted bifurcated patch technique [175–177,198,199]. It remains our procedure of choice for surgical treatment of localized supravalvar aortic stenosis.

For more extreme cases of discrete supravalvar aortic stenosis, it may be necessary to employ a more radical technique, first described by Brom (Figure 30.9) [37,200–202]. This approach, which effectively eliminates the potential stenotic segment and restores normal aortic root geometry, can be used if important narrowing of the left coronary sinus is identified. It involves complete transection of the ascending aorta just above the sinotubular junction. Longitudinal incisions are then carried out into the three sinuses of Valsalva. Three separate triangular prosthetic or pericardial patches are then used to enlarge each sinus of Valsalva. To complete the procedure, an end-to-end anastomosis is fashioned between the reconstructed aortic root and the ascending aorta. This effectively restores the aortic root geometry providing equal diameters at the aortic annulus and sinotubular junction. A modification of the above-described technique was proposed in 1993 by Myers and associates [203]. Its main advantage is to use exclusively autologous tissue for repair, thereby maintaining the potential for growth. This sliding aortoplasty is carried out by cutting out corresponding triangular patches in the ascending aorta and then suturing them into each sinus of Valsalva in an effort to restore aortic root anatomy (Figure 30.10) [37,203].

It is also important to note that abnormalities of the coronary arteries resulting in stenosis and myocardial malperfusion must be addressed at the time of surgical repair. Both coronary artery ostia should be inspected at the time of repair. Patch enlargement of coronary ostial

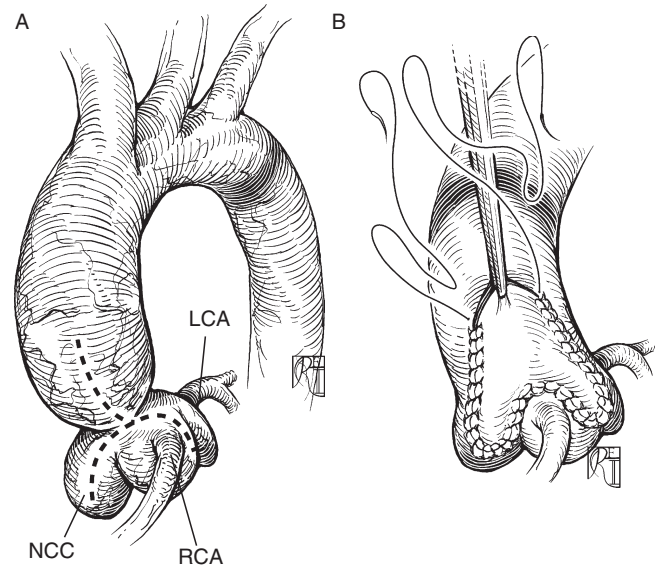

Figure 30.8 A, Projected incisions (dotted lines) for the two-sinus repair of supravalvar aortic stenosis as introduced by Doty [197]. Note that the incision in the right coronary artery (RCA) sinus is made to the left of the coronary artery orifice. **B,** A pantaloon patch is shown augmenting the two sinuses of Valsalva. (LCA, left coronary artery; NCC, noncoronary cusp.)

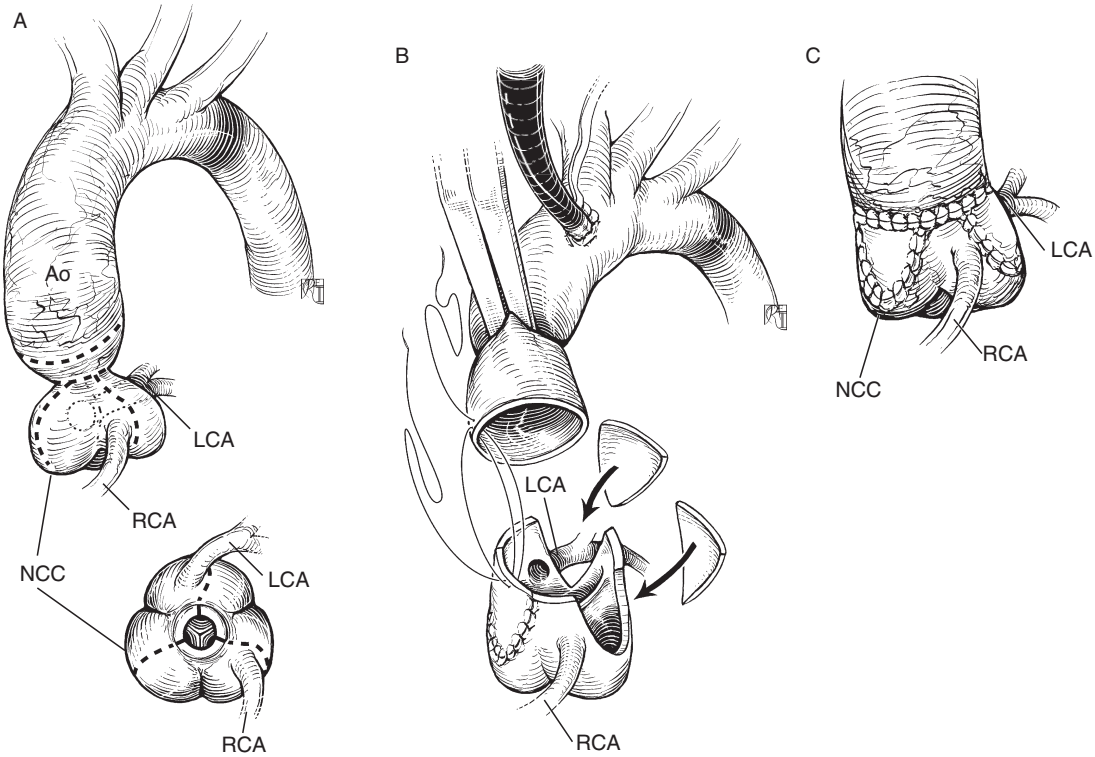

Figure 30.9 A, Projected incisions (dotted lines) for the three-patch repair of supravalvar aortic stenosis as introduced by Brom and colleagues [200]. The incisions in the coronary sinuses are performed to the left of the right coronary artery (RCA) and to the right of the left coronary artery (LCA). Care is taken to avoid any injury to the orifices. **B,** Three tailored pieces of either homograft or prosthetic material are used to augment individually the incised sinuses of Valsalva. The fibrous ring that could interfere with coronary flow is resected in all cases. **C,** The reconstructed neoaorta using the three-patch technique. (NCC, noncoronary cusp.)

obstruction has been described, as well as coronary artery bypass grafting using the internal mammary artery or other conduits [204–206].

Diffuse Supravalvar Aortic Stenosis

Surgical repair of the diffuse form of supravalvar aortic stenosis usually requires intervention at the aortic arch or beyond and, therefore, requires either deep hypothermic circulatory arrest or hypothermic low-flow bypass with direct perfusion of the brachiocephalic vessels. Experience with the diffuse form of supravalvar aortic stenosis is limited. Therefore, the operations reported in the literature are less well defined and their results less studied. Historically, a valved conduit from the left ventricular apex to the supraceliac abdominal aorta has been used for the severe form of diffuse supravalvar aortic stenosis [175,199]. This procedure, however, has been associated with high complication rates, including infective endocarditis, conduit stenosis, prosthetic valve dysfunction, and late mortality. In addition, it does not address actual or potential obstruction of the coronary arteries [207–209]. In recent years, simplification in the technique of implantation has led to a new interest in this approach for cases of very complex LVOTO [210]. However, currently, the preferred approach is the placement of an extended patch, starting from the sinus of Valsalva and extending to the aortic arch and the proximal innominate and left common carotid arteries (Figure 30.11) [37]. Good relief of the obstruction can be achieved with this technique. Indeed, any patch aortoplasty that is short of widening the entire ascending aorta and the aortic arch will be unlikely to correct the underlying anatomic abnormality and its associated physiologic derangement.

Results

Primary repair of localized supravalvar aortic stenosis has very low perioperative mortality. It also has a good late survival [211,212]. A study by Brown and associates reviewed more than 100 cases and established a 98% and 97% survival at 10 and 20 years, respectively [198]. Repair of the diffuse type of this disease is more complex and, in many studies, has a higher early mortality risk. This is thought to be due to a higher level of complexity of the

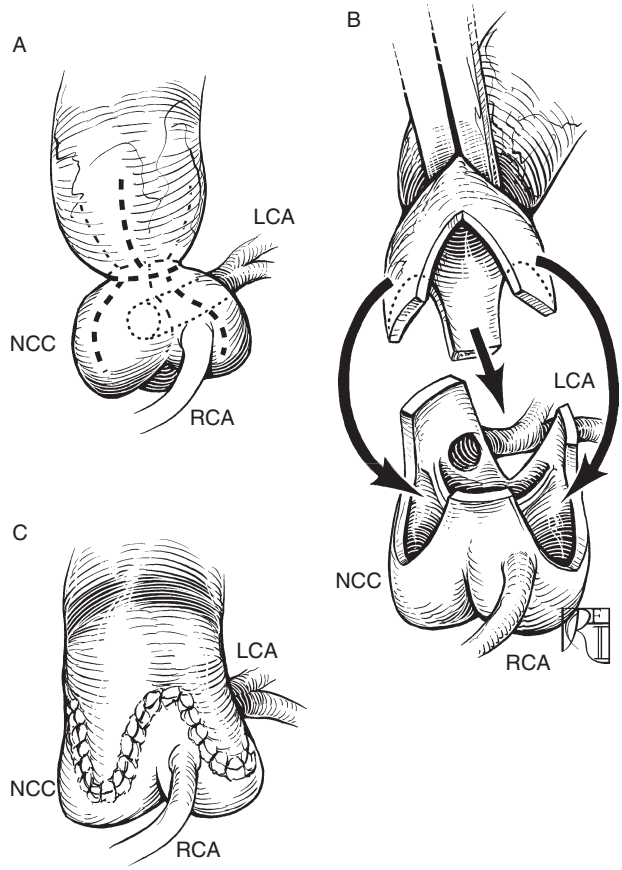

Figure 30.10 A, Projected incisions (dotted lines) for the native aortic reconstruction using a three-sinus augmentation as proposed by Myers and colleagues [203]. **B,** The supravalvar incisions are made in the same manner as in Figure 30.9. Corresponding incisions are made in the ascending aorta for eventual augmentation using native tissue. **C,** The neoaortic reconstruction without prosthetic or homograft material. (LCA, left coronary artery; NCC, noncoronary cusp; RCA, right coronary artery.)

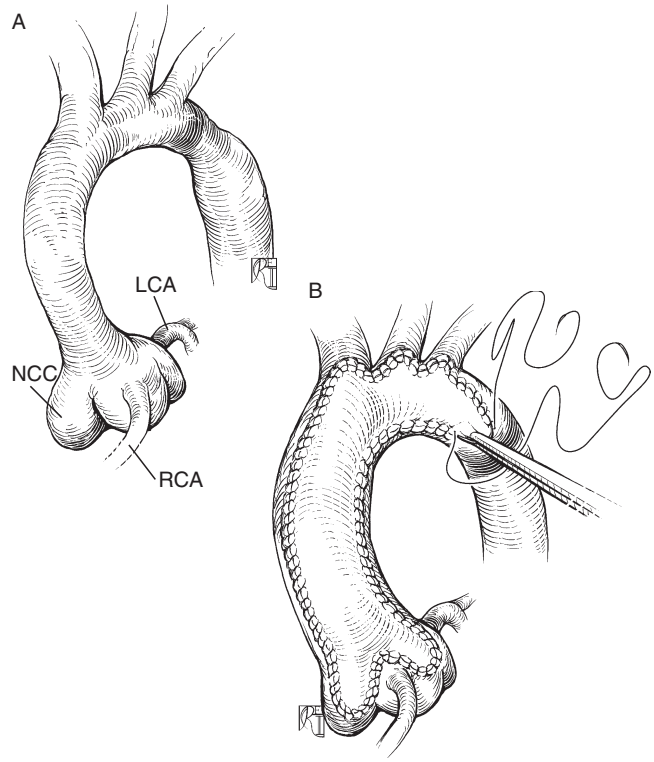

Figure 30.11 A, Shown is the narrow supravalvar area associated with hypoplasia of the ascending aorta and transverse arch. **B,** An extended patch of homograft or prosthetic material can be used to augment the entire arch of the aorta and the supravalvar area. procedure, as well as the possibility for incomplete relief of the obstruction [213].

Left Ventricular Outflow Tract Obstruction as Part of Multiple Obstructions in the Heart–Aorta Complex

Although the scope of this chapter is not to discuss LVOTO when present as part of complex cardiac malformations; for completeness, two clinical entities with multiple obstructions in the left heart-aorta complex will be discussed briefly: Shone's complex and HLHC. In both of these entities, there is no valvar aortic stenosis, as the LVOTO is subvalvar. Unlike Shone's complex, patients with HLHC have as the dominant feature hypoplasia of the structures of the left heart-aorta complex. Patients with HLHC must be distinguished from those with aortic valvar stenosis with LV hypoplasia, as aortic valvotomy is not necessary in HLHC.

Shone's Complex

In 1963, Shone and associates described a developmental complex with four obstructive anomalies that had a tendency to coexist: supravalvar ring of the left atrium, "parachute" deformity of the mitral valve, subaortic stenosis, and coarctation of the aorta [146]. The report was based on eight children, of whom only two exhibited all four obstructive anomalies. The six remaining cases exhibited two or three of the lesions. Although subaortic stenosis and a supravalvar ring of the left atrium were present in all cases, they were considered functionally significant in only six of the eight cases, and in three of the six cases which did not exhibit all four components of the complex. Coarctation of the aorta and a "parachute" mitral valve were present in only four cases. Of significance, hypoplasia of the left heart

was not a feature of any of these cases. The surgical treatment of these patients is challenging; the subaortic stenosis is only part of the overall problem. In many of these patients, long-term outcome is determined by the severity of the mitral valve anomaly and, to a lesser degree, by the subaortic stenosis.

Hypoplastic Left Heart Complex

The term *hypoplastic left heart complex* was first introduced by Tchervenkov and associates in 1998 to describe patients with hypoplasia of the left heart structures, without intrinsic valve stenosis or atresia [23]. Therefore, these patients have LVOTO by virtue of hypoplasia of the aortic valve and LVOT. In these critically ill neonates, there is forward flow in the ascending aorta and into the proximal branches of the aortic arch. The descending aorta circulation is via the PDA and is right-ventricle-dependent. Patients with HLHC bear some similarities to those with Shone's complex. However, hypoplasia of the structures of the left heart–aorta including hypoplasia of the left ventricle, a fundamental feature in HLHC, is not part of Shone's complex as described originally [146]. In order to clarify the terminology, the International Congenital Heart Surgery Nomenclature and Database Project considered HLHC as a subset of hypoplastic left heart syndrome [214]. Shone's complex, described in older patients and lacking the fundamental feature of hypoplasia, is considered a different entity.

The surgical treatment of patients with HLHC centers on whether the patient undergoes a two-ventricle repair or a single-ventricle palliation in the form of the Norwood operation. Although in Tchervenkov and associates' series most patients successfully underwent two-ventricle repair during the initial operation, many of these patients required reoperation for recurrent or persistent LVOTO [23].

CHAPTER 31

Hypoplastic Left Heart Syndrome

Jennifer C. Hirsch,[1] Eric J. Devaney,[2] Richard G. Ohye,[1] and Edward L. Bove[1]

[2]Rady Children's Hospital at the University of California, San Diego, CA, USA

Hypoplastic left heart syndrome (HLHS) refers to a constellation of congenital cardiac anomalies characterized by marked hypoplasia or absence of the left ventricle and severe hypoplasia of the ascending aorta. The systemic circulation is dependent on the right ventricle via a patent ductus arteriosus, and there is obligatory mixing of pulmonary and systemic venous blood in the right atrium. The term hypoplastic left heart syndrome was introduced by Noonan and Nadas [1] in 1958 to describe the morphologic features of combined aortic and mitral atresia. This followed Lev's [2] description in 1952 of congenital cardiac malformations associated with underdevelopment of the left-sided chambers and a small ascending aorta and aortic arch.

Hypoplastic left heart syndrome is a relatively common form of congenital heart disease, occurring in 7–9% of neonates diagnosed with heart disease in the first year of life [3]. Without surgical intervention, HLHS is a fatal lesion, accounting for 25% of cardiac deaths in the first week of life [4]. The first successful palliation of HLHS was reported by Norwood and colleagues [5] in a series of infants operated on between 1979 and 1981. This procedure has been technically refined over the years but the essential components remain 1) atrial septectomy, 2) anastomosis of the proximal pulmonary artery to the aorta with homograft augmentation of the aortic arch, and 3) aortopulmonary shunt or a right ventricle to pulmonary artery conduit. Staged palliation of HLHS with a Fontan operation using the right ventricle as the systemic ventricle was first reported in 1983 [6], and more recent reviews describe continued improvement in short- and long-term survival [7–13].

An alternative approach to staged reconstructive surgery is orthotopic cardiac transplantation. This was first performed successfully by Leonard Bailey and colleagues in November 1985 when he transplanted the heart and ascending aorta of an 8-day-old neonate into a 4-day-old, 2.8-kg infant [14]. This followed years of research, including experimentation with xenotransplantation [15]. The advantage of cardiac transplantation is replacement of an abnormal circulation with a normal four-chambered heart in one operation. The chief disadvantages of this approach are the limited availability of donor hearts, the requirement for lifelong immunosuppression, and late graft failure.

Dramatic improvements in both staged reconstructive approaches and transplantation have been achieved in recent years [16–19]. Currently, both staged reconstruction and transplantation have a role in the management of HLHS [20,21]. The surgical techniques and results of the two methods will be reviewed in this chapter.

Pathology

Pathologic findings in a series of 230 cases of HLHS included 105 with aortic atresia and mitral stenosis (45%), 95 with aortic and mitral atresia (41%), and 30 with severe aortic and mitral stenosis (13%) [22]. The dilated and hypertrophied right ventricle is the dominant ventricle and forms the apex of the heart. The tricuspid valve annulus is invariably dilated and significant anomalies in valve morphology have been described in 5–7% of patients [22,23]. Clinically significant tricuspid regurgitation has been reported in 8–10% of patients studied and has been identified as a significant risk factor in short- and long-term survival [24,25]. In 95% of these infants, the ventricular septum is intact and the left ventricular cavity is only a small slit with thick endocardial fibroelastosis [26]. The ascending aorta is usually very small, ranging in size by two-dimensional echocardiography from 1 to 8 mm, with a mean diameter of 3.8 mm and is less than 3 mm in 55% of cases. The portion of ascending aorta between the atretic

valve and the innominate artery serves only as a conduit for the retrograde flow of blood into the coronary arteries. The main pulmonary artery is very large and is the origin for the large ductus arteriosus carrying blood from the right ventricle into the aorta. A localized coarctation of the aorta is present in 80% of patients [25,27].

Lev had postulated that premature narrowing of the foramen ovale leads to a faulty transfer of blood from the inferior vena cava to the left atrium during fetal life in infants with HLHS [28]. Thus, altered intrauterine hemodynamics may be the physiologic cause of HLHS. Other authors have postulated that the embryologic cause is severe underdevelopment of the left ventricular outflow in the form of isolated aortic valve atresia. This aortic atresia results in the abnormal development of the remaining cardiac structures resulting from the associated blood flow patterns [29]. It is now recognized that in a subset of patients, midgestation fetal aortic stenosis will progress to HLHS. Fetal intervention with aortic valvuloplasty is now offered at select centers for this lesion in an effort to prevent progression to HLHS [30,31].

Although it was initially believed that infants with HLHS had a low incidence of associated genetic and extracardiac developmental abnormalities, recent studies have demonstrated that 28% have a genetic disorder and/or major extracardiac anomalies [32]. A detailed genetic evaluation should be performed in all infants with HLHS. Several studies have reported higher mortality rates with staged palliation for HLHS when associated with extracardiac anomalies and genetic syndromes [31,33,34].

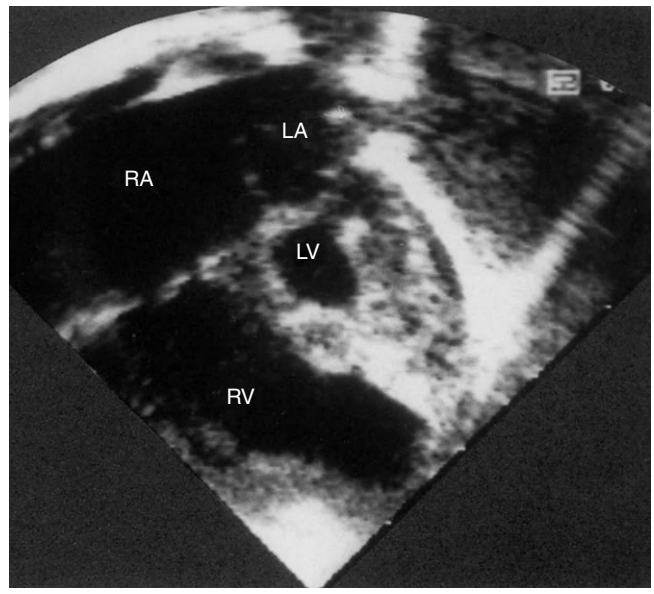

Figure 31.1 Apical four-chamber view (two-dimensional echocardiogram) demonstrating severe hypoplasia of the left ventricular cavity (LV) in an infant with aortic and mitral atresia. Right atrium (RA) and right ventricle (RV) are enlarged. The RV makes up the apex of the heart. (LA, left atrium.)

Clinical Picture and Medical Treatment

Increasingly, the diagnosis of HLHS is being made with fetal echocardiography and there is evidence that prenatal diagnosis improves preoperative clinical status and may even improve survival after first-stage palliation [35]. For patients not diagnosed prenatally, the diagnosis is made in the newborn period because of tachypnea and cyanosis within 24–48 hours of birth. When the ductus arteriosus begins to close, diminished systemic perfusion with pallor, lethargy, and diminished pulses rapidly occurs. Cardiac examination reveals a dominant right ventricular impulse, a single second heart sound, and a nonspecific soft systolic murmur at the left sternal border. Electrocardiogram demonstrates right atrial enlargement and right ventricular hypertrophy. Chest radiograph shows cardiomegaly and increased pulmonary vascular markings. In 2% of patients a reticular pattern of obstructed pulmonary venous return is seen because of a restrictive atrial septal defect. Ductal closure results in diminished systemic perfusion with the development of metabolic acidosis, renal failure, and hemodynamic collapse.

Diagnosis is by two-dimensional and color Doppler echocardiography for determination of cardiac morphology (Figure 31.1) [36] and evaluation of the arch hypoplasia (Figure 31.2) [36]. Doppler color flow shows that the blood flow in the ascending aorta is typically retrograde. Cardiac catheterization (Figure 31.3) [36] is rarely necessary, except to gain additional information in those patients with borderline left ventricular size in order to assist in decision making for the optimal method of treatment. Although initially believed to be deleterious by virtue of acutely decreasing resistance to pulmonary blood flow, current data supports the use of static balloon atrial septostomy to improve hospital survival in HLHS patients with highly restrictive atrial septal defects [37].

The initial support of these infants requires a very specific medical regimen [38]. The goals of preoperative management are to maintain ductal patency and provide the appropriate balance between the systemic and pulmonary vascular resistances. Intravenous prostaglandin E is infused at 0.03–0.1 μg/kg/minute to maintain patency of the ductus arteriosus. This dose may be titrated to keep the ductus arteriosus open, while minimizing the risk of apnea. Oxygen saturations are monitored by pulse oximetry. Acidosis is reversed with sodium bicarbonate and resuscitative efforts. The FiO_2 is adjusted to maintain relative hypoxemia (oxygen saturation, 75–80%), which aids in

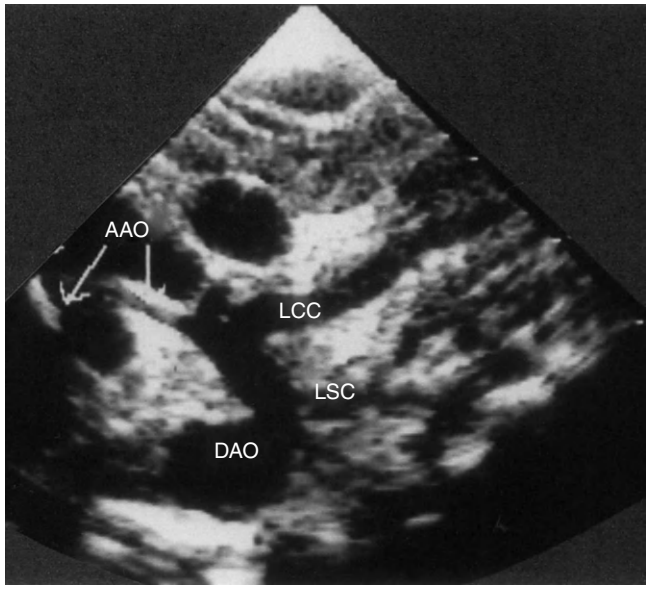

Figure 31.2 Suprasternal aortic arch view (two-dimensional echocardiogram) demonstrating severe hypoplasia of the ascending aorta (AAO), which is 3 mm in diameter in a patient with aortic valve atresia. The aortic arch flow is retrograde from the descending aorta (DAO) from the patent ductus arteriosus (not shown) into the left subclavian artery (LSC), left common carotid artery (LCC), right innominate artery (not shown), and AAO.

Figure 31.3 Anteroposterior view of a retrograde aortogram in a patient with HLHS showing the diminutive ascending aorta supplying the two coronary arteries and the normal caliber postductal descending aorta with coarctation.

preventing the pulmonary vasodilatation associated with high oxygen concentration. Even in the neonate who is being resuscitated from circulatory collapse, ventilation with a high concentration of oxygen is avoided, as it may only further decrease pulmonary vascular resistance and systemic blood flow. Blood transfusion should be performed to maintain hematocrit greater than 40%. Mechanical ventilation is avoided when possible, but ventilated infants may need to be sedated with intravenous fentanyl or morphine to prevent tachypnea. In cases of significant pulmonary overcirculation, hypoventilation to maintain a mild respiratory acidosis (pCO_2 45–55 mmHg) and elevate pulmonary vascular resistance may be employed. Occasionally, inhaled nitrogen can be added to reduce the FiO_2 to between 16% and 18% to further increase pulmonary vascular resistance. Inotropic support is advantageous in patients with depressed right ventricular function. Nourishment generally is provided via intravenous hyperalimentation, avoiding the added risk of necrotizing enterocolitis before surgery. Diuretics are added, as necessary when pulmonary congestion becomes apparent. This regimen balances the pulmonary and systemic vascular resistance, stabilizing the infant while therapeutic options are reviewed.

Therapy

Parents of these children are presented with three options: 1) supportive therapy only (leading usually to a rapid demise); 2) staged reconstruction; and 3) orthotopic cardiac transplantation. Each institution must assess its results with the various modes of therapy and parents must be counseled accordingly. As the results of palliative procedures and heart transplantation for HLHS have improved, in some cases even surpassing those of other complex forms of congenital heart disease, supportive therapy has been challenged [39,40]. The rest of this chapter reviews the techniques and results of staged reconstruction and cardiac transplantation.

Staged Reconstruction

The goal of staged reconstruction is a Fontan procedure, creating separate pulmonary and systemic circulations supported by a single (right) ventricle. The initial stage must provide unobstructed systemic blood flow from the right ventricle to the aorta and coronary arteries, relieve any obstruction to pulmonary venous return, and limit pulmonary blood flow by virtue of an appropriately sized systemic to pulmonary artery shunt. Owing to the relatively high pulmonary vascular resistance present in the newborn period, an arterial shunt is necessary, and the right ventricle is called upon to perform the increased

volume work of both the pulmonary and systemic circulations. Preservation of right ventricular function has been aided by using smaller initial aortopulmonary or right ventricle to pulmonary artery shunts to limit right ventricular volume overload and by an interim procedure between the Norwood and Fontan operations. This staging procedure, either a bidirectional Glenn anastomosis or a hemi-Fontan procedure is usually performed at 4–6 months of age [41]. These procedures provide adequate pulmonary blood flow while decreasing volume overload on the right ventricle, improving effective pulmonary blood flow until the patient can undergo a completion Fontan procedure [42]. As described in detail later in this chapter in the section Second-stage palliation: hemi-Fontan or bidirectional Glenn anastomosis, the hemi-Fontan is a modification of the bidirectional Glenn procedure. The latter is an anastomosis between the transected superior vena cava and the pulmonary artery (the shunt is taken down). The hemi-Fontan involves a side-to-side connection between the superior vena cava/right atrial junction and the pulmonary arteries, routine augmentation of the branch pulmonary arteries, and temporary patch closure between the pulmonary arteries and the right atrium. The current stages of reconstructive surgery are shown in Table 31.1 [36].

First-Stage Palliation: Norwood Procedure

Through a midline sternotomy, the thymus is excised to gain exposure of the aortic arch. Cardiopulmonary bypass is established by arterial cannulation of the distal main pulmonary artery and venous cannulation of the right atrial appendage. A snare is engaged around the arterial cannula after it is advanced into the ductus arteriosus to exclude the pulmonary arteries. A minimum of 20 minutes of cooling to a core temperature of 18 °C begins. During this cooling phase, the ascending, transverse, and proximal descending segments of the aorta are mobilized, and tourniquets are placed around each head vessel (Figure 31.4) [36]. The main pulmonary artery is then divided just proximal to the branch pulmonary arteries, and the opening closed with a polytetrafluoroethylene patch, pericardium, or homograft (Figure 31.5) [36]. The circulation is then arrested, the head vessels are occluded with snares, and a dose of 40 mL/kg of blood cardioplegia is administered. This can be given through a side port on the aortic cannula by clamping the descending aorta. The arterial and venous cannulae are removed. Alternatively, some groups have reported the use of regional low-flow cerebral perfusion in lieu of deep hypothermic circulatory arrest [43]. For this technique, the proximal anastomosis of the modified Blalock-Taussig shunt is performed before arresting the heart. The arterial cannula is placed into the shunt and perfusion given into the innominate artery. A vent is placed in the right atrium to scavenge venous return. The descending aorta is clamped with this technique. To date, there is no evidence in the literature to support any clinical superiority between deep hypothermic circulatory arrest and regional low-flow cerebral perfusion. The choice of perfusion strategy is largely based on center preference and surgeon facility with either technique.

Table 31.1 Staged reconstruction for hypoplastic left heart syndrome.

Procedure	Age
Stage one	**1–30 days**
Atrial septectomy	
Anastomosis proximal pulmonary artery to aorta with homograft aortic arch augmentation	
Aortopulmonary shunt	
Stage two	**4–10 months**
Bidirectional Glenn or hemi-Fontan	
Stage three	**18–24 months**
Completion Fontan	

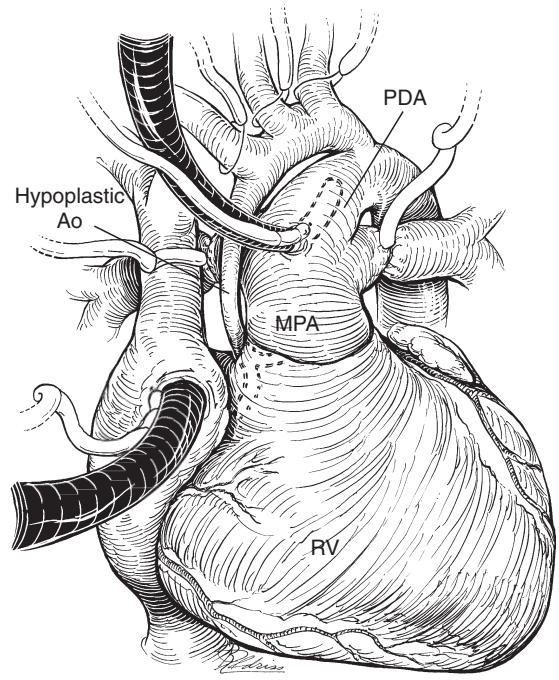

Figure 31.4 Initial steps during stage I reconstruction for hypoplastic left heart syndrome. Arterial cannulation is accomplished through the distal main pulmonary artery and venous cannulation in the right atrial appendage. The arch vessels are exposed and snares placed for occlusion during arch reconstruction. (AO, aorta; MPA, main pulmonary artery; PDA, patent ductus arteriosus; RV, right ventricle.)

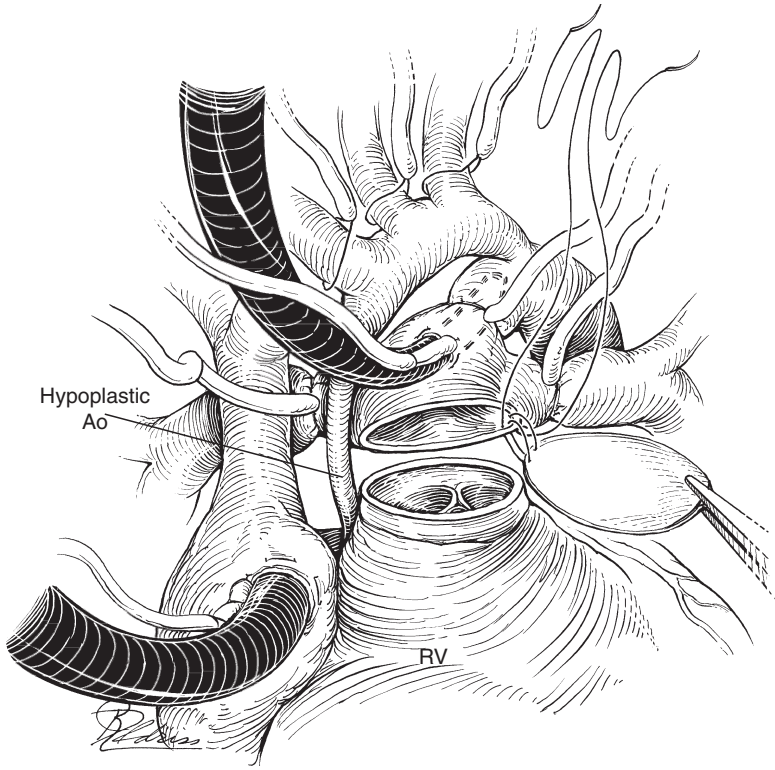

Figure 31.5 The main pulmonary artery is divided and the distal portion closed with a polytetrafluoroethylene patch. (AO, aorta; RV, right ventricle.)

Regardless of which perfusion technique is employed, the septum primum is then completely excised (atrial septectomy). This can be performed through a right atriotomy or, in some cases, through the atrial cannulation site. The ductus is ligated and divided. The remaining ductal tissue (on the undersurface of the aortic arch) is excised completely and the incision is extended at least 10 mm further down the descending aorta onto normal appearing and normal caliber aorta (Figure 31.6) [36]. This incision is then extended proximally under the transverse arch and down the diminutive ascending aorta until the level of the previously divided main pulmonary trunk is reached (Figure 31.7) [36]. Care must be taken to avoid spiraling this incision. A cryopreserved pulmonary allograft is trimmed to fashion a patch that will serve to enlarge the aorta and allow anastomosis to the proximal main pulmonary trunk (inset, Figure 31.7) [36]. Pulmonary homograft material is used for this gusset because it is pliable and relatively hemostatic. Augmentation of the aorta then begins by attaching the ascending aorta to the main pulmonary artery with interrupted monofilament sutures in the proximal corner near the coronary arteries. It is important to maintain a posterior orientation of the ascending aorta relative to the main pulmonary artery. The aorta is then patch augmented with the pulmonary allograft incorporating the

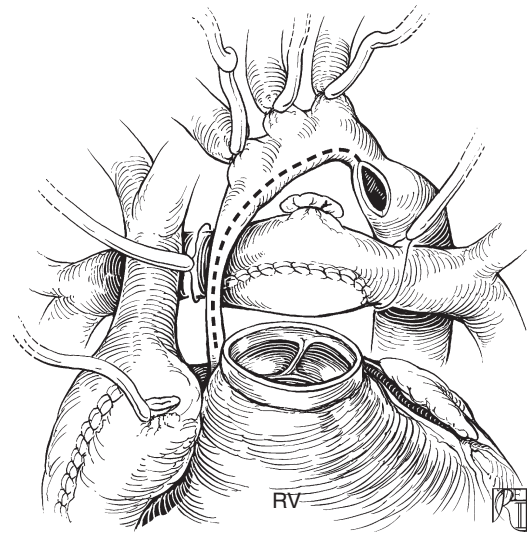

Figure 31.6 After establishing circulatory arrest and excising the atrial septum, the main pulmonary trunk is divided proximal to the bifurcation and the ductus is ligated. The remaining ductal tissue is completely excised from the aorta and the resulting opening is extended both proximally and distally as shown. (RV, right ventricle.)

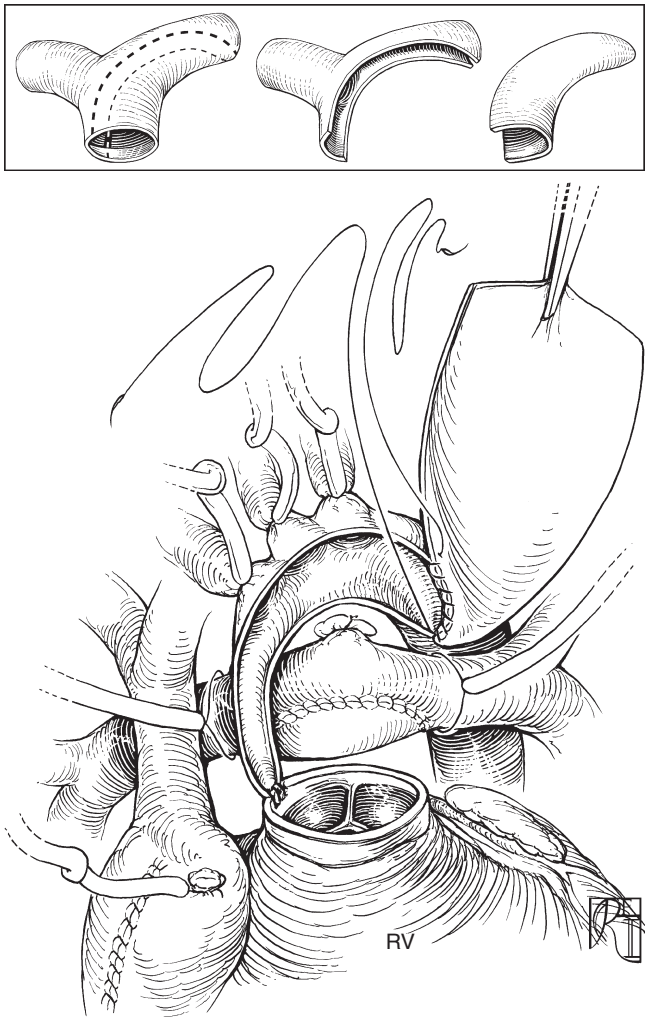

Figure 31.7 The appearance after completion of the aortic incisions. The proximal aorta is anastomosed to the adjacent pulmonary trunk with interrupted fine monofilament sutures. A patch of pulmonary allograft is trimmed and used to augment the remaining ascending, transverse, and proximal descending aortic segments (inset). (RV, right ventricle.)

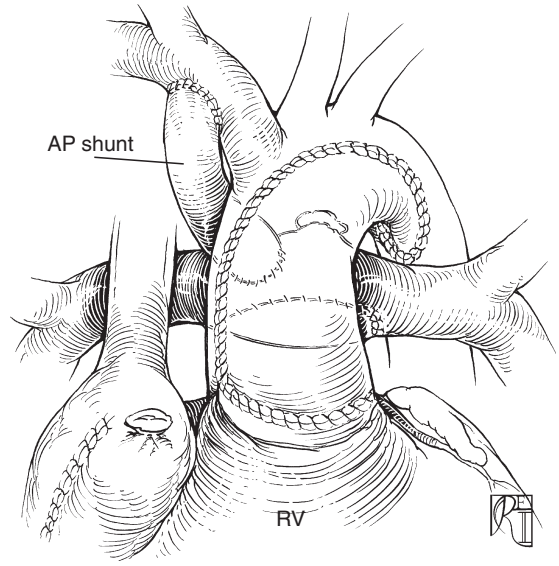

Figure 31.8 The final appearance of the Norwood reconstruction is shown. (AP, aortopulmonary; RV, right ventricle.)

main pulmonary trunk proximally. The heart is flushed with saline to displace air and the cannulae are replaced to begin bypass and commence systemic rewarming to 37 °C. Warming the patient to greater than 37.5 °C is avoided as this has been correlated with neurological complications following deep hypothermic circulatory arrest. A polytetrafluoroethylene shunt is placed from the innominate artery to the central pulmonary artery during rewarming (Figure 31.8) [36]. A 4-mm shunt is used for patients weighing over 4 kg; smaller patients receive a 3.5-mm shunt. The proximal portion of the shunt can be attached before cardiopulmonary bypass initiation and the shunt temporarily occluded or used to provide regional low-flow cerebral perfusion, as mentioned previously. The distal end of the shunt is placed centrally on the pulmonary arteries rather than onto the right pulmonary artery itself to promote even distribution of blood flow to both lungs. Fraser and Mee [44] have reported a modification of the Norwood technique that does not use homograft for the arch reconstruction.

Some groups have described improved survival in patients undergoing a Norwood procedure with the use of a right ventricle to pulmonary artery (RV-to-PA) conduit to provide pulmonary blood flow rather than the modified Blalock-Taussig shunt [45,46]. The modified Blalock-Taussig shunt results in significant diastolic run-off from the aorta, seen on Doppler/echocardiography as reversal of antegrade flow within the descending aorta during diastole. Since 70–80% of coronary blood flow occurs during diastole, this diastolic "steal" may significantly contribute to the decreased coronary flow seen after the Norwood procedure [47–49]. The RV-to-PA conduit has the theoretical advantage of eliminating the aortic diastolic run-off and coronary steal. The authors using the RV-to-PA conduit have noted a less complex postoperative course, in addition to improved survival. The clinically smoother course may be the result of the direct benefit of decreased diastolic run-off to other end organs, as well as indirectly from improved cardiac output. A 5- or 6-mm ringed polytetrafluoroethylene shunt is used if a RV-to-PA conduit is being used. The Single Ventricle Reconstruction trial (SVR), sponsored by the Pediatric Heart Network, is a multi-institutional randomized surgical trial evaluating the mod-

ified Blalock-Taussig shunt versus the RV-to-PA conduit. Results of this trial are forthcoming and should help define any potential superiority between shunt types.

A hybrid approach to the Norwood procedure has been proposed in an attempt to improve early survival by shifting the major surgical intervention until the second stage when the patient is older and end organ function has matured [50,51]. This approach involves stenting the ductus arteriosus to ensure unobstructed systemic outflow, placing bilateral pulmonary artery bands to restrict pulmonary blood flow, and a balloon atrial septostomy to alleviate any restriction to pulmonary venous return at the atrial septum. A comprehensive stage II procedure is performed at 4–6 months of age, which includes removal of the ductal stent, aortic arch reconstruction with Damus-Kaye-Stansel, and bidirectional Glenn or hemi-Fontan. Nationwide Children's Hospital has championed this procedure and reported a 97.5% survival rate with the hybrid stage I palliation and a 92% survival for patients who underwent a comprehensive stage II procedure [52]. For some centers, this is the routine procedure offered, whereas for most, the hybrid Norwood is reserved for select and often high-risk patients [51].

Postoperative Management

After weaning from cardiopulmonary bypass, an atrial monitoring catheter is placed to measure central venous pressure and an infusion of inotropes begins. At the University of Michigan, we routinely employ continuous infusions of milrinone and low-dose dopamine, adding epinephrine in doses of 0.02–0.06 μg/kg per minute if hypotension is significant. Ventilation with an initial FiO_2 of 100% to achieve a pCO2 of approximately 35 mmHg is initiated and adjusted depending on the systemic arterial oxygen saturation and the systemic perfusion. If poor peripheral perfusion with systemic saturations in excess of 80–85% is noted, the FiO_2 and minute ventilation are decreased to avoid excess pulmonary vasodilatation. The opposite maneuvers are used if the systemic oxygen saturation is less than 70–75%. Postoperative management is aimed at maintaining the delicate balance between the systemic and pulmonary vascular resistances, and therefore relative systemic and pulmonary blood flow. Many regimens of ventilation, inotropic and vasodilatory support have been employed, and multiple indicators of the adequacy of perfusion (e.g., mixed venous O_2 saturations, lactate, near infrared spectroscopy) have been used with varying degrees of success [18,53–57]. Ideally, the systemic arterial saturation should be maintained at 70–80%, which generally indicates that an optimal pulmonary-to-systemic blood flow ratio of less than 1 has been achieved. However, measurement of mixed venous and even pulmonary venous O_2 saturations is necessary to accurately assess Qp/Qs. In practice, we have found that serial lactate measurements provide an excellent indication of low cardiac output and have come to rely on these determinations rather than mixed venous O_2 saturations. Some centers have reported the use of phenoxybenzamine (an α blocker) to improve systemic oxygen delivery after the Norwood procedure [18,58].

Despite these measures, most centers continue to report a significant percentage of early deaths following neonatal palliation. This has stimulated investigation into the physiology of single-ventricle patients using mathematical, experimental, and clinical models [59–64]. Many of these efforts have been flawed by the inability to create an analogous animal model that accurately measures pulmonary, systemic, and coronary blood flow. Further studies will help to delineate the relationship between O_2 delivery, O_2 demand, and coronary blood flow critical to survival in this challenging subset of patients.

Results of First-Stage Palliation

At the University of Michigan, the experience with first-stage palliation of HLHS from January 1990 to August 1995 included 158 patients [65]. All patients had classic HLHS, defined as a right ventricular dependent circulation, in association with atresia or severe hypoplasia of the aortic valve. Patients were subdivided into "standard risk" (n = 127) and "high-risk" (n = 31) populations. High-risk patients included those undergoing the Norwood procedure beyond the first month of life, patients with severe obstruction to pulmonary venous return, and those with significant noncardiac congenital conditions (e.g., prematurity, low birthweight, and chromosomal anomalies). There were 120 hospital survivors (76%). Hospital survival was significantly better among the 127 standard risk patients (86%) when compared with those in the high-risk group (42%). The risk factor analysis failed to reveal any effect on outcome of morphologic subgroup, ascending aorta size, shunt size, initial pH at hospital presentation, or duration of circulatory arrest. These findings have been supported by a recent analysis of patients with single ventricle malformations undergoing a Norwood procedure at the University of Michigan from May 2001 to April 2003 (n = 111) [33]. Noncardiac abnormalities ($p = 0.0018$), gestational age ($p = 0.03$), and weight less than 2.5 kg ($p = 0.0072$) again correlated with decreased survival [33].

At the Children's Hospital of Philadelphia, 840 patients underwent stage I surgery for HLHS between 1984 and 1999 [66]. Hospital survival steadily improved from 56% (1984–1988) to 71% (1995–1998). In that series, age over 14 days at the time of surgery and weight less than 2.5 kg at stage I were associated with increased mortality. There was no association between anatomic subtype and mortality in that series, except for patients with an intact atrial septum [67]. In the subgroup of infants with HLHS and an intact atrial septum (18 out of 316 infants over a 6.5-year period), there were only three long-term survivors (83% mortality).

At Boston Children's Hospital, 78 neonates underwent palliative reconstructive surgery between 1983 and 1991. There were 29 hospital deaths (37% mortality) [68]. Analysis of deaths revealed a greater risk of hospital death for infants with aortic atresia and mitral atresia, especially those with ascending aortic dimensions of less than 2 mm. However, these morphologic subtypes have not been associated with increased risk in our experience. A risk assessment scoring system has been devised to predict survival following the Norwood procedure and includes ventricular function, tricuspid regurgitation, ascending aortic diameter, restriction at the atrial septal defect, blood type, and age at time of surgery [69]. Within a single institution, this scoring system had an area under the receiver operator curve of 0.8534 demonstrating a very high predictive value for mortality within the first 48 hours following surgery [69]. Despite excellent predictive characteristics, this scoring system has not been widely accepted.

The most recent data reflect a trend toward continuing improvement in survival for the Norwood operation. Hospital survival for 100 consecutive patients with HLHS undergoing first-stage palliation with a modified Blalock-Taussig shunt at the University of Michigan from April 2000 to April 2002 was analyzed. Overall hospital survival for the entire group was 85% (85/100). For standard-risk patients, as described above, the survival to hospital discharge was 92% (76/83) and for high-risk patients survival was 53% (9/17). Tweddell and colleagues reported a series of 81 consecutive patients (77% with HLHS) undergoing a Norwood operation with a modified Blalock-Taussig shunt with a 93% (75/81) hospital survival [70]. Sano and associates described a hospital survival of 88% (77/88) for patients with HLHS undergoing a Norwood procedure using a right ventricle-to-pulmonary artery conduit [45].

After discharge from the hospital, regular cardiovascular evaluations are important. The infant should be carefully observed for aortic arch obstruction, tricuspid insufficiency, and increasing cyanosis secondary to a limited atrial septal defect, shunt stenosis, or pulmonary artery distortion. Most centers have maintained these patients on aspirin to prevent shunt thrombosis [58]. Aspirin resistance has been identified in 26% of patients with congenital heart disease [71]. The use of clopidegrel should be considered in this subset of patients.

Second-Stage Palliation: Hemi-Fontan or Bidirectional Glenn Anastomosis

To minimize the time during which the right ventricle is subject to volume overload, the hemi-Fontan operation or a bidirectional Glenn anastomosis is typically performed between 4 and 6 months of age [41,42,72,73]. Cardiac catheterization and echocardiography are obtained before this procedure to evaluate pulmonary vascular resistance, pulmonary artery anatomy, tricuspid valve regurgitation, and right ventricular function. Both the hemi-Fontan and the bidirectional Glenn shunt are performed through a median sternotomy. To perform a bidirectional Glenn procedure, cardiopulmonary bypass is achieved with neoaortic arch cannulation and separate right-angle inferior and superior vena cavae cannulas. Alternatively, a single cannula is placed in the right atrium, and the superior vena cava is vented and occluded during the anastomosis. The aortopulmonary shunt is ligated and divided at the time of initiation of cardiopulmonary bypass. If there is any stenosis of the pulmonary artery secondary to the prior shunt or patch, it is repaired with patch augmentation. The azygous vein is ligated and divided. The superior vena caval flow is controlled with a snare, and a vascular clamp is placed at the junction of the superior vena cava and right atrium. The superior vena cava is transected and anastomosed in an end-to-side fashion to the superior aspect of the right pulmonary artery. The cardiac end of the transected superior vena cava is then oversewn.

The hemi-Fontan procedure has the same physiology as a bidirectional Glenn anastomosis but includes an anastomosis of the pulmonary arteries to an incision in the atriocaval junction. Cannulation for cardiopulmonary bypass is accomplished with arterial cannulation in the distal ascending aorta (allograft tissue) and venous cannulation through the mid portion of the right atrial wall. The patient is cooled to 25 °C, and the intraatrial portion of the cavopulmonary connection is performed under a brief period of low-flow bypass. Alternatively, cannulation of the inferior vena cava and high on the superior vena cava can be used to perform the procedure entirely on cardiopulmonary bypass. The aortopulmonary shunt is divided and the pulmonary arteries mobilized from right to left upper lobe (Figure 31.9) [36]. A patch of pulmonary allograft tissue is fashioned for augmentation of the pulmonary arteries (inset, Figure 31.10) [36]. The azygous vein is ligated. The allograft patch is begun at the left upper lobe, incorporating a separate end-to-side anastomosis for a left superior cava, if necessary (Figure 31.10) [36]. The inferior aspect of the right pulmonary arteriotomy is sewn to a separate incision in the right atriocaval junction (Figure 31.11) [36]. The incision is limited to proximal to the atriocaval junction to avoid possible injury to the sinoatrial nodal artery. A patch is placed within the right atrium, which will isolate superior vena caval return into the pulmonary arteries and provide an unobstructed pathway for connection of inferior vena caval return at the time of the Fontan procedure (Figure 31.12) [36]. The atrial septal defect is inspected and enlarged if necessary. This is best done by cutting back the coronary sinus into the left atrium. Tricuspid valve repair is also performed as needed.

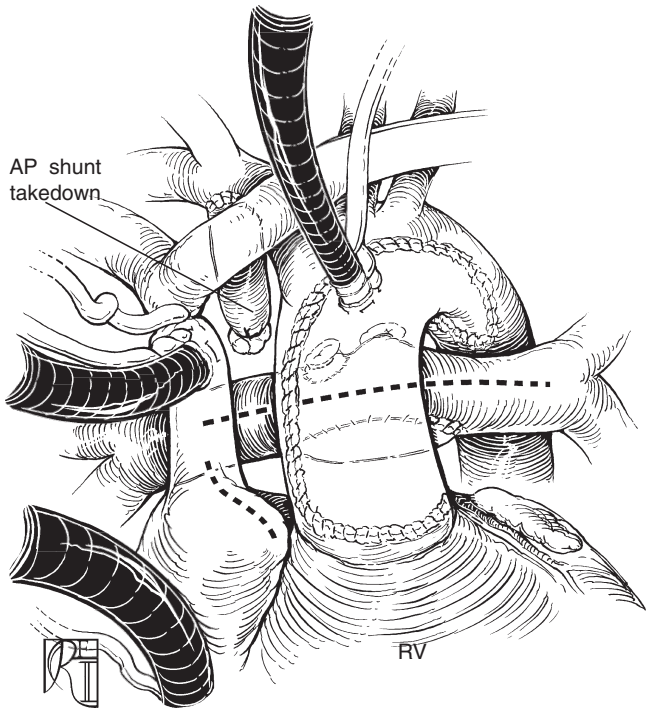

Figure 31.9 The lines of incision in the right atrial appendage and pulmonary artery confluence for the hemi-Fontan procedure are indicated. The systemic-to-pulmonary artery shunt has been ligated and divided. (AP, aortopulmonary; RV, right ventricle.)

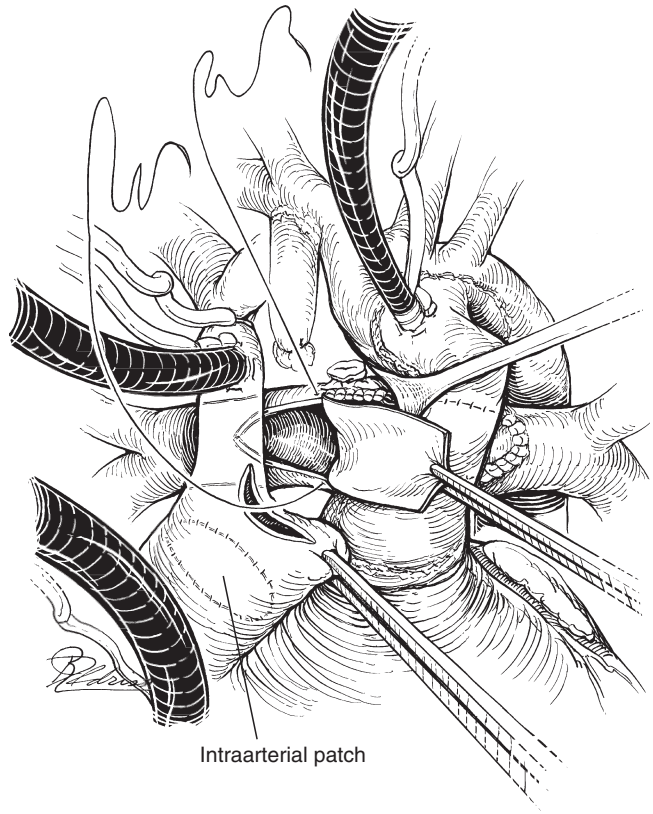

Figure 31.10 A patch of homograft is fashioned and used to augment the left pulmonary artery.

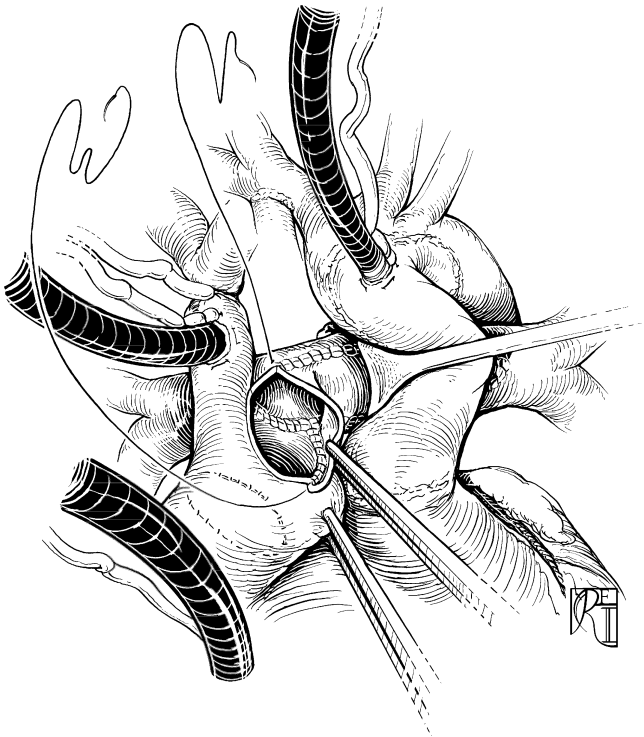

Figure 31.11 The posterior aspect of the right atriotomy is anastomosed to the inferior wall of the right pulmonary artery. The homograft patch is then used to roof the cavopulmonary connection.

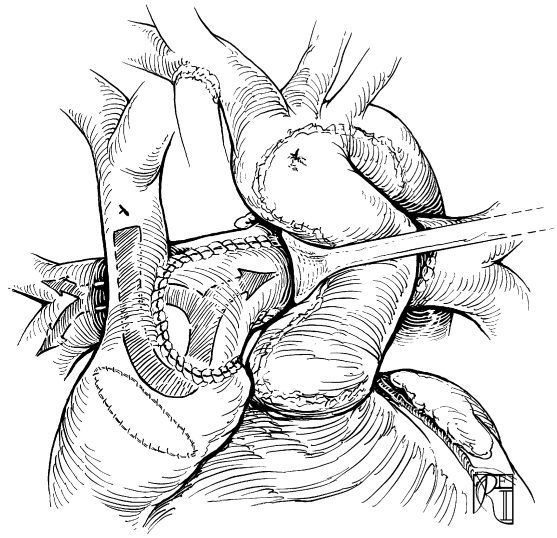

Figure 31.12 The completed hemi-Fontan is shown. A polytetrafluoroethylene patch is in place to prevent the superior vena caval return from entering the right atrium.

The advantage of the hemi-Fontan is that it shortens the time on cardiopulmonary bypass and dissection required for the completion Fontan, requiring only the removal of the intraatrial patch and placement of a lateral tunnel in the right atrium from inferior vena cava to superior vena cava. In addition, the routine augmentation of the branch pulmonary arteries helps to optimize the anatomy for the completion Fontan procedure.

The hospital records of 114 patients undergoing the hemi-Fontan procedure for HLHS between August 1993 and April 1998 at the University of Michigan Medical Center were reviewed [74]. The overall hospital survival was 98% (112/114). Sinus rhythm was present in 92%. At the time of publication, 79 of these patients had undergone the completion Fontan procedure with 74 survivors (94%). A similar study from the Children's Hospital of Boston also revealed that a cavopulmonary anastomosis done as a second-stage procedure for HLHS reduced mortality and improved intermediate survival [75]. At the Children's Hospital of Philadelphia, where this strategy was first employed, overall survival after the bidirectional cavopulmonary anastomosis (1989–1999) was 90%, and there was 100% survival of patients having a bidirectional cavopulmonary anastomosis between 1995 and 1998 [66].

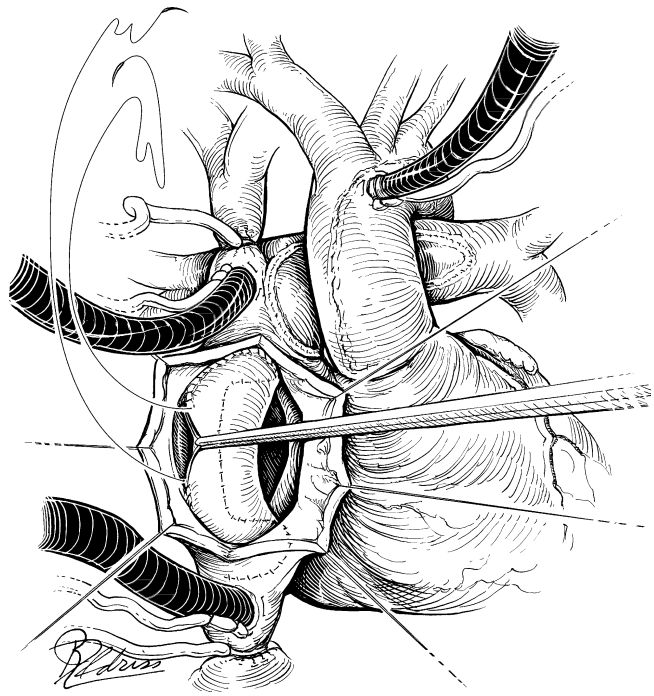

Figure 31.13 A polytetrafluoroethylene (PTFE) tunnel is shown being constructed for a lateral tunnel Fontan. The PTFE patch separating the cavopulmonary connection and the right atrium has been removed.

Third-Stage Palliation: the Fontan Procedure

The completion Fontan procedure usually is performed at 18–24 months of age. The child is evaluated with cardiac catheterization before surgery. The Fontan technique that we have employed for HLHS anatomy is the total cavopulmonary connection with a lateral tunnel (Figures 31.13, 31.14) [36,76]. This technique minimizes the possibility of obstruction of the pulmonary venous return, which can be caused by an atriopulmonary anastomosis. Fenestration of the baffle may help prevent complications in high-risk patients and shorten the period of pleural drainage [77,78]. Technical details are reviewed in Chapter 28, *The Functionally Univentricular Heart and Fontan's Operation*. One hundred consecutive patients with classic HLHS underwent a Fontan procedure at the University of Michigan between June 2000 and August 2004 [12]. Hospital survival was excellent at 97% with durable intermediate survival of 96% at median follow up of 34 months. All patients are in New York Heart Association class I or II. Prolonged pleural drainage (greater than 2 weeks) was associated with the late development of protein-losing enteropathy ($p = 0.035$) [12]. In the largest reported series of the Fontan procedure from the University of Michigan (n = 636), 52% (n = 330) of patients had HLHS [13]. In this series, long-term survival was excellent at 97%. The association between prolonged chest tube drainage (greater than 2 weeks) was again associated with the development of protein-losing enteropathy ($p < 0.0001$) as well as dimin-

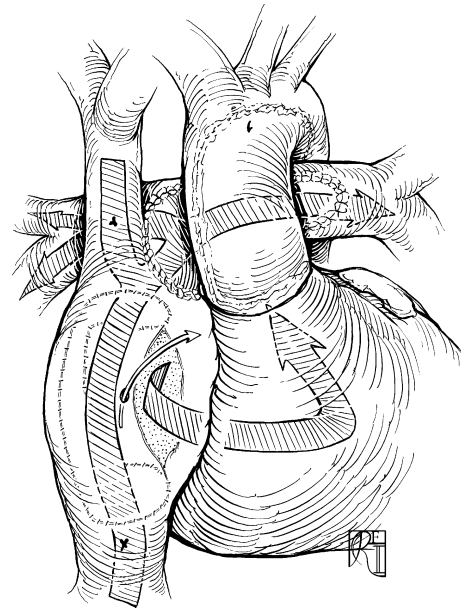

Figure 31.14 The completed Fontan procedure showing the systemic venous return from the superior and inferior vena cavae directed to the pulmonary artery. The smaller arrow illustrates the fenestration.

ished short-term ($p = 0.026$) and long-term (<0.0001) survival [13]. At the Children's Hospital of Philadelphia, overall survival after the Fontan procedure for stage III was 87%, and hospital survival after the Fontan operation has improved from 76% (1984–1988) to 100% (1995–1998) [66]. Most of these patients had a lateral tunnel with fenestration. In that series, 61 of the patients are now over 10 years of age. Several other centers have also reported significant improvements in survival following the Fontan procedure for HLHS [7,9,79,80]. A number of groups are now advocating the use of an extracardiac conduit to complete the Fontan procedure [10,81–83]. This technique may offer significant advantages, concerns include the risk of thromboembolic complications inherent to prosthetic conduits in the venous system as well as issues with somatic growth. Superiority has not been established between the extracardiac and the lateral tunnel Fontan.

Detailed computational fluid dynamic methods have been applied to the study of cavopulmonary connections [84,85]. This data has placed a greater emphasis on streamlining the cavopulmonary anastomotic design to optimize clinical results, limit energy loss, and equalize the distribution of inferior vena cava return into the branch pulmonary arteries. The lateral tunnel Fontan performed after the hemi-Fontan has been shown to be the most energy-efficient cavopulmonary connection with equal distribution of inferior vena cava return [85]. The turbulence within the cavopulmonary connection is magnified at increasing flow rates, which may contribute to the decreased exercise tolerance seen in many patients following the Fontan procedure [84].

Ongoing considerations for the Fontan procedure in this subgroup of patients include minimization of thromboembolic events, preservation of right ventricular and tricuspid valve function, and prevention of arrhythmias.

Neurodevelopmental Outcomes

Patients with HLHS, like any patient with cyanotic congenital heart disease, are at risk for neurodevelopmental delay for multiple reasons. Cyanosis, congestive heart failure, and central nervous system abnormalities are associated with HLHS and can contribute to developmental delay. In addition, cardiopulmonary bypass and hypothermic circulatory arrest at the time of repair can cause neurologic injury. In a study from our institution, Goldberg and colleagues evaluated 51 patients with single ventricle physiology, 26 patients with HLHS, and 25 patients with other cardiac anomalies [86]. The primary testing methods were the Wechsler Preschool and Primary Scale of Intelligence—revised for children 34–87 months of age and the Weschler Intelligence Scale—third edition for children 72 months to 17 years of age. Additional tests included the Bayley Scales of Infant Development, the Vineland Adaptive Behavior Scales, and the Child Behavior Checklist. The results showed that children with HLHS scored statistically lower than non-HLHS children with single ventricles. However, neither group scored significantly different from the population standards. As has been seen in children with congenital heart disease in general, patients in this study scored significantly better on tests of verbal intelligence when compared with motor skills assessments. Socioeconomic status, hypothermic circulatory arrest, and perioperative seizures were significant risk factors for impaired neurodevelopmental outcome. Duration of cardiopulmonary bypass, cardiac arrest requiring resuscitation, and clinical shock or pH less than 7.10 did not correlate with a poor neurodevelopmental result.

Orthotopic Cardiac Transplantation

Despite improving results following staged palliation of HLHS, the mortality of the reconstructive surgical approach has remained high in many centers. Because of this high mortality, interest in neonatal heart transplantation for HLHS continues in select centers and for high-risk patients. Heart transplantation provides a structurally and physiologically normal heart in one operative procedure. All results of neonatal cardiac transplantation must be analyzed realizing that 10–25% of infants listed for transplantation will die awaiting a donor heart [87]. Immunosuppression techniques and postoperative rejection surveillance with treatment of rejection and infection are discussed in Chapter 42, *Heart Transplantation*. This section will concentrate on techniques specific to neonates and their results.

Surgical Technique

Most donor hearts for neonates come from infants who have been the victims of birth asphyxia, sudden infant death syndrome, or trauma. Currently, all donor procurements are performed at the donor site of origin. Cardiopulmonary resuscitation and aggressive use of inotropic support in neonatal donors are not considered contraindications for cardiac transplantation. A donor-to-recipient weight ratio of up to 4.0 has been successful [87]. The donor cardiectomy is modified in that the entire aortic arch is harvested, well beyond the insertion of the ligamentum arteriosum.

The surgical technique of heart transplantation for infants with HLHS was originally described by Bailey and coworkers [88]. The implant is performed with cardiopulmonary bypass and profound hypothermia to 20°C. The technique originally described by Bailey and colleagues used deep hypothermia and circulatory arrest for the entire implant and averaged circulatory arrest times of 56 minutes [89]. Since that time, technical refinements have been

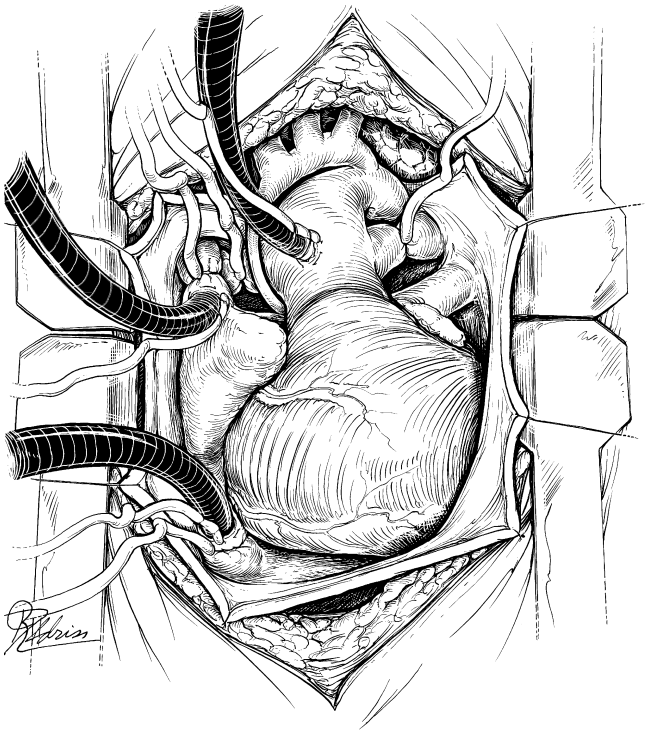

Figure 31.15 Cannulation for orthotopic cardiac transplantation in an infant with hypoplastic left heart syndrome. Arterial perfusion is via the main pulmonary artery (MPA). Note snares around right and left pulmonary arteries to prevent flow to the lungs. Venous return is with bicaval cannulation.

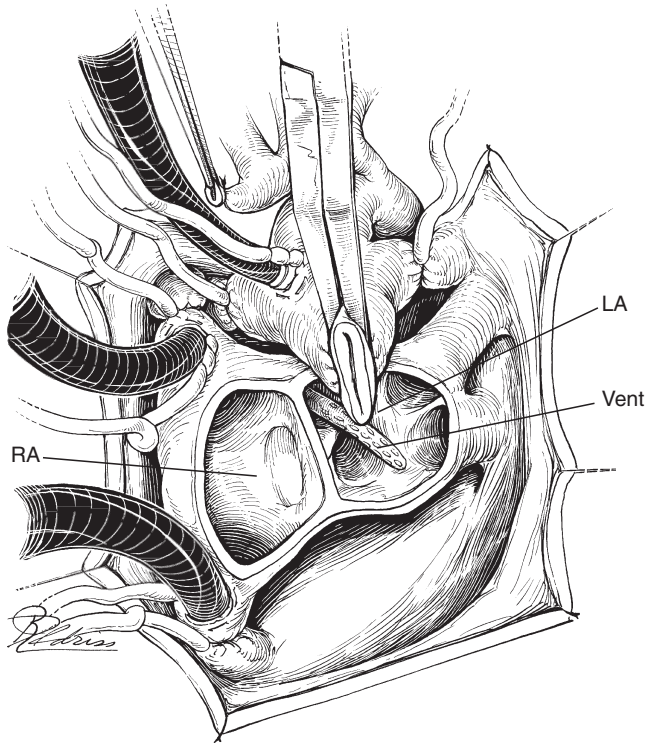

Figure 31.16 The hypoplastic heart has been excised after placement of a cross-clamp on the main pulmonary artery (MPA) and ligation and division of the tiny ascending aorta (Ao). Snares around the superior and inferior venae cavae have been engaged. Excision of the donor heart is performed with extracorporeal circulation continuing. (LA, left atrium; RA, right atrium.)

described, which help to minimize circulatory arrest and myocardial ischemia [38,90] (Figures 31.15–31.19) [36]. The decrease in donor myocardial ischemic time allows acceptance of donors from a wider geographical area.

Postoperative Support

In the current era, most transplant programs treat infant transplant recipients with triple therapy immunosuppression using corticosteroids, tacrolimus, and mycophenolate mofetil (MMF). Methylprednisolone is given at a dosage of 10 mg/kg intravenously at the start of cardiopulmonary bypass and again when circulation is resumed after arch reconstruction. A tapering dosage of methylprednisolone is used until the child tolerates oral feedings and then switched to prednisone with a target prednisone dose of 0.5 mg/kg/day. With no evident rejection (by echocardiography or biopsy), the steroids may be weaned to 0.2 mg/kg/day over the next several months, and some centers discontinue it completely.

In the absence of prohibitive renal dysfunction and oliguria, infants are initially started on tacrolimus, which can be administered intravenously at 0.5 µg/kg per hour or orally (usually NG) at 0.05 mg/kg per dose twice daily. Perioperative blood levels of 12–15 ng/mL (by whole blood high-pressure liquid chromatography) are attained. Alternatively, if the initial postoperative renal function is poor, antithymocyte globulin (ATG) therapy can be used for induction, until the renal function normalizes.

Mycophenolate mofetil is an antiproliferative agent and potent inhibitor of de novo purine biosynthesis. Mycophenolate mofetil, as a component of triple therapy, has been shown to increase the 1-year survival and decrease the incidence of significant (≥ grade 3A) rejection in heart transplant recipients. However, reports indicate that opportunistic infections, particularly herpes simplex, are more common in patients treated with MMF [91]. The starting dose for MMF is 1200 mg/m^2 in divided doses twice per day, to a maximum total dosage of 3000 mg/day but titrated to maintain a white blood cell count greater than 4000 k/mm^3. Many transplant centers now use therapeutic MMF monitoring based on recent evidence that levels of 2.0–2.5 µg/mL during the first post-transplant year are associated with fewer episodes of significant (≥ grade 3A) rejection [92]. Azathioprine and antithymocyte globulin are

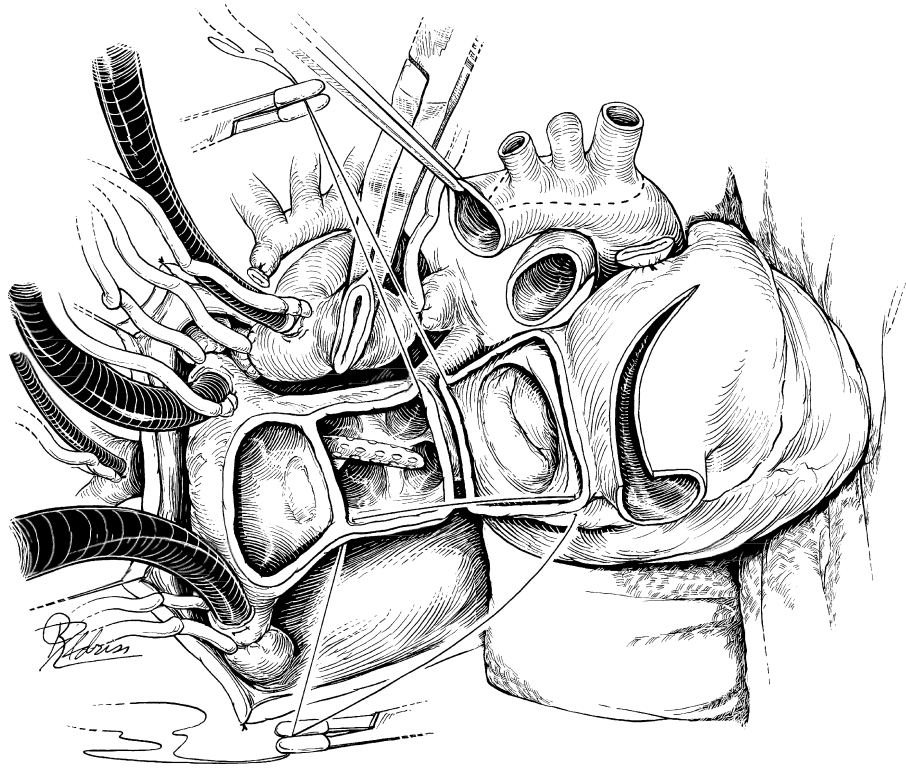

Figure 31.17 The donor heart is brought into the field, and the left atrial anastomosis is performed while extracorporeal circulation is maintained. The donor arch is tailored as indicated by the dotted lines.

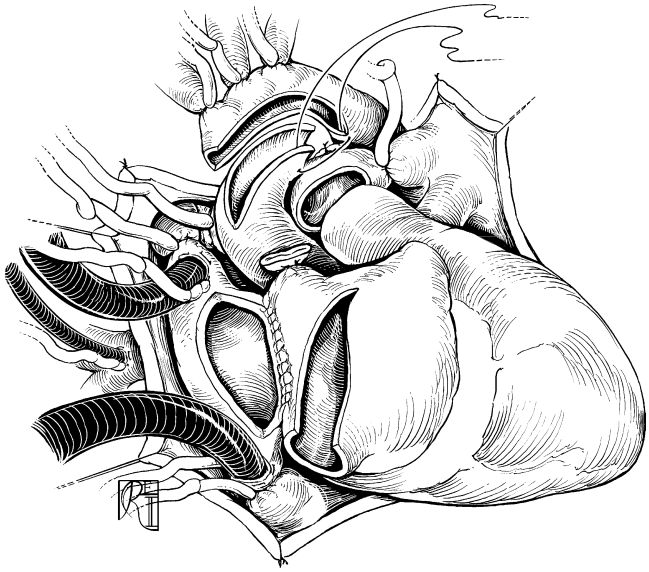

Figure 31.18 Circulatory arrest is initiated after the head vessels have been controlled by temporary occlusion. The ductus arteriosus is ligated and divided. The recipient aortic arch is prepared by aortotomy across the transverse arch and coarctation site (distal to the divided patent ductus arteriosus).

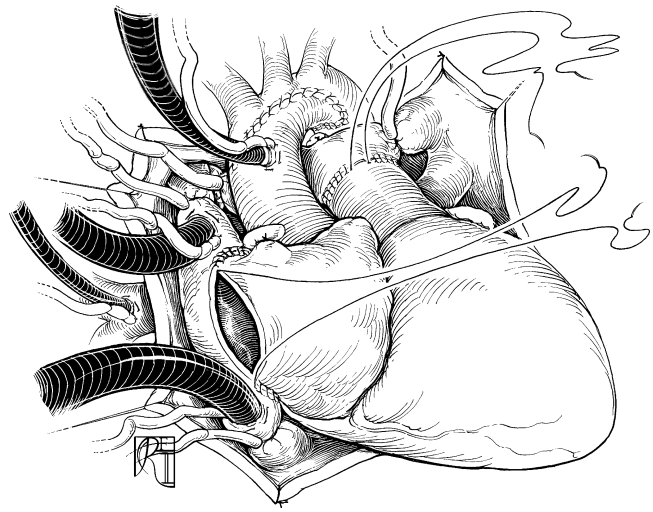

Figure 31.19 The aortic arch reconstruction is completed, procedures to remove air are performed, and the arch is cannulated, reinstituting cardiopulmonary bypass. The right atrial and the pulmonary artery anastomoses are performed with the heart perfused while the infant is rewarmed. The catheter in the left ventricle is now used as a vent.

major risk factors for increased Ebstein-Barr viral load and the development of post-transplant lymphoproliferative disease. Based on these findings, regimens incorporating MMF are preferred in the pediatric population over azathioprine-based protocols [93].

Rejection surveillance is based on clinical signs (appetite, activity, and heart rate), serial echocardiography, electrocardiography, and endomyocardial biopsy [39]. Noninvasive monitoring with serial echocardiograms is used more frequently than invasive techniques because of the limited intravenous access in small babies [94,95]. Rejection is usually treated with intravenous methylprednisolone, but rejection associated with hemodynamic compromise is treated with more aggressive therapy including steroids, ATG, and use of mechanical support as needed to maintain adequate cardiac output until myocardial function recovers. Prophylactic immunizations, including diphtheria-pertussis-tetanus and inactivated polio vaccine, begin 2 months after transplantation and are re-dosed according to the American Academy of Pediatrics recommendations, while live-attentuated viruses such as measles-mumps-rubella are withheld. More detailed information on immunosuppression and rejection surveillance is outlined in Chapter 42, *Heart Transplantation*.

Results

A multi-institutional study from the Pediatric Heart Transplant Study Group evaluating outcomes for patients with HLHS for transplantation from January 1993 to December 1998 demonstrated a decreased percentage of unpalliated HLHS patients being listed for transplantation (27% in 1993 vs. 14% in 1998) [96]. Overall, 25% of infants with HLHS die on the waiting list. Of the 175 (67%) patients who ultimately received a transplant, the 5-year actuarial survival was 72% with 76% of deaths occurring within 3 months of transplant. Overall survival including waiting list and post-transplant mortality was 68% at 3 months and 54% at 5 years [96]. The Registry of the International Society of Heart and Lung Transplantation reported the actuarial survival following heart transplantation in infants with the diagnosis of congenital heart disease to be approximately 70% at 1 year and 60% at 5 years [97]. Although the infant age group had a significantly higher early mortality compared with older infants and children with congenital heart disease, late survival for all age groups reached the same level as for infants. The major causes of death in the infant population are rejection and nonspecific graft failure. Infection accounted for a minority of the deaths. The prevalence of chronic rejection, often taking the form of coronary vasculopathy, is growing in the pediatric population. Beyond 3 years post-transplant, chronic rejection coronary artery disease was the leading cause of death. Improving immunosuppressive therapies, developing noninvasive methods of predicting cardiac rejection, and understanding the nature and treatment of coronary graft vasculopathy are challenges for the future of pediatric cardiac transplantation.

Conclusion

Hypoplastic left heart syndrome is a congenital cardiac lesion considered lethal until 1980. Now there are clearly two surgical options, staged reconstruction and cardiac transplantation. Staged reconstruction entails three procedures with an overall 5-year survival of approximately 75% for patients without significant non-cardiac anomalies or genetic syndromes. Long-term durability of the tricuspid valve and right ventricle at systemic workloads remains to be determined. Cardiac transplantation offers a single operation with perhaps a lower operative mortality, yet 25% of neonates listed for transplantation do not receive donor hearts. In addition, neonates post-transplant face a lifetime of immunosuppression with the attendant risks of rejection and infection. Both options have shown remarkable improvements in results with ongoing evolution of surgical techniques and improvements in perioperative care. Supportive care only, without intervention, is rarely offered for neonates with HLHS unless multiple noncardiac anomalies or genetic syndromes are present. The recommendations of any clinician in a given pediatric cardiac surgical unit must take into consideration that center's results and expertise with the two approaches.

CHAPTER 32

Aortico-Left Ventricular Tunnel

Stephanie Fuller and Thomas L. Spray

The Children's Hospital of Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Aortico-left ventricular tunnel is a rare congenital communication between the ascending aorta and the left ventricle (LV). The incidence is estimated at 1 in 1000 infants born with congenital heart disease [1]. In 1963, Levy and colleagues [2] described three cases of aortico-left ventricular tunnel. Affected patients usually present with symptoms of congestive heart failure and dilation of the ascending aorta within the first year of life. The prognosis is good following surgical repair, although long-term progressive aortic insufficiency exists in some patients.

Pathophysiology and Anatomy

The aortico-left ventricular tunnel is an abnormal, paravalvular, endothelialized communication between the ascending aorta and the left ventricle which creates a bidirectional flow of blood from the aorta to the left ventricle. The paravalvular aortico-left ventricular tunnel typically originates from an aortic orifice cephalad to the sinotubular junction and the right coronary cusp and follows a descending path along the aortopulmonary window before entering the fibrous trigone immediately below the left-right commissure of the aortic valve. Most cases arise from the right coronary sinus. Origin from the left coronary sinus is rare [3–5]. In a postmortem series of 37 patients, the aortic opening was reported to be above the right coronary artery ostium in 14 (38%) of the patients, below the right coronary artery in 9 (25%) and at the level of the right coronary artery in 6 (16%) [6].

On gross inspection, a visible bulge is apparent along the anterolateral aspect of the aorta, which represents the fibromuscular tunnel wall that lies in direct histologic continuity with the aorta. The posterior wall contains the true aortic wall with the inferomedial aspect or the floor of the tunnel involving the muscle of the right ventricular outflow tract [7]. Hovaguimian and colleagues [4] classified aortico-left ventricular tunnels into four types: those with a slit-like aortic orifice with no valvular distortion (type I); those with a larger, oval-shaped aortic orifice with an aneurysmal extracardiac component with or without valvar distortion (type II); those with an oval aortic orifice and an aneurysmal septal (intracardiac) component with or without right ventricular outflow tract obstruction (type III); and those with a combination of type II and III (classified as type IV) (Figure 32.1) [8].

Interestingly, careful analysis of several pathologic specimens by Ho and colleagues [7] suggests that despite this classification scheme, the tunnels never actually engage or cross the interventricular septum. Rather, the tunnels travel downward in the fibrofatty plane between the aortic root and the subpulmonary infundibulum to enter the left ventricular outflow tract in the immediate subcommissural triangle below the right and left valvar cusps just superficial to the intracardiac myocardium and immediately above the actual aorticoventricular junction (Figure 32.2) [7]. The anatomic relations of the tunnel have both pathophysiologic and therapeutic implications. Consideration must be given to the etiology of aortic valvar insufficiency as well as coronary flow, particularly when the right coronary artery arises within the tunnel.

Pathogenesis

Although the exact pathogenesis of aortico-left ventricular tunnel is not determined, proposed etiologic events to explain formation of the aortico-left ventricular tissue include an *in utero* rupture of a sinus of Valsalva aneurysm [3,8–10], degeneration of the true aortic wall analogous to *in utero* cystic medial necrosis [11], dissection of an aberrant or anomalous coronary artery [1], and malformation of the

bulbus cordis [1,3,12]. The bulbus cordis matures into components of both the subpulmonary infundibulum and the aortic vestibule and comprises the territory through which the developing coronary arteries move to attach to the sinus segment. Aberrant maturation of the bulbus cordis may account for the association between aortico-left ventricular tunnel and valvar pulmonary stenosis, valvar aortic stenosis, and proximal coronary artery anomalies [12]. Aortico-left ventricular tunnel typically originates from an aortic orifice cephalad to the sinus segment of the aorta and it is unlikely that a rupture of a sinus of Valsalva aneurysm could account for the typical appearance of this anomaly. Myers and colleagues [9] suggest instead that sinus aneurysm rupture occurs only in the rare occurrence of aortic to right ventricle fistulization. Although the suggestion of Myers *et al*. is an attractive hypothesis, Vargas and colleagues [13] clearly document an aortic origin of an aortic-right ventricular tunnel cephalad to the left sinotubular junction, which would make antecedent sinus rupture equally unlikely.

Presentation and Diagnosis

The age at presentation and severity of symptoms depend on the size of the tunnel. Neonatal and infant presentation reflects a large communication with severe left ventricular volume overload. Correct prenatal diagnosis of aortico-left ventricular tunnel has been difficult and only two known series have been reported. In the first, prenatal diagnoses were correct in only one of four presumed cases [13], and in the second, the diagnosis was correct in two of three cases [3]. Two additional single case reports have been published [14,15]. Although several fetuses were electively aborted, only three prenatally diagnosed patients survived until correction. The earliest survivor was detected at 28 weeks gestation. Prenatal echocardiography usually demonstrated preserved general cardiac architecture with valvar aortic insufficiency and/or stenosis with dysplastic valve leaflets and severe left ventricular hypertrophy and dilatation. A distinct paravalvular tunnel with regurgitant diastolic flow could be identified in three cases. Overall

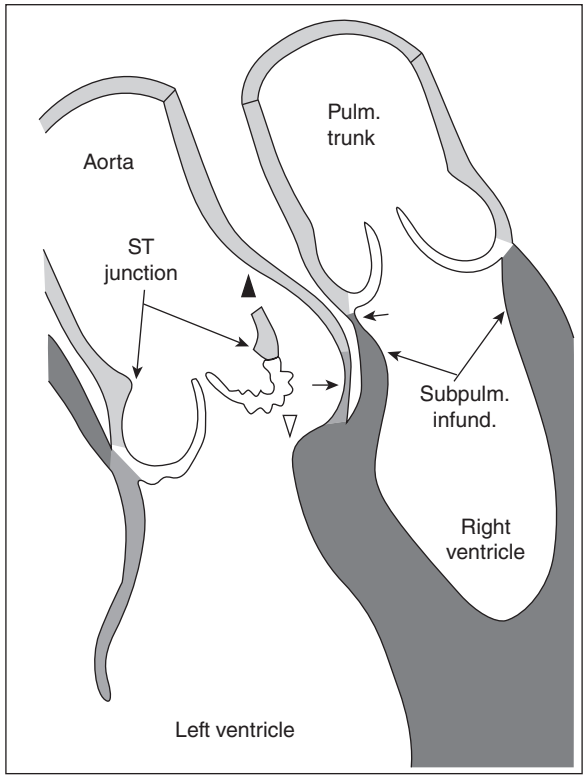

Figure 32.2 Longitudinal section of aortico-left ventricular tunnel. The tunnel originates above the sinotubular ridge (closed triangle). The ventricular orifice (open triangle) is in the area normally occupied by the interleaflet triangle. The tunnel is in an extracardiac tissue plane between the pulmonary trunk and aorta. The fine hatching (indicated by small arrows) represents fibrous areas, and stippled areas are the arterial walls. (ST junction, sino-tubular junction.) (Reproduced with permission from Ho *et al*. [7].)

survival was rare; patients with sufficient regurgitant flow to allow early prenatal diagnosis may represent the most severe end of the clinical spectrum. Reported postmortem examination of these pathologic hearts invariably demonstrated extensive myocardial fibrosis and severe aortic valve dysplasia.

Postnatally diagnosed aortico-left ventricular tunnel has been well documented in the literature, with presentation dependent on the amount of regurgitant paravalvular flow and the significance of associated coexistent anomalies such as valvar aortic regurgitation, aortic stenosis, pulmonary stenosis, and subpulmonary right ventricular outflow tract obstruction. Typical patients present with a "to and fro" murmur and congestive heart failure of varying severity. Differential diagnosis includes ventricular septal defect with aortic insufficiency, ruptured sinus of Valsalva aneurysm, coronary artery fistula, and tetralogy of Fallot with absent pulmonary valve syndrome.

Physical examination reveals pathognomonic systolic and diastolic murmurs and wide pulse pressure with bounding peripheral pulses. Although right ventricular outflow tract obstruction with or without valvar pulmonary stenosis can be the result of aneurysmal dilation of the intracardiac portion of the tunnel, cyanosis is an uncommon sign. Characteristics attributable to chronic volume overload dominate including left ventricle hypertrophy, left ventricle dilatation, and diminished ventricular function. Echocardiography is the diagnostic modality of choice, although cardiac catheterization has been recommended to detail associated lesions [16]. Color Doppler by echocardiography may be useful if it is able to differentiate the direction of blood flow in the aortic root and the tunnel. Demonstration of a paravalvular aorticoventricular communication with regurgitant diastolic flow confirms the diagnosis and demonstration of aortic insufficiency in a neonate should raise suspicion of an aortico-left ventricular tunnel.

Treatment

Surgical correction remains the mainstay of therapy. Medical management alone is thought to be ineffective, although rare patients have presented as late as 31 years of age without surgical treatment [17]. Spontaneous closure of an aortico-left ventricular tunnel has also been documented, raising the question of whether small asymptomatic lesions could be serially observed [1]. The natural progression is congestive heart failure and sudden death.

Current practice dictates surgical closure of the aortic orifice at the time of diagnosis either directly, via patch aortoplasty, or with combined closure of the aortic and the ventricular openings (Plates 32.1, 32.2, see plate section opposite p. 594). Although durable results can be achieved with direct closure alone [1], this would appear most cogent to type I aortico-left ventricular tunnels with a slit-like aortic orifice. Further, pathologic examination of autopsy specimens suggests that the ventricular orifice is not surrounded by firm muscular margins and may not be amenable to direct closure [7].

Patch aortoplasty has been advocated by most authors for all types of aortico-left ventricular tunnel to avoid distortion of the aortic valve and to obtain a long-term tension-free closure [16,18]. In performing patch closure, care must be undertaken to avoid impingement of the left-right aortic valve commissure because the orifice is usually located just above the right sinotubular junction. Similarly, the location of the ventricular end within the left-right interleaflet triangle requires great care to be undertaken when closing the ventricular orifice to avoid distortion of the hingeline of the right coronary leaflet. Although distant from the noncoronary-right coronary interleaflet triangle, anterior extensions of the left bundle branch may be jeopardized by

sutures placed through the ventricular wall leading some surgeons to close the ventricular orifice through the incised tunnel itself [4,7].

Regardless of initial technique, progressive aortic regurgitation is a primary concern. Fifty percent of patients eventually require aortic valve replacement [18]. Early repair may prevent the late consequences of chronic volume overload, premature deterioration of the valve leaflets secondary to turbulent flow and subsequent dilatation of the aortic annulus and ascending aorta [8,12,18]. There may be a further theoretical advantage to closure of the ventricular orifice by buttressing the right-left commissure and supporting the lateral margin of the right coronary cusp left unsupported by the ventricular tunnel opening [7].

Conclusion

Aortico-left ventricular tunnel is a rare cardiac malformation of unclear etiology that results in the clinical syndrome of aortic insufficiency and left ventricular volume overload. Most infants will require repair in the neonatal period before hospital discharge. Treatment is surgical closure, although recently transcatheter closure has been reported in an adolescent [19]. Short-term prognosis is excellent, although some patients may eventually require valve replacement because of progressive valvar insufficiency.

CHAPTER 33

Congenital Anomalies of the Mitral Valve

Richard D. Mainwaring[1] and John J. Lamberti[2]

[1]Stanford University School of Medicine, Stanford, CA, USA
[2]Rady Children's Hospital, San Diego, CA, USA

The mitral valve is the inlet valve to the anatomic left ventricle [1]. As a consequence of this embryologic relationship, the mitral valve is the inlet valve to the systemic ventricle when there is ventriculoarterial concordance. Isolated congenital abnormalities of the mitral valve are relatively rare [2]. Congenital mitral valve lesions are often associated with other cardiac anomalies such as the Shone complex. The anatomic mitral valve may be abnormal in a variety of connective tissue disorders. Abnormalities of the inlet valve to the systemic ventricle may also occur when it is not an anatomic "mitral valve," but rather is a trileaflet valve (derived from a common atrioventricular orifice) or has Ebstein's malformation. The anatomic mitral valve may be congenitally stenotic, or insufficient, or a mixture of both. This chapter discusses the treatment of congenital mitral stenosis and insufficiency in patients when the mitral valve is the systemic atrioventricular valve. Our goal is to describe the modalities of therapy useful in the treatment of congenital mitral stenosis and all forms of mitral insufficiency occurring in infants and children.

Historical Notes

The surgical treatment of mitral valve disease began in 1923 when Cutler operated on an 11-year-old girl with rheumatic mitral stenosis who survived for an additional 4½ years following this intervention [3]. Starkey reported his experience with closed and open techniques for repair of congenital mitral stenosis and insufficiency in 1959 [4]. In 1962, Creech and colleagues reported the successful operation in a 2-year-old with congenital mitral insufficiency [5]. Young and Robinson replaced the mitral valve in a 10-month-old infant successfully in 1964 [6]. Over the subsequent decades, improved techniques for the diagnosis and treatment of congenital mitral valve disease have resulted in reproducible and excellent clinical results, with the overwhelming majority of patients now amenable to valve repair techniques [7–10].

Normal Mitral Valve Anatomy

The normal mitral valve is a complex apparatus composed of an annulus, leaflets, chordae tendineae, and papillary muscles [1]. The function of the mitral valve is dependent on the integrity of its components and the performance of the left ventricle. Figure 33.1 is a cross-sectional drawing of the heart showing the anatomic relationships of the normal mitral valve [11]. A fibrous annulus separates the atrium and the ventricle. The leaflets are attached to the annulus and are related to important adjacent structures. The mitral valve annulus extends along the left atrioventricular (AV) sulcus and is fixed medially to the central cardiac skeleton at the aortic root. The mitral valve is a bileaflet valve, with two well defined commissures in the anterolateral and posteromedial positions. The posterior (or mural) leaflet is longer and narrower and is usually divided into three scallops. It subtends an arc of 210 degrees. The anterior (or septal) leaflet is larger and wider and is trapezoidal in shape. The anterior leaflet attaches to the annulus along an arc of approximately 150 degrees. The surface of the leaflet is rough in appearance at the site where the leaflets oppose each other during systole. Each leaflet has a more proximal clear zone and then a thicker basal zone at the region of attachment to the annulus.

The chordae tendineae arise from two papillary muscles that are attached to the anterolateral and posteromedial ventricular wall. The posterior muscle is supplied by branches of the posterior descending coronary artery while the anterolateral papillary muscle is supplied by branches of the circumflex coronary artery. Each papillary muscle

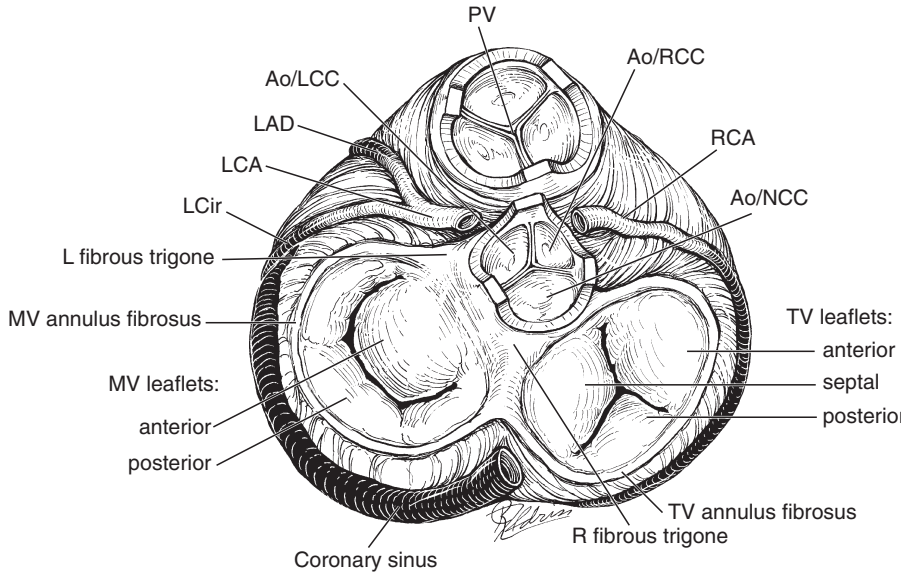

Figure 33.1 Cross-sectional drawing of the heart shows the anatomic relations of the normal mitral valve. (Ao/LCC, aortic valve left coronary cusp; Ao/NCC, aortic valve noncoronary cusp; Ao/RCC, aortic valve right coronary cusp; L, left; LAD, left anterior descending coronary artery; LCA, left coronary artery; LCir, left circumflex coronary artery; MV, mitral valve; PV, pulmonary valve; R, right; RCA, right coronary artery; TV, tricuspid valve.)

anchors chordae tendineae from both leaflets. Three varieties of chordae tendineae are recognized: first-order chordae tendineae, which originate at or near the apices of the papillary muscles and insert into the free edges of the leaflet as a fine strand; second-order chordae tendineae, which also originate at or near the apices of the papillary muscles and insert into the ventricular surface of the leaflet a short distance from the free edge and are usually thicker and less numerous than the first-order group; and third-order chordae tendineae, which are cordlike or fold-like structures sometimes containing muscle that originate from the ventricular wall and insert near the line of closure or along the basal area of the leaflet. Third-order chordae are more common along the posterior leaflet. The chordae are composed of collagen covered with a layer of endocardium. At the junction with the valvar leaflet the chordae merge imperceptibly with the leaflet tissue. The anatomy of the papillary muscles varies considerably between individuals. Some papillary muscles are broad-based, others are fingerlike. A third type is a combination of broad-based and fingerlike attachments.

The size and shape of the papillary muscles have important implications for patients with congenital heart disease. Experimental studies in animals have elegantly defined the functions of the mitral valve leaflets and mitral apparatus in both normal and pathologic states [12–14]. Two-dimensional and three-dimensional echocardiographic techniques have further refined our knowledge with regard to the function of the leaflets in normal and pathologic states [15]. Proper closure of the mitral valve during systole is dependent on sequential contraction of the atria and then ventricles and is also interdependent on the performance of the left ventricle. An in-depth understanding of the normal anatomy and function of the mitral valve is necessary to optimize the chances for a successful repair.

Pathologic Anatomy, Classification, and Analysis

Abnormalities of the mitral valve may involve one or more components of the valve and may result in stenosis, insufficiency, or a combination of both. A segmental approach is useful from an anatomic point of view, but surgical treatment requires a more functionally oriented classification. This chapter focuses on abnormalities of the mitral valve associated with an adequate-sized left ventricle. Marked hypoplasia of the annulus or left ventricle represents a form of hypoplastic left heart syndrome (see Chapter 31, *Hypoplastic Left Heart Syndrome* for further review). We focus first on lesions primarily associated with mitral stenosis then on those associated with mitral insufficiency. It should be noted that most congenital anomalies of the mitral valve will have elements of both stenosis and insufficiency.

Mitral Stenosis Lesions

Segmental analysis of stenotic lesions begins with the supravalvar region (Figures 33.2, 33.3) [9,11]. Supravalvar

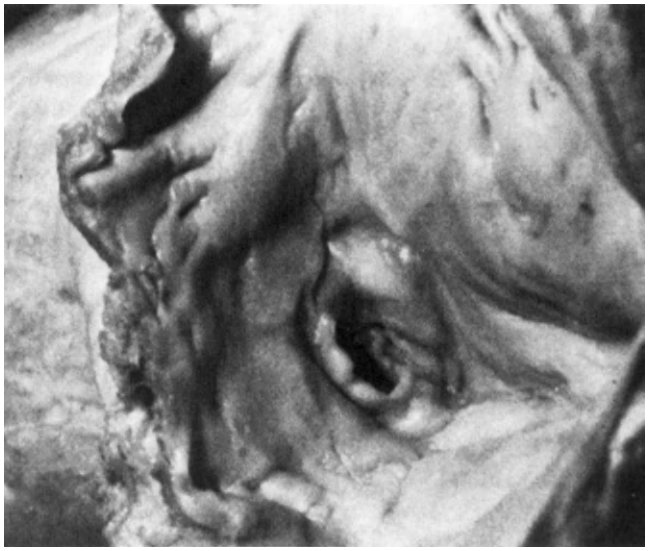

Figure 33.2 Supravalvar mitral fibrous ring viewed from the left atrium.

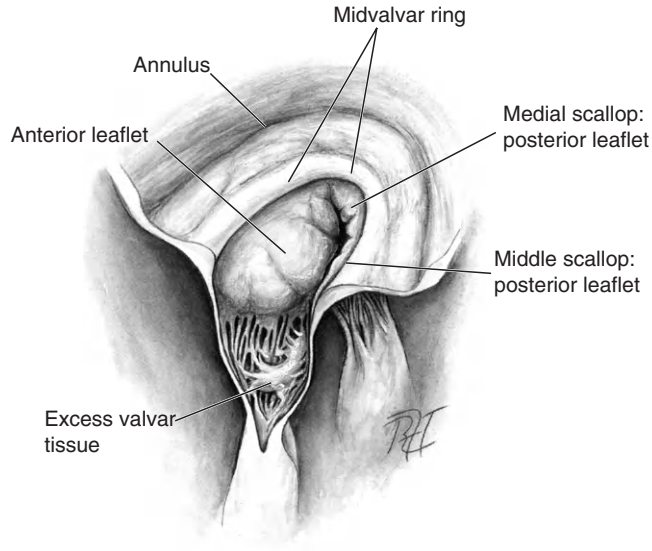

Figure 33.4 In rare instances a fibrous mitral ring within the substance of the mitral valve leaflets causes valvar stenosis (midvalvar ring) and leaflet restriction. Associated obstructive lesions often can be identified that necessitate therapy, such as excess valvar tissue and fused papillary muscles. (Reproduced with permission from Zias *et al.* [9].)

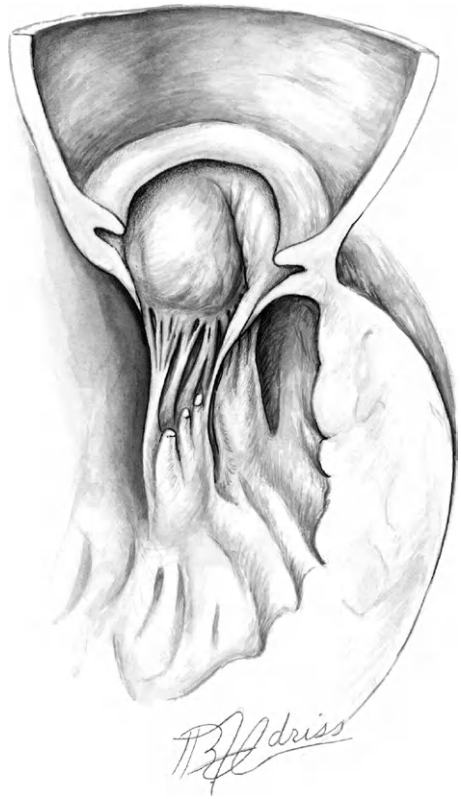

Figure 33.3 Lateral cutaway view shows mitral stenosis caused by supravalvar fibrous ring. The plane between the ring and the mitral orifice has been exaggerated for emphasis. The mitral valve itself is relatively normal with normal chordal architecture. (Reproduced with permission from Zias *et al.* [9].)

mitral stenosis is not the same as cor triatriatum and should not be confused with that entity. The "membrane" in cor triatriatum separates the atrium into two chambers. The atrial appendage originates downstream from the membrane in cor triatriatum, whereas the left atrial appendage is upstream from a supravalvar stenosing ring. In supravalvar mitral stenosis a ridge of endocardial thickening is present just above the mitral annulus [16]. This thick fibrous plate of tissue may resemble a membrane in its central portion. It may be attached at the level of the annulus or just above the annulus. This lesion is associated with congenital mitral valve stenosis and may occur in association with the Shone complex [17]. The membrane usually has a single central opening that may be eccentric in position. The size of the opening determines the degree of obstruction, and the area of the opening correlates well with the onset and degree of symptomatology. The underlying mitral valve may be functionally normal, but typically the valve is small and in some patients may be anatomically abnormal. Zias *et al.* [9] described a case of mid-valvar mitral ring (Figure 33.4) [9,11].

Congenital mitral valve stenosis may be associated with a supravalvar ring, or it may occur as an isolated lesion. Hypoplasia of the valve and its annulus can also result in significant obstruction. When hypoplasia of the valve and annulus is associated with an inadequate left ventricle, the patient must be treated as having a single ventricle. A

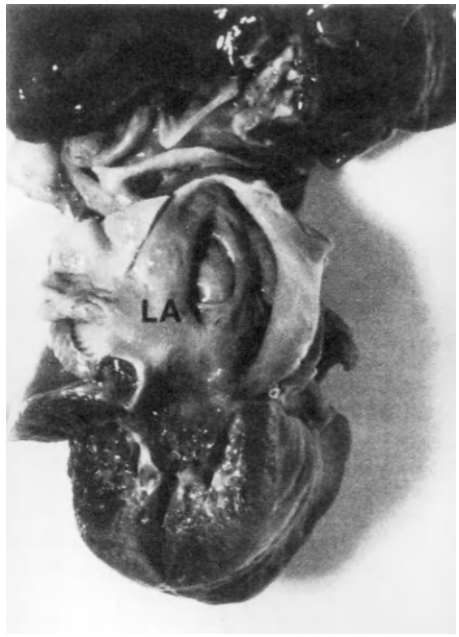

Figure 33.5 Severe mitral stenosis due to funnel valve. The left atrium (LA), funnel valve, and left ventricle are open through a sagittal cut. The commissures are fused. Thick, short chordae insert into stubby, conglomerated papillary muscles. The secondary orifices are slit like and minute. The left ventricular cavity is moderately hypoplastic, and the left atrium is markedly enlarged.

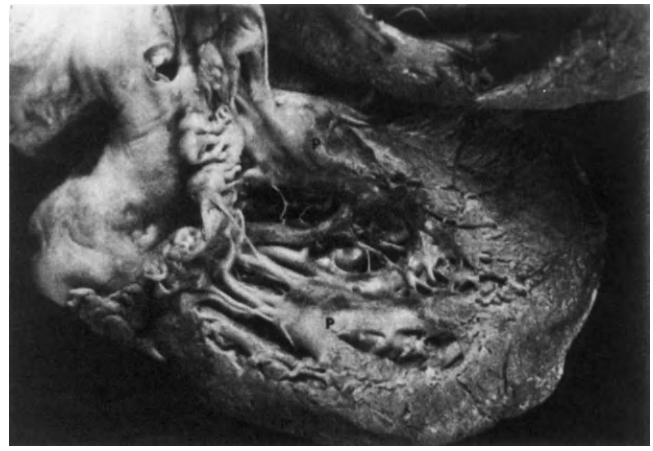

Figure 33.6 Severe congenital mitral valve stenosis involving all components of the mitral valve. The left ventricle is opened through a cut in the posterior aspect of the lateral wall. Both mitral valve leaflets are deformed, thickened, and redundant with many accessory folds. The commissures are poorly developed. Short and thick chordae insert to gigantic papillary muscles (P) and reduce the secondary orifice.

hypoplastic valve and annulus can be associated with a functionally adequate left ventricle, particularly if a ventricular septal defect is present. The hypoplastic valve may appear quite similar to a "normal" mitral valve with two leaflets and appropriate-appearing chordae tendineae. The leaflets may have reasonable function and nonfused commissures. Often the leaflets are thickened and the commissures fused. The chordae tendineae may be thick and short with inadequate development of interchordal spaces. If the chordae are shortened, a funnel-like appearance may occur (Figure 33.5) [11]. There are cases in which fusion of the leaflets will result in two orifices, a central orifice and an accessory orifice [18]. In the arcade mitral valve the anterior and posterior group of papillary muscles join together and fuse with the entire edge of the leaflet without the presence of well formed chordae. Only one papillary muscle may participate in the arcade in some cases. The arcade anatomy can produce mitral stenosis or insufficiency or a mixed lesion and may be associated with a parachute valve. The term hammock valve has been used by Carpentier to describe a valve that has fused commissures and a central orifice that is obstructed by numerous intermixed short chordae attached to abnormal hypertrophied papillary muscles [19].

Parachute mitral valve is an extreme form of congenital mitral stenosis. In this abnormality, all chordae attach to a single papillary muscle [20]. In most circumstances, the entire leaflet is connected to the posterior papillary muscle, with an absence of the anterior papillary muscle. On rare occasions the situation is reversed and the entire leaflet is connected to an anterior papillary muscle. Figure 33.6 depicts a severe case of congenital mitral stenosis involving all elements of the valve apparatus [11]. A valve that is functionally stenotic in infancy due to hypoplastic leaflets and shortened chordae may become centrally insufficient later when the left ventricle dilates. Congenital mitral stenosis may be associated with tetralogy of Fallot, ventricular septal defect, and multiple other congenital heart lesions.

Mitral Insufficiency Lesions

Congenital mitral insufficiency may be associated with many of the previously described abnormalities for congenital mitral valve stenosis. Dilatation of the mitral annulus will result in mitral insufficiency even if the valve is relatively normal in its anatomic appearance. Secondary annular dilatation can occur due to cardiomyopathy, both acquired and familial, and in association with lesions producing dilatation of the left ventricle, such as aortic insufficiency. Patients presenting with an anomalous left coronary artery may have impressive mitral regurgitation. The common AV valve found in a complete AV canal defect is often associated with insufficiency of the left AV orifice. However, this trileaflet valve is not an anatomic mitral valve. An isolated cleft of the anterior leaflet may produce important mitral insufficiency [21,22]. In Marfan's disease, the mitral valve can be quite abnormal with billowing

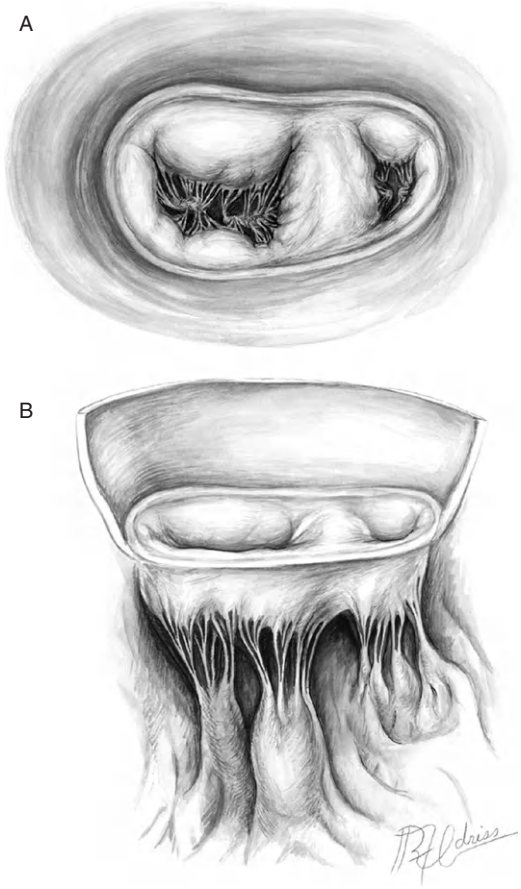

Figure 33.7 Left atrial (**A**) and cutaway atrioventricular (**B**) views of double-orifice mitral valve. More commonly, the smaller of the two orifices is in the right lateral position. The degree of stenosis is variable. Effective orifice-enlarging reparative techniques have not been developed. (Reproduced with permission from Zias *et al.* [9].)

leaflets and elongated chordae. In addition, Marfan patients may also have a markedly dilated annulus [23,24]. "Double-orifice mitral valve" refers to a valve with two separate orifices, each supported by its own tensor apparatus (Figure 33.7) [9,11,25]. This entity most commonly occurs in the setting of an AV canal defect [18], but it has been described with intact atrial and ventricular septae [8]. Double-orifice mitral valve may or may not result in insufficiency.

Mitral valve prolapse occurs in infants and children but is generally a benign condition [26]. The leaflets are redundant and thickened. The posterior leaflet is more commonly involved, and the excess valvar tissue balloons into the left atrial cavity. Often this valvar elongation is associated with annular dilatation. The architecture of the valve is abnormal in addition to the elongation of the valve structures. Carpentier has described chordal agenesis as a rare cause of congenital mitral insufficiency. Some patients presenting with predominant mitral insufficiency will have anatomic findings similar to a hammock or arcade valve. In these patients there is also a deficiency of leaflet and chordal tissue.

The Carpentier classification of congenital mitral valve disease was first reported in 1976 and has been the most commonly used descriptive system [27]. This classification is predicated on analysis of the mitral valve leaflet at operation. Type 1 lesions have normal leaflet motion but produce valvar insufficiency from a dilated or deformed annulus, or by a defect or cleft in the leaflet. These lesions are subdivided into annular dilatation, cleft leaflet, and partial leaflet agenesis. Type 2 lesions involve leaflet prolapse and result from the absence or elongation of the chordae or papillary muscles producing insufficiency. Type 2 defects are subdivided into chordal elongation, papillary muscle elongation, and chordal agenesis. Type 3 lesions involve restricted leaflet motion and mitral stenosis (although valvar insufficiency can also be observed with certain lesions). Stenosis results from commissural fusion, imperforation, thickening, or shortening of the subvalvar apparatus.

There are two practical limitations to the Carpentier classification. Pure stenosis and pure insufficiency are infrequently observed, and leaflet function does not always correlate with the physiologic alterations. It is worth noting that this system was developed before the advent of routine two-dimensional echocardiography and, thus, was the only methodology available. Evaluation of the leaflets in the operating room by direct vision may be difficult despite saline irrigation of the flaccid left ventricle. Preoperative echocardiography now provides a significant enhancement in the information available to evaluate the valve and allow planning of the repair. The intraoperative transesophageal echocardiogram sometimes provides another increment of information regarding the pre-repair physiologic and functional performance of the valve. In this era, preoperative catheterization and angiography add little to the data base and are only necessary if other lesions are present or if there is severe pulmonary hypertension.

Mitruka and Lamberti [28] proposed a classification system for congenital abnormalities of the mitral valve based on the presence of stenosis or insufficiency. This classification system is directed at the physiologic consequences of altered valve anatomy and permits a systematic and segmental approach to diagnosis and treatment. In this classification scheme, type I lesions are supravalvar and type 2 lesions are valvar. In type 2 lesions, group A are annular defects and group B are leaflet abnormalities. Type 3 lesions are subvalvar with group A involving abnormalities of the chordae tendineae and group B involving defects of the papillary muscles. Type 4 are mixed lesions. When numerous defects of the valve apparatus exist, the predominant defect causing the abnormal function will direct the classification of the lesion. Multiple types of mitral valve pathology can be coded in the hierarchical system by

selecting the predominant lesion as the first diagnosis and each additional lesion as a subsequent diagnosis in decreasing order of importance. A detailed explanation of the defects and the classification are provided in the reference [28].

Pathophysiology

Mitral valve abnormalities may have markedly different symptoms depending on the age of the patient. In older children and teenagers, significant mitral valve abnormalities present with symptoms including dyspnea on exertion, limited exercise tolerance, orthopnea, or paroxysmal nocturnal dyspnea. This age group may have limited exercise capacity because of the inability to increase cardiac output. The degree of impairment can be quantified using exercise testing. In some older children and teenagers, the onset of exercise limitation may be so insidious that the patient and/or family minimizes the degree of impairment. In contrast, infants and small children with significant mitral valve disease may be completely asymptomatic at rest. Fatigue and tachypnea with feeding or exertion may be signs of progressive mitral valve disease. Infants with associated pulmonary hypertension may have failure to thrive or recurrent pulmonary infections.

The physical findings may be subtle in early, isolated congenital mitral valve disease. Later, when there is heart failure and pulmonary hypertension, the physical exam becomes more characteristic of mitral valve disease in older patients. Mitral stenosis produces an apical mid-diastolic murmur. There may be presystolic accentuation of the murmur, and an opening snap may be audible. The morphology of congenital mitral stenosis is different from that seen in rheumatic heart disease and, thus, the opening snap is less predictable. Mitral regurgitation produces an apical pansystolic murmur that radiates to the axilla. When regurgitation is severe, a mid-diastolic rumble may also be heard. The second heart sound is accentuated in the presence of significant pulmonary hypertension and the precordium will be active with a right ventricular lift.

The diagnosis can usually be established by noninvasive techniques. In isolated mitral valve disease the chest X-ray will reflect left atrial dilatation and enlargement of the right ventricle. In more severe cases, the left main-stem bronchus is elevated and the left lower lobe may be collapsed. Radiologic signs of pulmonary venous congestion are present. Abnormalities on the chest X-ray may be obscured by the increased pulmonary vascularity and gross cardiomegaly. Left ventricular enlargement develops when mitral regurgitation progresses. Left ventricular failure may occur when the regurgitation fraction is greater than 50% and the end-diastolic volume is markedly increased. Important electrocardiographic findings include left atrial hypertrophy and right ventricular hypertrophy. When additional lesions are present, the electrocardiogram will reflect the consequences of this physiology. Atrial fibrillation is rare in infants and children, although other atrial arrhythmias may occur.

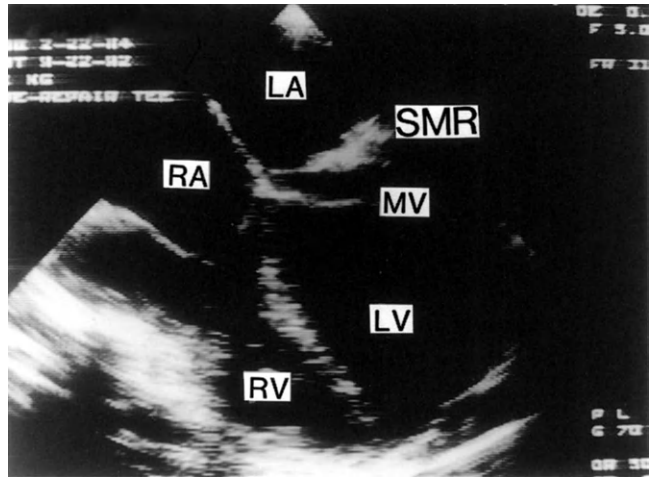

Figure 33.8 Transesophageal two-dimensional echocardiogram of an 8-year-old girl with recurrent supra-annular stenosing ring. The patient has a hypoplastic mitral annulus with a normal-sized left ventricle and an aneurysm of the membranous septum. (LA, left atrium; LV, left ventricle; MV, mitral valve; RA, right atrium; SMR, supra-annular mitral ring.)

Two-dimensional echocardiography in combination with color-flow studies and Doppler interrogation can provide precise information regarding the anatomy and function of the mitral valve. However, surface echocardiograms may not always provide the exact nature or extent of the mitral valve abnormality. A supravalvar ring may be difficult to detect by surface echocardiography, whereas transesophageal echocardiography (TEE) is particularly useful in evaluating the mitral valve. Figure 33.8 depicts a recurrent supravalvar ring detected by TEE in an 8-year-old girl [11].

Principles of Treatment

Infants and children with signs or symptoms due to congenital mitral valve disease may present a challenge in management. Most infants and children with mitral valve disease are treated medically for as long as feasible. Digoxin therapy has traditionally been instituted, although the utility of digoxin is debatable, particularly when the lesion is predominantly mitral stenosis. Diuretics and unloading therapy are useful in treating patients with significant mitral regurgitation. Afterload reduction is optimized using an angiotensin-converting enzyme (ACE) inhibitor. The purpose of medical therapy is to alleviate symptoms and to permit continued growth and development. Careful

monitoring of ongoing medical management is necessary because medical treatment may mask the development of deteriorating ventricular function or worsening pulmonary artery hypertension. It is well established that chronic left atrial and pulmonary artery hypertension may eventually result in atrial dysrhythmia and chronic right heart failure.

Medical management is the first line of therapy for mitral valve disease because surgical options may be limited in younger, smaller patients [29,30]. There is no "ideal" medical device for mitral valve replacement in this patient population [31,32]. Traditionally, surgical intervention is contemplated when symptoms become severe or when exercise limitations are unacceptable. Valve repair techniques have evolved to the point that nearly all pediatric patients with favorable anatomy can undergo a successful repair. The dilemma remains for younger patients when the anatomy is not favorable for valve repair. At present, mechanical valves are the only suitable replacement option for the mitral valve in an infant, child, or young adult. The "unnatural" history following mechanical valve replacement for the mitral position is guarded in an infant or small child, making this an unattractive solution for the pediatric population [31–35].

Surgical intervention is indicated when symptoms severely compromise the lifestyle of the patient or when it is obvious that growth and development are failing. An earlier operation may be indicated when the mitral valve lesion is associated with other "correctable" defects. Relief of associated obstructing lesions, such as coarctation of the aorta or aortic stenosis, and repair of lesions producing a volume load, such as patent ductus arteriosus and ventricular septal defect, in combination with mitral valve repair may improve mitral valve function and delay the need for mitral valve replacement. When an associated congenital heart defect requires surgery, the abnormal mitral valve should always be inspected and repaired at the same time unless the mitral valve abnormality is deemed minor. Evaluation by two- and three-dimensional echocardiography usually permits an accurate assessment of the potential for valve repair. We recommend "prophylactic" surgery for relatively asymptomatic patients if the underlying mitral valve physiology is moderately or more severe and the anatomy is favorable for valve repair.

Balloon dilatation of rheumatic mitral valve stenosis is a safe and effective treatment in adults [36]. A number of centers have extrapolated this data and proposed that balloon dilatation might be effective for congenital mitral stenosis. The results for balloon dilatation of the congenitally obstructed mitral valve have not been satisfactory compared with rheumatic valves [37,38]. This should not be surprising because the pathology is quite different. We strongly discourage the use of balloon dilatation for congenital mitral stenosis based on the risk/benefit analysis versus surgery. Complications such as acute massive mitral regurgitation and residual atrial septal defect [39] rarely occur following surgical mitral valvuloplasty.

When repair is not possible, mitral valve replacement is necessary. Bileaflet mechanical prostheses are the valve of choice for infants and small children. There is now strong evidence that all mechanical valves require the indefinite use of anticoagulation. Despite the use of anticoagulation, thromboembolic events and late valve entrapment by pannus formation can occur [40]. Coumadin anticoagulation in infants and children carries its own long-term risk, and smaller patients will eventually outgrow the prosthesis and require reoperation [41,42]. In general, mitral valve replacement in infants and children should be avoided if at all possible.

A variety of bioprosthetic valves have been tried in the mitral position in an attempt to avoid long-term coumadin anticoagulation. Several reports document the poor short- to mid-term results obtained when porcine valves are implanted in the left heart of children. If the problem of early calcific degeneration can be solved, bioprosthetic valves might become useful in infants and children. There are a few reports of the successful use of an extracardiac conduit between the left atrium and the left ventricle [43]. When a porcine valve is placed in an extracardiac conduit, it seems to be protected from accelerated degeneration. Homograft valves do not perform well when implanted on rigid stents in the mitral position. Donald Ross proposed the "top-hat" technique for replacement of the mitral valve with a pulmonary autograft [44]. Brown [45] and others [46,47] have suggested that the top-hat pulmonary autograft may be a viable solution for some young patients requiring mitral valve replacement early in life. Wider application and additional follow-up are necessary before routine consideration can be given to use of the top-hat technique. The mitral homograft [48] was suggested as a possibility for replacement without the need for anticoagulation. Unfortunately, the mitral homograft procedure has not been demonstrated to be a durable substitute for the mitral valve. In summary, the current surgical approach to mitral valve pathology should entail an aggressive effort at valve repair because there is no satisfactory long-term substitute in infants, children, and young adults with mitral valve disease.

Surgical Technique

The surgeon should carefully review all preoperative imaging studies in advance of the operation. We utilize TEE whenever possible, and it is important to be present to visualize the pre-repair TEE. At that time, the surgeon and cardiologist can review these findings and compare them with the preoperative data base. The surgeon will subsequently have the opportunity to corroborate the non-

invasive findings with the intraoperative ones. In addition, changes in valve and ventricular function related to anesthesia can be noted and integrated with the preoperative analysis.

An operation on the mitral valve requires excellent exposure and considerable attention to detail. We use continuous cardiopulmonary bypass. Myocardial protection consists of repetitive doses of antegrade blood cardioplegia in conjunction with systemic hypothermia (28–30 °C). Retrograde cardioplegia may be useful in certain specific situations such as the presence of significant aortic valve insufficiency or coronary artery obstruction. Retrograde cardioplegia is relatively straightforward to use because the right atrium is often open and the coronary sinus is readily visualized. We use a purse-string suture around the coronary sinus to maximize right ventricular protection (the balloon of the catheter can sit at the ostium of the coronary sinus). Systemic hypothermia is important for two reasons. First, pulmonary venous return can interfere with visualization of the posterior aspect of the mitral valve in infants and small children. Moderate hypothermic bypass allows reduction of pump flow and control of pulmonary venous return, especially in patients with pulmonary hypertension. Hypothermia also reduces rewarming of the heart through contact with the descending aorta or by coronary collateral flow from bronchial artery connections.

The cannulation techniques are adapted to the size of the patient and the associated surgical procedures. In all patients, direct cannulation of the venae cavae permits optimal exposure. We use a right-angle cannula for this purpose. Aortic cannulation is performed in a standard fashion. The mitral valve can be approached through the dome of the left atrium, in the traditional fashion posterior to the intra-atrial groove, or through the atrial septum. A combination of incisions may be necessary in very small patients. Mobilization of the inferior and superior venae cavae and dissection of the intra-atrial groove usually permits excellent exposure with the traditional incision between the pulmonary veins and the intra-atrial groove in larger patients. In reoperations, we favor the transseptal approach if there is a prior right atriotomy scar. We do not usually extend the septal incision into the dome of the left atrium unless the left atrium is small and exposure is difficult [49]. In small infants, the superior-septal approach can be very useful. Blood cardioplegia is administered and repeated at 20–30-minute intervals. In reoperations we do not dissect the heart completely if adhesions are dense on the left side. Instead, widely opening the pleura allows the heart to fall posteriorly into the left chest.

Careful inspection of the valve is extremely important before beginning the surgical repair. A variety of atrial retractors can be used. A deep retractor may push the mitral annulus away from the surgeon and interfere with proper visualization. In smaller patients, a combination of traction sutures and small retractors may provide optimal visualization. Inspection begins at the supravalvar region, including the orifices of the pulmonary veins and the base of the left atrial appendage. The leaflets are then assessed for size, mobility, and prolapse. A small nerve hook is useful for this portion of the procedure. The chordae and the papillary muscles are then inspected. Saline can be injected into the ventricle with a piston syringe and a small red rubber catheter. The leaflets should float up and oppose. When the anatomy is clearly defined, the repair can begin. There is no reason to hurry through this process, as good myocardial protection allows cross-clamp times up to 3 hours without long-term sequelae. It is a reasonable maxim that a "good" repair is always better than placing a mechanical valve in a child. Therefore, when in doubt about the feasibility of repair, it is prudent to attempt a repair and evaluate what can be accomplished before removing the native valve. In the event that valve repair is not feasible, then there is no choice but to proceed with valve replacement.

The basic techniques for valve repair have been well described by Carpentier and colleagues [7,8,27], Duran *et al.* [50], and others [29,51,52]. A supravalvar mitral ring can be excised, but care should be taken at the periphery of the ring not to cut through the endocardium (Figure 33.9) [11]. If an endocardial opening is created, repair can be performed with fine interrupted monofilament sutures. After removal of the supravalvar ring, the mitral valve is inspected. The orifice size should be calibrated. We use Amato dilators in infants and small children and standard valve sizers in larger children to calibrate the orifice before, during, and after the repair. Our goal is to achieve competence with an orifice at the lower limits of normal size. Commissural fusion is addressed next, followed by appropriate treatment of fused subvalvar chordal attachments. In some cases incision of the commissure entails splitting fused chordal structures. Incision of the chordae can be carried down into the papillary muscles (Figure 33.10) [9,11]. When the leaflets are mobilized, an assessment of the functional orifice size is carried out. If the orifice is adequate for this size patient, we then test for insufficiency. Injection of saline into the ventricle permits gross assessment of leaflet function. Repeat cardioplegia with manual distortion of the aortic annulus can produce aortic regurgitation to fill the left ventricle and allow excellent visualization of the competence of mitral leaflet apposition.

Evaluation of a primarily regurgitant valve consists of assessment of annulus size followed by the standard stepwise assessment of the commissures, leaflets, and chordal structures. Repair consists of ensuring that the leaflets are adequately mobilized, repairing the leaflets if necessary, and closing any clefts that may be present. If inadequate leaflet tissue is present, advancement of the leaflet edge can be carried out with an autologous pericardial patch at the

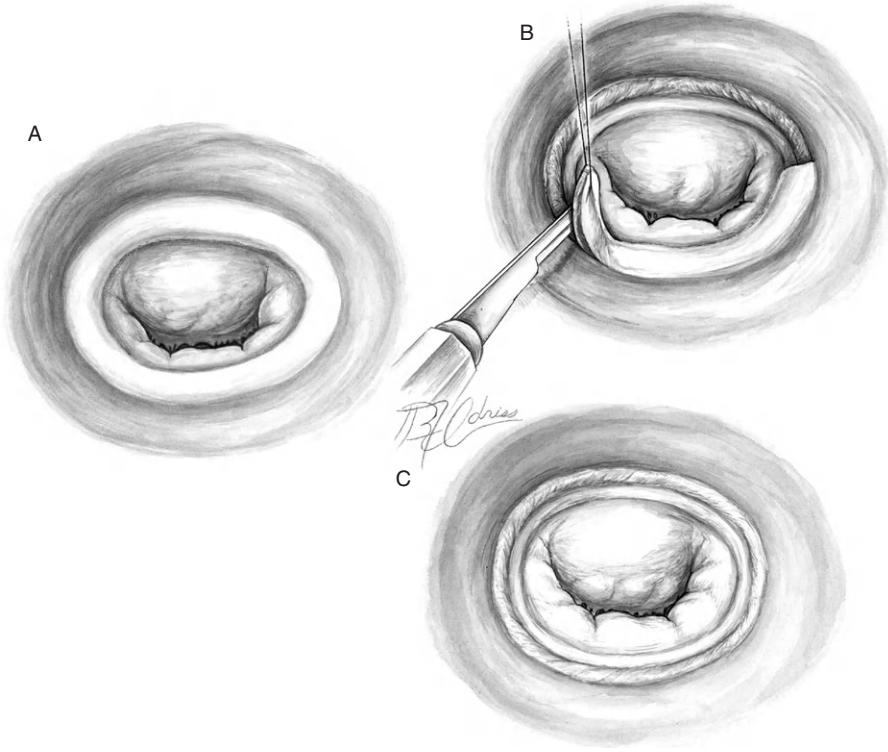

Figure 33.9 Technique for resection of a supravalvar mitral ring in the setting of a relatively normal mitral valve. **A,** Surgeon's view of supravalvar mitral ring. **B,** Sharp resection of the ring is performed under direct vision. A traction suture placed through the ring may facilitate exposure of the plane. **C,** Final result.

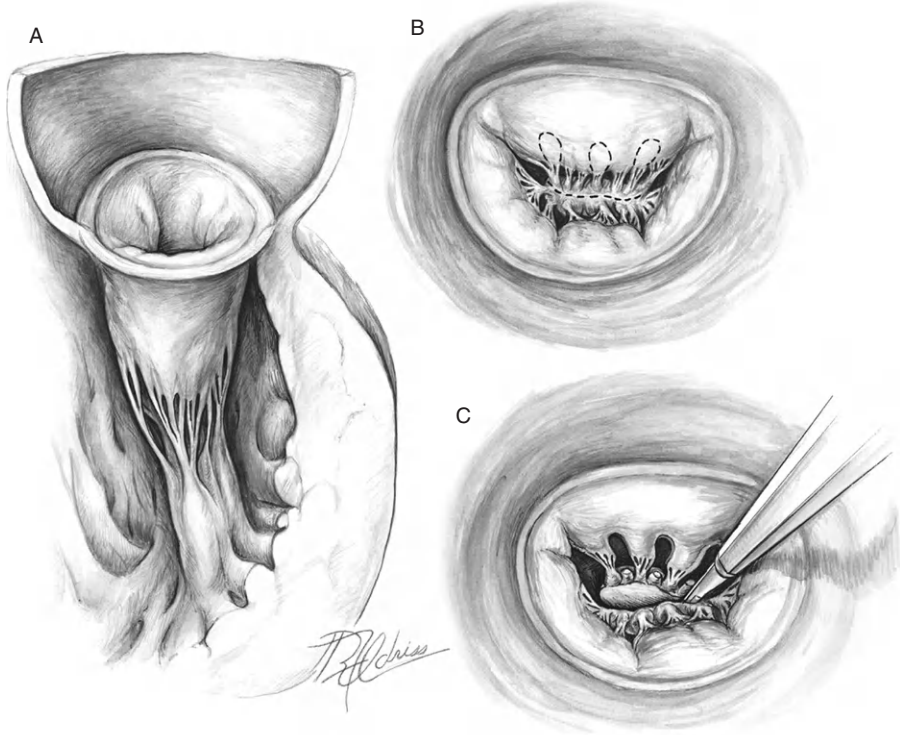

Figure 33.10 Cutaway atrioventricular view (**A**) and left atrial views (**B** and **C**) of stenotic parachute mitral valve. **A,** Single papillary muscle or fused papillary muscles usually arise from the posterior left ventricular wall. **B,** Dotted lines show the areas of proposed leaflet fenestrations and papillary muscle incision to open the ventricular inlet. **C,** Leaflet fenestrations are accomplished to maximize blood flow into the left ventricle during diastole while valvar tissue is preserved for effective coaptation during systole. The fused papillary muscle is being incised to facilitate valvar mobility. (Reproduced with permission from Zias *et al.* [9].)

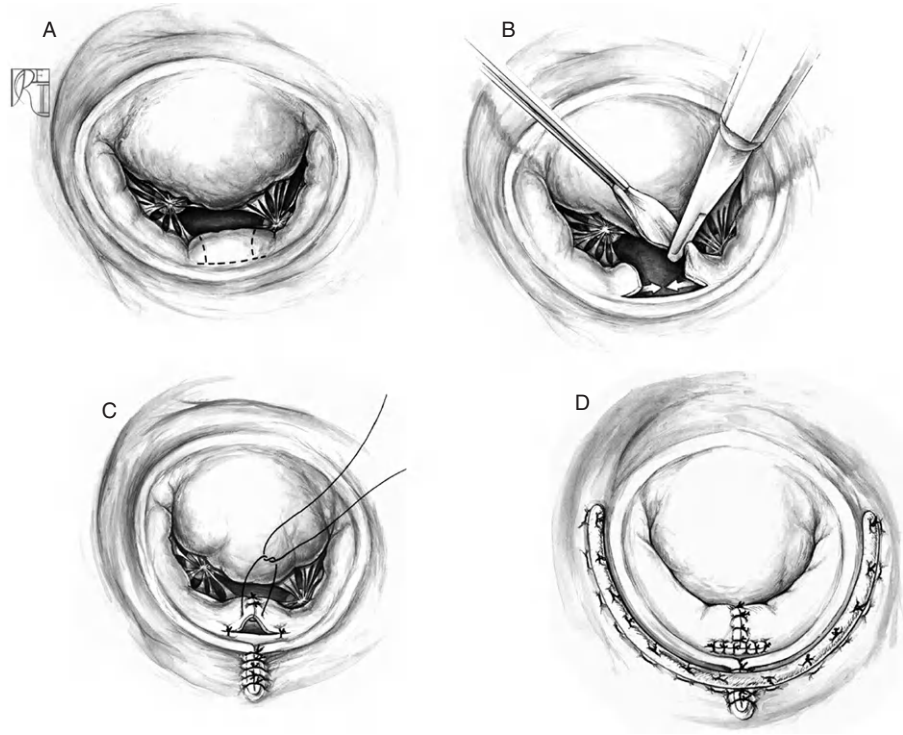

Figure 33.11 **A,** Artist's representation of insufficient mitral valve due to annular dilatation. Dotted lines represent the proposed posterior leaflet quadrangular resection and valvar incisions. **B,** After quadrangular resection, linear incisions are made in the posterior leaflet to accomplish sliding valvuloplasty (arrows). **C,** Posterior annulus is brought together with care not to injure the circumflex coronary artery. Resultant tightening of the annulus brings the remaining scallops of the posterior leaflet in position for valvar repair. **D,** The repair is strengthened by a semicircular Gore-Tex strip. The anterior annulus was not included in the annuloplasty technique owing to somatic growth considerations. (Reproduced with permission from Zias *et al.* [9].)

base of the leaflet [7]. We do not use pledgeted sutures along the clefts in the leaflet since we believe that pledgets reduce the mobility of the leaflet and may provide a nidus for calcification. There is ample evidence to suggest that leaflet repair can be carried out with interrupted monofilament sutures. Chordal repair or replacement can be accomplished by a variety of techniques. When posterior leaflet chordal rupture has occurred, resection of the middle third or more of the posterior leaflet can be accomplished (Figure 33.11) [9,11]. Following such a quadrangular resection, an annuloplasty can be performed. In older patients chordal transfer by leaflet flip may be useful in the treatment of anterior leaflet chordal rupture. Successful Gore-Tex replacement of chordae has been reported in adults [53] and Gore-Tex chordal replacement in children has shown promise [54–56]. We obtained an excellent result using Gore-Tex chordae in a 2-month-old infant presenting with a flail anterior leaflet due to chordal agenesis. In general, we recommend avoidance of a ring annuloplasty unless the annulus is adult size. The Wooler commissural annuloplasty [57] is quite useful in infants and children (Figure 33.12) [11,57]. It is performed with a 2-0 or 3-0 braided suture and small Teflon pledgets. The effects of a Wooler annuloplasty stitch may not always be predictable, and we have modified our technique to place a snare on the stitch and evaluate the result before tying [40] (Figure 33.13). In the event that the desired effect is not achieved, the suture can be easily removed. The Wooler annuloplasty permits substantial reduction in regurgitation without interfering with annular growth [58,59]. If an annuloplasty ring is thought to be necessary, we prefer a flexible ring [60]. In patients that have not completed their somatic growth, a partial ring may be useful. Subaortic obstruction can occur after ring placement, and care must be taken to avoid using an oversized semirigid ring.

Reparative techniques may be quite effective in patients with mitral regurgitation from certain acquired causes. Children with a dilated cardiomyopathy may develop severe mitral valve insufficiency secondary to annular dilatation. Surgical repair of the mitral valve may be quite effective in improving hemodynamics and obviate the need for cardiac transplantation [61]. Rheumatic heart disease is infrequently seen in the United States but is still common in other parts of the world. Standard techniques of annuloplasty and chordal repair can be employed after commissurotomy and valvuloplasty have been performed.

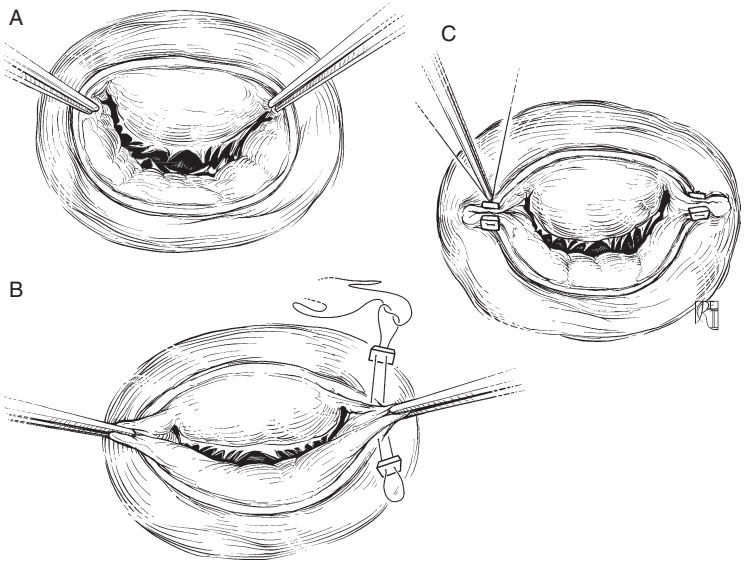

Figure 33.12 Artist's depiction of Wooler [57] or segmental annuloplasty. Variants of this technique have been described by numerous authors. **A,** The surgeon identifies the commissure and the adjacent aortic annulus. **B,** Mattress sutures of nonabsorbable material are reinforced with Teflon or pericardial pledgets. Placement of the sutures along the annulus determines the degree of annular reduction. The purpose of the sutures is to reduce the posterior annulus without disturbing leaflet coaptation. **C,** After the sutures are tied, the orifice is calibrated with a dilator, and the valve is tested with saline solution. Additional sutures may be necessary. Sometimes the annular plication distorts the leaflet coaptation, and the sutures must be removed or repositioned.

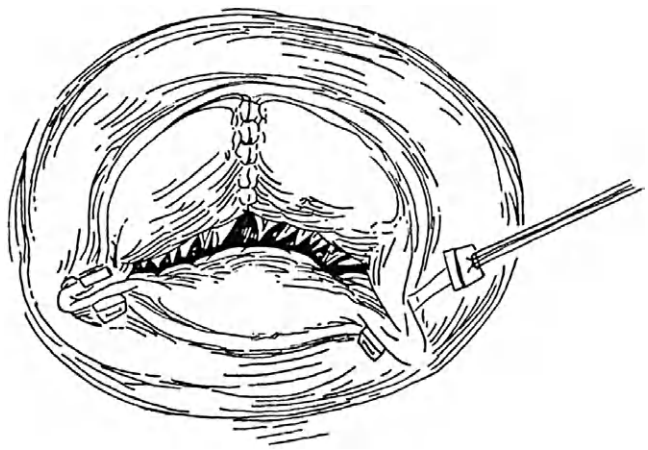

Figure 33.13 Technique for repair of left-sided atrioventricular valve regurgitation in the setting of a trileaflet valve (atrioventricular septal defect). The cleft has been closed, and a Wooler annuloplasty performed at the "anterior commissure." In the presence of residual regurgitation, a second annuloplasty stitch is placed at the posterior commissure. A snare has secured the stitch to evaluate the effectiveness of this annuloplasty. The stitch can be tied if proven effective, or easily removed if it does not achieve the desired result of improving leaflet coaptation. (Illustration courtesy of Erin Mainwaring.)

Mitral valve prolapse associated with rheumatic heart disease rarely requires operation in infants and children.

Repair of the congenitally stenotic mitral valve is quite difficult in most cases. Arcade, hammock, or parachute valves are severely abnormal, and repair is designed to facilitate the patient's somatic growth while delaying the inevitable mitral valve replacement. The leaflets are thickened and the chordae are generally thick and abnormal in number and shape. In some cases an adequate orifice can be created, but care must be taken to avoid injury to the papillary muscles and the chordal attachments with resultant severe insufficiency.

The marfanoid valve is amenable to repair in some patients using a combination of annuloplasty and chordal shortening. Chordal shortening techniques have been described by Carpentier and colleagues [7,8], Duran [50], and Oury *et al.* [51]. Most authors recommend shortening the chorda at its attachment to the papillary muscle rather than attempting to shorten the chorda itself. Figure 33.14 demonstrates this technique [11,51,54]. After the papillary muscle has been incised, the chorda is drawn down into the cleft in the muscle head. A suture is placed through the base of the chorda and then through the muscle and anchored over a pericardial strip. Another approach to chordal shortening involves the use of Gore-Tex chords of the appropriate length alongside the elongated chords (Figure 33.15) [54–56].

Reconstructive techniques can be associated with hemolysis. The preponderance of evidence would suggest that hemolysis occurs when there is a residual regurgitant jet that strikes prosthetic material such as Teflon pledgets or a Dacron ring. We do not use Teflon pledgets on the chordae but instead use small pieces of autologous pericardium. Patients with rheumatic heart disease may have progressive valvar dysfunction following placement of a Dacron ring that results in worsening of the regurgitant jet and hemolysis. Duran and colleagues [62] recommended covering the posterior aspect of the Dacron ring when performing annuloplasty for rheumatic disease in children and young adults. We would concur with this recommendation and use a thin strip of pericardium to cover the posterior portion of the ring.

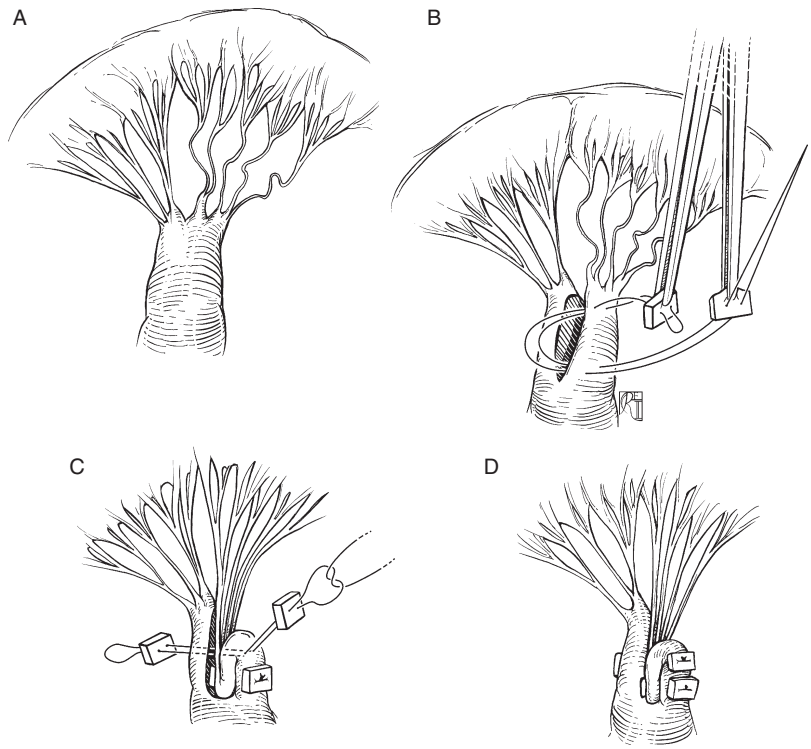

Figure 33.14 Chordal shortening technique. **A,** Elongated redundant chordae that allow prolapse of a segment of the leaflet are identified. **B,** Careful incision of the papillary head results in a trough into which the base of the chordal attachments can be drawn with a pledgeted mattress suture. **C,** Chordal shortening procedure is reinforced by a second pledget-supported mattress suture through both sides of the papillary head. **D,** Final result.

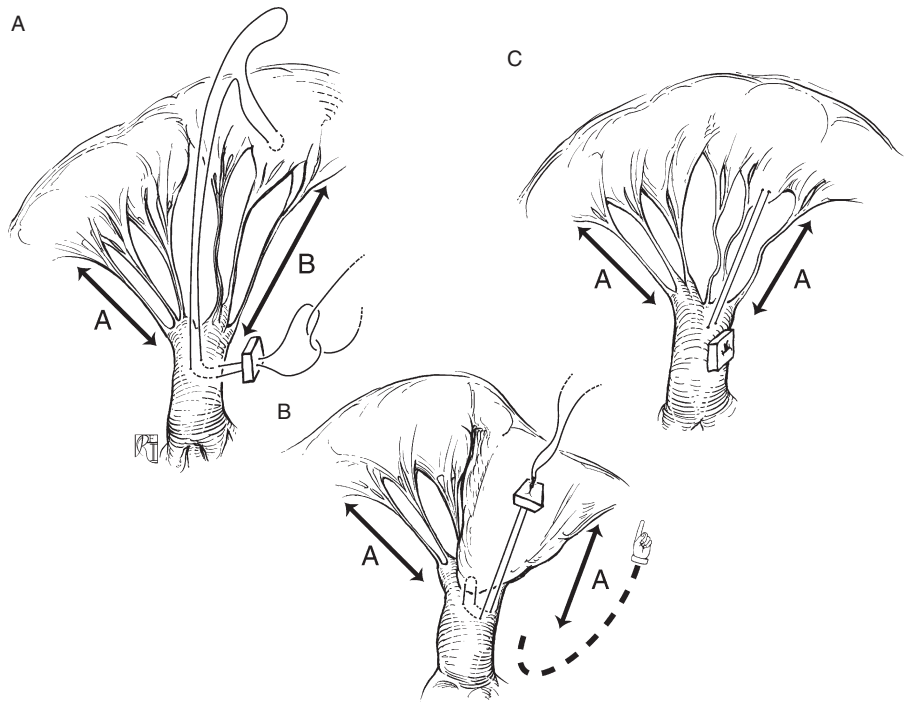

Figure 33.15 Another method for achieving chordal shortening and reinforcement involves use of polytetraflouroethylene artificial chordae. **A,** The redundant elongated chordae are characterized by solid line B. A mattress suture is placed through the free edge of the leaflet at the site where the chordae are missing or elongated. The mattress suture is then brought down to the head of the papillary muscle, and a pledget is added. **B,** Leaflet is drawn down to the papillary head. This maneuver allows the surgeon to tie the knots over the pledget at the appropriate length (solid line A). **C,** Leaflet has been elevated to its normal position, and the effect of the artificial cord on leaflet height is assessed.

Reoperation for left AV valve regurgitation following repair of AV canal defects is often very successful [40,52]. In our experience the septal cleft elongates as the leaflets grow, resulting in central insufficiency. We have seen disruption of the previous sutures as a rare cause of the "recurrent" cleft. The reoperated AV defect is a trileaflet valve that is amenable to annuloplasty at the lateral commissures and septal cleft repair by simple sutures (Figure 33.13). The same techniques can be used to repair a regurgitant tricuspid valve in a patient with corrected transposition or single ventricle. Finally, multiple annuloplasty sutures may be useful in repairing the abnormal multileaflet valve of some forms of single ventricle. We have used chordal shortening procedures in patients with single ventricle on occasion and believe there are circumstances where this is a useful and important technique. Operations for endocarditis of the mitral valve in infants and children usually require valve replacement. In some cases the leaflet can be repaired with a patch of autologous pericardium. This approach is useful when the mitral valve lesion represents extension from the aortic valve annulus.

When a complex repair is performed, the surgeon may be uncertain regarding the need for additional annuloplasty sutures or further commissural splitting. In either case, the surgeon is attempting to achieve the most competent valve possible without creating stenosis. On some occasions we will close the atrium and partially re-warm to obtain a "brief look" of the valve repair with TEE. We maintain a vent in the left atrium during the early phase of myocardial recovery to decompress the left ventricle and aid in air removal. After 20 minutes of recovery, when cardiac function is satisfactory, we wean the patient from bypass and evaluate the repair by TEE [63]. When TEE is not possible because of the size of the patient or other anatomic factors, we use epicardial echocardiography to assess the quality of the repair. A left atrial pressure line is placed, and the left atrial pressure monitoring provides additional information regarding valve function. Atrioventricular synchrony is also important in ensuring optimal function of the repaired mitral valve. We use pacing wires in valve repair cases, and AV pacing is used when appropriate during evaluation of the repair. At this time the surgeon can correlate the anatomic observations at surgery with the echocardiographic findings, left atrial trace, and other available data. Residual abnormalities detected in this fashion can then be addressed by reinstituting bypass, repeating the cardioplegia, and reopening the left atrium. On several occasions we have used this strategy to improve the repair of a congenitally stenotic valve. The brief look permits assessment of the support of the leaflets and allows a more aggressive approach to be taken if necessary. When both stenosis and insufficiency are revealed, a decision must be made, taking into account the patient's age, weight, clinical status, and ventricular function, to either accept this result or replace the valve.

The technique for mitral valve replacement in older infants and children is similar to that in adults. However, the small annulus encountered in some patients requires adjustments in technique. In adults preservation of chordal attachments is considered important in preserving ventricular function following mitral valve replacement. In infants and small children chordal preservation may not be feasible for several reasons. First, the annulus may be quite hypoplastic, and complete excision of leaflet tissue and chordae along with the tips of the papillary muscles may be necessary to allow placement of an adequate-sized prosthesis. Second, care must be taken to avoid the possibility that remnants of the native valve leaflet or chordae interfere with mechanical valve leaflet function. We routinely use small Teflon pledgets to reinforce the sutures when the annulus is thin and there is minimal tissue for suturing. In general, it is not possible to enlarge the mitral annulus. If the annulus is too small to accept a standard mechanical valve, a modified valve with a reduced sewing ring can be implanted above the annulus [35]. Supra-annular valve implantation requires placement of sutures in the wall of the atrium just below the orifices of the left lower lobe pulmonary veins and at the base of the left atrial appendage. In the anterior aspect, sutures may be placed through the true annulus at the region of aortic to mitral continuity. In some cases the supra-annular valve is tilted slightly. A tilting disk valve may be easier to orient than a bileaflet valve. Oversizing the mitral prosthesis can result in subaortic obstruction. A complete AV canal defect is one instance when the "annulus" can be enlarged. Replacement of the left AV valve early or late after repair in this circumstance often requires that the mitral prosthesis be sewn to the ventricular septal defect patch. In small patients the ventricular septal patch can be incised allowing implantation of a larger valve. The atrial septum is then reconstituted with a larger pericardial patch after valve implantation. In all valve replacement procedures, intraoperative monitoring of left atrial pressure and examination of the prosthetic valve by TEE ensures that leaflet function is unimpaired prior to decannulation.

The technique for implanting a left atrium to left ventricular apical conduit has been described [43] wherein the conduit can be implanted through a left thoracotomy or a median sternotomy. Cardiopulmonary bypass is necessary. A conduit equal in size to the diameter of the base of the left atrial appendage is selected and prepared. The conduit is attached to the apex of the left ventricle using a fish-mouth ventriculotomy, which avoids obvious coronary branches. We do not use an apical stent. Monofilament polypropylene is used as a continuous suture for each anastomosis. The ventricular anastomosis is reinforced with a Teflon strip. Figure 33.16 depicts the 6-year follow-

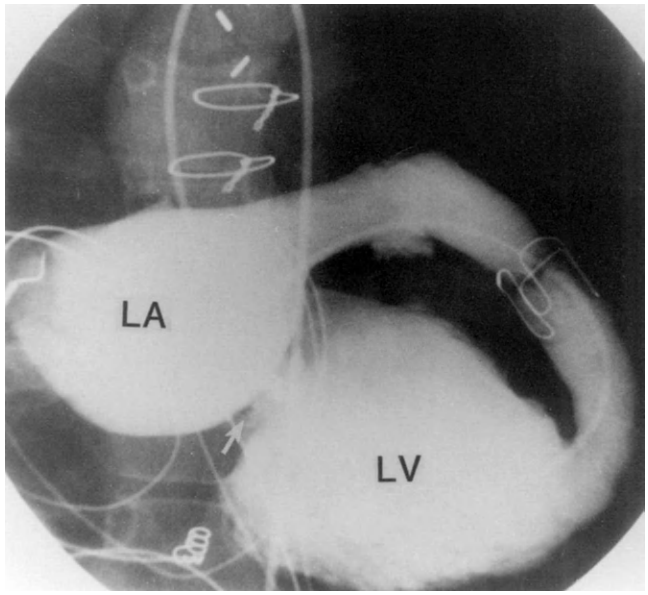

Figure 33.16 Left atrial angiogram obtained 6 years after implantation of a left atrial-to-left ventricular conduit. The conduit contains a 14-mm porcine valve. The catheter passes retrograde through the aortic valve into the left ventricle and then retrograde through the conduit to the left atrium. The hypoplastic mitral valve is indicated by the white arrow. The patient also had a recurrent supravalvar mitral ring. (LA, left atrium; LV, left ventricle.)

up angiogram of a patient born with supravalvar stenosing ring, marked hypoplasia of the mitral valve and annulus, small ventricular septal defect, normal-sized left ventricle, bicuspid aortic valve, and coarctation of the aorta [11]. The conduit was implanted in 1986 when the patient was 2.5 years old. The valve and conduit were replaced 6 years later. At each conduit operation, the native mitral valve was enlarged by resecting supravalvar fibrous tissue and cautiously opening the commissures. When the patient was 18.5 years old, the mitral valve orifice was enlarged once again and the apical conduit removed. The patient is currently functioning at New York Heart Association (NYHA) class II some 23 years after the first conduit was implanted and 7 years after the second conduit was removed.

Postoperative Care

The postoperative care of a child following repair or replacement of the mitral valve is guided by the preoperative status of the patient and the clinical condition of the patient following operation. After separation from cardiopulmonary bypass, the patient undergoes rigorous intraoperative evaluation of the repair. TEE and direct measurement of left atrial pressure (using a 20- or 22-gauge catheter) provide important information regarding the quality of the repair. A "v" wave may be present even after a satisfactory repair, as the size and shape of the "v" wave are determined by the amount of regurgitation and compliance of the left atrium. The optimal postoperative left atrial pressure is the lowest value that still provides a satisfactory cardiac output and adequate systemic perfusion pressure. Excessive volume transfusion to provide an arbitrary left atrial filling pressure is not recommended, as this may predispose to postoperative pulmonary complications and delay in weaning from the ventilator. The left atrial pressure tracing is also useful in detecting atrial arrhythmias.

Atrial and ventricular pacing wires are placed in all patients undergoing surgery on the mitral valve. We prefer the use of two atrial electrodes placed about 8–10 mm apart. The use of two electrodes provides security if one electrode fails. In addition, the small size of the artifact produced by bipolar atrial pacing makes interpretation of the electrocardiogram simpler. In some patients we have used the left atrial appendage as well as the free wall of the right atrium for lead placement. Atrioventricular sequential pacing may be useful in optimizing cardiac output at the lowest left atrial pressure. If the patient is not in sinus rhythm, atrial pacing or AV sequential pacing is used to minimize valve regurgitation. Mild or mild-to-moderate residual regurgitation may be acceptable following repair if the alternative is implanting a prosthesis in a very small patient. Moderate residual regurgitation is indicative of an inadequate repair, and additional sutures in a cleft or another annuloplasty stitch should be pursued.

Cardiac output is assessed clinically and assumed to be adequate if the systemic arterial blood pressure is normal for the patient's age and weight and if there is adequate urinary output without acidosis. Noninvasive mixed venous cerebral and renal tissue oxygen saturation measurements (near infrared spectroscopy) may provide additional information regarding the adequacy of cardiac output. When a patient has significant pulmonary artery hypertension, we implant a pulmonary artery pressure monitoring line and measure mixed venous oxygen saturation as needed. The pulmonary artery catheter can be placed through the free wall of the right ventricle or through the right atrium and positioned in the pulmonary artery before discontinuation of cardiopulmonary bypass. In our experience the routine use of thermodilution cardiac output catheters is rarely necessary.

We routinely use dopamine at 2–5 μg/kg/min. Most patients receive vasodilator therapy, which is especially important in those with abnormal left ventricular function. Nitroprusside and/or milrinone are titrated to provide a satisfactory cardiac output. Epinephrine may be useful when significant ventricular dysfunction is present.

We do not routinely use intravenous heparin for anticoagulation during the first 36 hours after mitral valve replacement. Subcutaneous low molecular weight heparin may be useful in patients unable to take oral coumadin early after operation. Oral coumadin therapy is begun on the second postoperative day following removal of the chest tubes and pacemaker wires. Anticoagulation with coumadin is continued indefinitely in all patients following mechanical valve replacement.

The management of postoperative complications, including bleeding, low cardiac output, and multisystem organ failure, are similar to other operations requiring the use of cardiopulmonary bypass in a child with pulmonary hypertension and left ventricular dysfunction. Most complications can be prevented by meticulous attention to the details of the operation. Careful dissection in all patients, especially in reoperations, will minimize bleeding following cardiopulmonary bypass. Patients in severe biventricular failure often have hepatic dysfunction and abnormal clotting factors following operation. Multiple blood products may be necessary to achieve adequate hemostasis. Myocardial preservation and the elimination of intracardiac air before weaning from cardiopulmonary bypass should minimize postoperative cardiac dysfunction. The routine use of TEE and left atrial pressure monitoring should eliminate a poor repair or a malfunctioning prosthetic valve as a cause of a low cardiac output state following operation. Judicious fluid administration is necessary during the early postoperative interval to minimize extravascular water in the lungs.

Hemolysis can occur after extensive valve repair. Hemolysis may be associated with a peribasilar leak after prosthetic valve implantation or with mild-to-moderate regurgitation following repair. Hemoglobinuria that persists for more than a few hours following completion of operation should be carefully evaluated by standard laboratory tests. Low-grade hemolysis following valve repair may have a benign clinical course. If transfusion is necessary to maintain the hematocrit, early consideration should be given to mitral valve replacement. Beta blockade may reduce hemolysis and allow healing of the rough surfaces responsible for hemolysis. The use of β-blockade requires adequate left ventricular function.

Complete heart block can occur following mitral valve replacement in infants and small children. When the annulus is hypoplastic, the surgeon is faced with a dilemma regarding excision of leaflet tissue along the crest of the ventricular septum and suture placement in the region of the AV node and the bundle of His. If complete heart block is present at the completion of operation, permanent wires should be implanted. In select patients, biventricular pacing may improve valve function after a complex repair. We have also noted that temporary pacing from the left ventricle may improve early postoperative valve function.

Results

The operative mortality for congenital mitral valve disease is primarily related to the anatomic and physiologic abnormalities of the valve. Patients in whom the left-sided AV valve is reparable can undergo this operation with an extraordinarily low risk and favorable long-term outcomes [7–10,29,30,52,64,65]. Patients with primary mitral insufficiency have a greater likelihood of achieving a durable repair than patients with primary mitral stenosis, and thus the prognosis for the insufficiency group is far better. The need for mitral valve replacement, particularly in infants and young children, is a marker of a poorly functioning mitral valve and/or associated congenital heart defects. Other risk factors that influence outcomes include left ventricular dysfunction, the presence of severe pulmonary hypertension and chronic lung disease from recurrent infections, and the need for an emergency operation.

Oppido *et al*. recently reported their results on the surgical treatment of congenital mitral valve disease from the Royal Children's Hospital in Melbourne, Australia [64]. Their report summarized an experience with 71 patients from 1996 to 2006, of whom 70 underwent primary mitral valve repair. Figure 33.17 demonstrates the actuarial curves for this patient population [64]. At 60 months of follow-up, overall survival was 94 ± 2.8% and the freedom from reoperation was 76 ± 5.6%. A suboptimal repair was found to be a significant predictor for reoperation, with the caveat that many of the re-repairs were successful.

At the Rady Children's Hospital San Diego (RCHSD), a heterogeneous group of 216 patients have undergone an operation to treat abnormal function of the systemic AV valve. This group of patients was identified through the RCHSD database but excludes patients undergoing primary repair of an AV septal defect. The diagnoses of all patients are listed in Table 33.1. The age of the patients

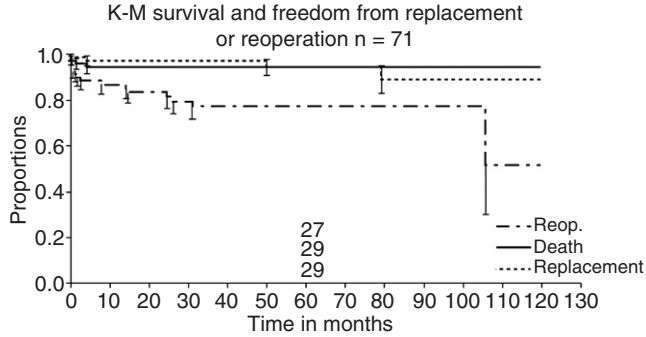

Figure 33.17 Kaplan-Meier curves showing freedom from death (solid line), reoperation (thick dashed line), and prosthesis (thin dashed line) in 71 patients undergoing mitral valve surgery. (Reproduced with permission from Oppido *et al.* [64].)

Table 33.1 Diagnoses of patients undergoing systemic AV valve repair/replacement. (AV, atrioventricular; LV, left ventricle; MR, mitral regurgitation; TGA, transposition of great arteries.)

Repair (listed in decreasing order of frequency)
Left AV valve regurgitation after repair of an AV septal defect
Systemic AV valve regurgitation in single ventricle (all forms)
Congenital mitral stenosis and or insufficiency
Rheumatic heart disease
Tricuspid valve regurgitation (late onset) after atrial switch for TGA
Mitral valve prolapse
Marfan's syndrome
Supravalvar mitral ring
Anomalous origin of left coronary from main pulmonary artery
Stent injury to mitral valve
Mitral regurgitation late after arterial switch operation
Replacement
Left AV valve regurgitation/stenosis after prior repair of an AV septal defect
Replacement of a mitral prosthesis
Cardiomyopathy with severe MR and preserved LV function
Severe AV valve regurgitation in single ventricle
Congenital mitral stenosis and/or insufficiency
Rheumatic heart disease
Corrected TGA
Hemolysis post complex repair
Mitral leaflet tumor

Alfieri stitch/create double-orifice valve

ranged from 4 months to 19 years (median age 5 years). There were 41 primary operations and 165 secondary operations. In 168 patients (78%) the AV valve could be repaired. The most common techniques used for valve repair were segmental annuloplasty and cleft closure. Each repair was tailored to the anatomic findings for that specific patient. Table 33.2 lists the repair techniques that were used in this cohort. There were two early failures (1%) in the repair group requiring valve replacement for intractable hemolysis. Forty-eight patients (22%) had valves that were deemed unsuitable for valve repair and therefore underwent valve replacement. Collectively, there were seven operative deaths in this series (4.6%). Two deaths occurred in the valve-repair cohort (1%), both of whom were infants with single-ventricle physiology. There were five deaths in the valve-replacement group, for a cohort mortality rate of 11%. Postoperative death was related to the age of the patient at operation, the severity of illness, and the need for valve replacement at the time of surgery. Long-term follow-up revealed good-to-excellent status in most patients (NYHA class I or II). In the valve-repair group, 13 patients have required subsequent valve replacement, although there has been no late mortality in this group. There have been five late deaths in the valve-replacement cohort, of which two were directly valve related.

A review of the literature confirms that mitral valve replacement carries a higher mortality and poorer prognosis than valve repair [31,32,34,35,41,42]. For infants, the operative mortality has been reported to be as high as 33% [35]. Improved techniques of myocardial preservation and the use of low-profile valves have reduced hospital mortality in recent years to approximately 10% for infants, with a lower risk in older children. Selamet Tierney *et al*. have recently suggested that supra-annular placement of the mitral prosthesis is associated with worse long-term survival [42]. We have not noted a decrement in survival attributable to supra-annular placement of a mitral valve prosthesis at RCHSD. It is likely that the need for supra-annular placement is a surrogate marker for several other risk factors.

The long-term results after mechanical valve replacement do not compare favorably with valve repair [17]. Morbidity because of anticoagulation may occur, and it is now generally accepted that all patients with a mechanical valve should be anticoagulated with coumadin. Management of coumadin anticoagulation has been relatively straightforward in most patients, yet in spite of adequate levels of anticoagulation, we have seen late obstruction of mechanical valves in infants and children because of tissue overgrowth (pannus). Fibrous tissue overgrowth into the annulus results in interference of leaflet motion and has been seen in less than 2 years following implantation of a mechanical valve. Acute thrombosis occurs in some patients when clot forms at the entrapped leaflet. Thrombolytic therapy may be useful in an emergency situation, but acute thrombosis is invariably secondary to the trapped leaflet and requires surgical intervention to debride the pannus or re-replace the valve.

The functional results after valve repair are quite satisfactory. Long-term survivors of valve repair often have residual murmurs and echocardiographic evidence of mild regurgitation, but their quality of life is excellent. Mild cardiomegaly is well tolerated and afterload reduction can delay the need for late valve replacement. In our experience, 90% of patients undergoing successful valve repair have not required reoperation during a follow-up period of up to 21 years. The late results of mitral valve replacement

in infants and small children are unsatisfactory, with 5-year survival rates of 50% to 80% [31–35,41,42]. Infants requiring mitral valve replacement will require re-replacement within 5 years. Porcine heterograft mitral valves fail at a rapid rate and should not be used except under unusual circumstances. Porcine valves can be expected to last 3 years in infants and perhaps 5 years in children.

The left atrium-to-left ventricular apical conduit has been successfully employed in one of our patients. This type of conduit is suitable for a patient born with a normal-sized left ventricle and a very small mitral annulus. As mitral annulus enlargement is usually not possible, the patient is faced with replacement of the mitral valve with a very small mechanical valve. When the annulus is so small that a suitable mechanical valve is not available to fit the patient, an apical conduit may be useful. We consider this a last resort because the long-term effects of the apical incision on the left ventricle are not well defined.

In summary, current surgical technique permits repair of the systemic AV valve in many infants and children requiring operation. The long-term results of successful valve repair are good to excellent. Repair avoids the short- and long-term morbidity and mortality of valve replacement as well as allowing for growth of the valve and annulus.

CHAPTER 34

Total Anomalous Pulmonary Venous Connection

Nicola Viola[1] and Christopher A. Caldarone[2]

[1]Southampton General Hospital, Southampton, UK
[2]The Hospital for Sick Children, Toronto, ON, Canada

Overview

Total anomalous pulmonary venous connection (TAPVC) constitutes a heterogeneous group of lesions in which all of the pulmonary veins (PV) are connected to the right atrium or its tributaries. A concomitant right-to-left shunt, commonly via an interatrial communication, is required for survival after birth. Significant obstruction to pulmonary venous drainage results in pulmonary edema and cardiogenic shock which is rapidly lethal if untreated. Surgical results for the treatment of TAPVC have greatly improved over the last three decades, reducing operative mortality to less than 10% in most centers.

Embryology

Successful connection between the pulmonary venous system and the left atrium is the result of three distinct processes that involve the formation of the primitive lung and the primitive left atrium. At first, primitive lung buds originate as out-pouchings from the trachea on day 26–27 of gestation. A plexus of vessels, the splanchnic plexus, develops around the lung buds and allows the drainage of blood into the anterior cardinal veins (the primordial superior vena cava (SVC), coronary sinus, and azygous vein) and into the umbilicovitelline veins (which develop into the portal system). At approximately day 27–28 of gestation, a solitary pulmonary vein evaginates from the forming left atrium towards the venous plexus through the dorsal mesocardium. By day 28–30 of gestation fusion between the solitary vein and the pulmonary plexus is completed. Finally, between days 30 and 48 the solitary vein bridging between the left atrium and the lungs retracts back towards the posterior wall of the left atrium, a process made possible by the complete involution of the pulmonary-to-systemic vein connections. The correct axial orientation of the interatrial septum during this period is a necessary condition to enable the appropriate connections to form.

As a result of this process, four fully formed veins open into the posterior aspect of the left atrial cavity. Failure of all the pulmonary veins to divide from the splanchnic venous system and, possibly, a concomitant leftward displacement of the developing atrial septum is hypothesized to be the primary defect in embryological development responsible for TAPVC [1–4]. Unilateral lesions produced at the same stage (partial anomalous pulmonary venous connection), lesions occurring at a later stage (atresia of common pulmonary vein or cor triatriatum) or as a result of abnormal reabsorption of the common vein into the left atrium (congenital pulmonary vein stenosis and an abnormal number of pulmonary veins) are important related pulmonary venous anomalies.

Classification

Total anomalous pulmonary venous connection was classified on an embryological basis by Neill and colleagues [5], with a more recent modification proposed by Lucas [6]. Four types were identified: type one, pulmonary veins connected to right atrium; type two, pulmonary veins connected to SVC/azygous vein (right common cardinal system); type three, pulmonary veins connected to left SVC/coronary sinus (left common cardinal system); type four, pulmonary veins connected to portal vein/ductus venosus (umbilicovitelline system).

Almost contemporarily, Darling *et al.* proposed a classification, based on autopsy examinations, which has become widely recognized and is based on the level of the connection of the anomalous connecting vein [7]. In type 1, or supracardiac, the common vein connects to structures above the heart (right SVC, azygos vein, left SVC, or innominate vein). In type 2, or cardiac, the connecting vein

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.
© 2013 Blackwell Publishing Ltd. Published 2013 by Blackwell Publishing Ltd.

is attached to cardiac structures (e.g., the right atrium or the coronary sinus). In type 3, or infracardiac, the connection is situated below the diaphragm to the inferior vena cava (IVC)/portal vein system. Type 4, or mixed, represents a combination of the above conditions [7].

Some authors have stratified these categories by the presence/absence of obstruction to pulmonary venous drainage. Obstructions can be found at the level of the connecting vein, owing to intrinsic narrowing or extrinsic compression, or at the level of the interatrial communication (Table 34.1). Burroughs and Edwards defined three groups of connection between the pulmonary and the systemic veins [8]. Group I, the least obstructed, is constituted by the shortest connections as in Darling's cardiac type (type 2). Group II, with intermediate length and moderate risk of obstruction, corresponds to Darling's supracardiac type (type 1). Group III, has the longest routes of venous drainage and high risk of obstruction and corresponds to Darling's infracardiac type (type 3) [8]. Smith *et al*. tried to merge the anatomical and physiological elements into a simplified classification, based on the observation that almost all infracardiac connections are obstructed and connections above the diaphragm are seldom obstructed, and divided TAPVC into supradiaphragmatic and subdiaphragmatic types [9].

Table 34.1 Mechanisms of obstruction in TAPVC.

Intrinsic stenosis	Stenosis of the individual pulmonary veins Stenosis of the confluence
	Stenosis of the connecting vein (single or multiple)
	Stenosis at the site of the abnormal connection drainage into a solid parenchymal organ (infracardiac type)
Extrinsic compression	Anatomical "vice" position (supracardiac type) between bronchus and pulmonary artery
	Connecting vein anterior to aortic arch (supracardiac type)
	Small esophageal hiatus (infracardiac type)
Mixed compression	Combination of intrinsic and extrinsic mechanisms
Restrictive interatrial communication	

Most recently, the unified nomenclature system presented at the International Nomenclature and Database Project for Pediatric Cardiac Surgery was introduced. Using embryological principles to organize all pulmonary vein lesions into a unified classification, the Darling's classification is adopted for TAPVC because of simplicity and wide acceptance. The presence/absence of obstruction should be mentioned, and the nature and level of obstruction should be added as the last element to complete the diagnosis (Table 34.2) [2].

Cardiac Anatomy, Associated Lesions

As mentioned, a communication between the systemic and the pulmonary venous return is necessary for survival after birth. In the overwhelming majority of cases this is ensured by an interatrial communication. Rarely the communication can be represented by one or multiple ventricular

Table 34.2 Congenital Heart Surgery Nomenclature and Database Project: TAPVC.

Hierarchy Level 1 Pulmonary vein anomaly	Hierarchy Level 2 Darling's type	Hierarchy Level 3 Obstruction	Hierarchy Level 4 Type of obstruction
TAPVC	Type I (Supracardiac)	Nonobstructed	
		Obstructed	Intrinsic narrowing Extrinsic compression Obstructive interatrial septum
	Type II (Cardiac)	Nonobstructed	
		Obstructed	Intrinsic narrowing Extrinsic compression Obstructive interatrial septum
	Type III (Infracardiac)	Nonobstructed	
		Obstructed	Intrinsic narrowing Extrinsic compression Obstructive interatrial septum
	Type IV (Mixed)	Nonobstructed	
		Obstructed	Intrinsic narrowing Extrinsic compression Obstructive interatrial septum

septal defects or a patent ductus arteriosus [10,11]. Shunts at atrial level are typically of adequate size and the interatrial gradient is usually low [12,13].

The right atrium can be thick and enlarged, and Mathew *et al.* found that the left atrium is generally half the size of the expected normal, owing to a small posterior component rather than a small appendage area [14]. In most cases the left ventricle has normal size and muscular mass [15–17]. On the contrary, the right ventricle can be enlarged and hypertrophied, especially in supradiaphragmatic nonobstructive lesions [18].

Up to 90% of patients with heterotaxy and asplenia have TAPVC. Tetralogy of Fallot, double-outlet right ventricle, and interrupted aortic arch have also been reported as associated lesions [10,19–21].

Natural History

The clinical presentation of TAPVC depends on two critical elements: the degree of obstruction to the pulmonary venous drainage and the degree of obstruction to the compensatory right-to-left shunt.

At one end of the spectrum, there are neonates with completely unobstructed circulation (typically supracardiac and cardiac types). These patients present with signs and symptoms of a large left-to-right shunt. Tachypnea and arterial desaturation are present to various degrees together with signs of right ventricular volume overload. If untreated, this condition can lead to congestive heart failure. Late sequelae include pulmonary edema, pulmonary hypertension, and cyanosis.

At the other end of the neonatal clinical spectrum are neonates with severe pulmonary venous flow obstruction. In these cases, the resulting pulmonary venous and pulmonary arterial hypertension produces severe acute pulmonary edema, right ventricular antegrade flow reduction owing to the excessive increase in afterload, extreme hypoxemia, and circulatory collapse. The presence of a restrictive atrial septal defect results in reduced preload to the left ventricle, diminished systemic cardiac output, and severe cardiogenic shock. Obstructed TAPVC is rapidly lethal and presents formidable challenges to its treatment.

Diagnosis

Unobstructed TAPVC is sometimes difficult to diagnose in the first few days of life because patients may have very mild cyanosis and the absence of a murmur. After the first few months of life, infants may present with tachypnea, mild cyanosis, failure to thrive, and feeding difficulties. On examination, a loud and continuously split S2 together with a systolic ejection murmur over the pulmonary valve are common findings. Hepatomegaly, venous congestion and fine crackles on lung auscultation are possible in cases of noncompensated cardiac failure. Neonates with an obstructed circulation become critically ill immediately after birth. In those cases hypoxia and profound cyanosis, hypotension and metabolic acidosis are commonly encountered [21,22].

Chest radiographs of unobstructed TAPVC show plethoric lungs and a large cardiac silhouette. A typical finding is the so-called snowman silhouette where the heart and the mediastinal enlargement owing to a prominent pulmonary artery, vertical vein, and SVC form an eight-shaped figure. The snowman sign is characteristic of supracardiac TAPVC, but is generally not appreciable before the age of 6 months [23]. Obstructed neonatal TAPVC shows severe pulmonary edema in the presence of a normal size and shape of the heart.

Two-dimensional and Doppler echocardiography are the primary diagnostic tools for most patients. Diagnostic findings are a distended right ventricle, a vascular confluence coupled with absent venous drainage to the left atrium on the Doppler interrogation, the presence of an accessory common vein or a dilated coronary sinus, and turbulent flow in the right atrium with a right-to-left shunt. Echocardiography has shown excellent sensitivity and specificity in fetal diagnosis and as prognostic tool [24–26]. In general, echocardiography has supplanted angiography in the vast majority of cases [22,23,27–31].

Cardiac catheterization is avoided in unstable neonates to reduce delay to treatment and contrast-related renal injury. It can be useful in nonobstructive cases to better define connections of mixed type and to identify possible associated anomalies. The site of the anomalous connection can be precisely located with a step up in oxygen saturation along the systemic vein system. Intracardiac oxygen saturation measurements characteristically demonstrate equivalent saturations in all cardiac chambers, the pulmonary artery, and the aorta.

In nonemergency cases of TAPVC, contrast-enhanced magnetic resonance angiography (MRA) can be used to provide a complete anatomic and functional diagnosis [32]. From an anatomical point of view, it allows excellent visualization of all pulmonary veins and other pulmonary-to-systemic venous connections. When compared with echocardiography, MRA has been shown to offer superior imaging of the entire pulmonary venous anatomy [33]. From a functional point of view, the amount of anomalous drainage and the resulting Qp/Qs can be calculated by using phase-contrast MRA, which depicts the velocity, volume, and pattern of blood flow of pulmonary venous flow (Plate 34.1, see plate section opposite p. 594). Moreover, a description of the secondary effects on pulmonary arterial size and blood flow, ventricular size and function are obtainable in the same study. This important information is difficult or impossible to obtain using other modalities [32,34,35].

Operative Management and Anesthetic Considerations

Despite the significant differences in physiology and clinical presentation, both obstructed and nonobstructed TAPVC pose an absolute indication for surgical repair, given the poor prognosis recorded in untreated cases. In patients with evidence of pulmonary venous obstruction, surgical repair is conducted promptly after diagnosis [36,37]. In our institution, patients with unobstructed TAPVC are electively repaired at 1–2 months of age. Alternatively, other programs choose to repair unobstructed TAPVC at the time of presentation during the neonatal period.

Medical management of patients with nonobstructed pulmonary venous connection is directed at compensating right ventricular failure, hypoxia, and congestive heart failure with mild inotropic support, diuresis, and avoidance of high levels of inspired oxygen. Assisted ventilation is rarely needed. In selected cases, alpha-blockade can be used to reduce the incidence of pulmonary hypertension.

Medical maneuvers in patients with obstructed TAPVC are limited in terms of efficacy. Neonates with obstructed TAPVC often require intubation and hyperventilation with 100% oxygen to maintain $PaCO_2$ below 30 mmHg and promote respiratory alkalosis. Sodium bicarbonate is used to correct the ensuing metabolic acidosis and enhance the action of inotropic and diuretic treatments, often necessary to support the failing ventricles. Prostaglandin E1 can be infused to maintain patency of the ductus arteriosus, which has the effect of improving systemic cardiac output through a right-to-left shunt, although this often occurs at the expense of an already reduced pulmonary circulation in conditions of severe hypoxia. Medical efforts are minimally effective in correcting the ensuing hemodynamic and metabolic crisis and their use is limited to provide some short-lived palliation until definitive repair is accomplished.

In some centers, cardiac catheterization has been used in critically ill patients for diagnosis and percutaneous palliation of obstructed TAPVC. A restrictive interatrial communication can be relieved with balloon septostomy. Moreover, several authors have proposed the use of percutaneous angioplasty and stenting of the obstructed common vein to palliate shock and improve preoperative optimization of the metabolic state (Figures 34.1, 34.2) [38–43]. In seven such cases reported over the last decade, four were of supracardiac type where a discrete obstruction could be identified. One patient required repeated stent implantations due to in-stent restenosis [42]. In one patient the procedure was performed with extracorporeal membrane oxygenation (ECMO) support [39]. These initial experiences have yielded promising results in obtaining hemodynamic stabilization in preparation for surgery.

Some centers have reported good result using ECMO in the critically ill neonate as preparation for surgery [44–46]. Postoperative ECMO is used in patients with severe residual pulmonary hypertension [47–49]. Once in the operating room, the anesthetic management is directed toward reducing the pulmonary vascular resistance by the use of fentanyl in high doses, aggressive correction of hypocalcemia, hypoglycemia, and lactic acidosis. Isoproterenol may be useful in normotensive patients for afterload reduction.

Surgical Repair of Supracardiac Type

Surgical repair of supracardiac TAPVC is accomplished via sternotomy with two venous cannulae (IVC and SVC) and an aortic cannula. Immediately after the initiation of cardiopulmonary bypass, the ductus arteriosus is ligated

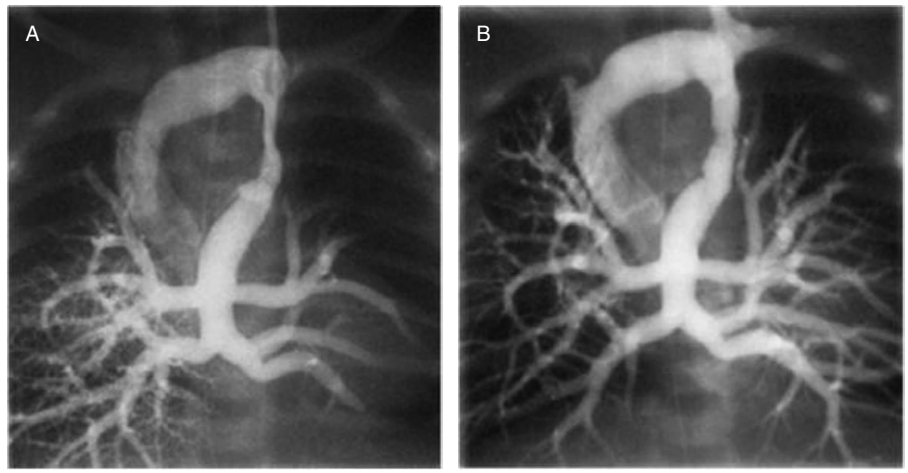

Figure 34.1 Total anomalous pulmonary venous connection of supracardiac type to the innominate vein. **A,** Both right and left pulmonary veins are unobstructed. The vertical vein, however, is severely stenotic at the junction with the innominate vein. **B,** Emergency percutaneous stent dilation was performed with acceptable short-term result. (Courtesy of Dr Shi-Joon Yoo and Mr Omar Thabit.)

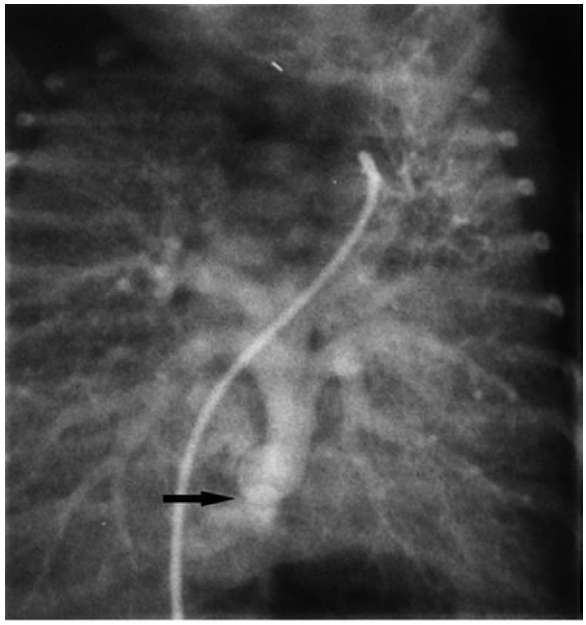

Figure 34.2 Infracardiac total anomalous pulmonary venous connection. The vertical vein is stenosed at the insertion in the venous duct (black arrow). (Courtesy of Dr Shi-Joon Yoo and Mr Omar Thabit.)

and divided. The patient is cooled to mild hypothermia at 28–30 °C or, rarely, deep hypothermia at 18–20 °C to allow deep hypothermic circulatory arrest. The aorta is cross-clamped and cardiac arrest induced with antegrade cold blood cardioplegic solution.

The heart is retracted cephalad and to the right exposing the left posterior pericardial area [50]. This maneuver is enhanced by the absent connection between the pulmonary veins and the atrium. The vertical communicating vein is ligated near its connection with the innominate vein or SVC, to avoid tethering of the vein ostia near the site of planned anastomosis. When severe preoperative obstruction is present, leaving the vertical vein patent may contribute to the relief of postoperative pulmonary vein hypertension [51], although significant residual left-to-right shunt may require reintervention [52]. A longitudinal incision is made in the confluence and the posterior wall of the left atrium. Because collateral pulmonary flow can be extensive, cardiopulmonary bypass flow rates may need to be decreased temporarily to facilitate visualization and placement of the incision. Small cardiotomy suction cannulas can then be placed in the pulmonary venous confluence and perfusion flow rates restored. Through a left atriotomy, the interatrial communication is closed primarily or with a patch of autologous pericardium. The left atrium and the confluence are then anastomosed to create the largest possible anastomosis. Some authors advocate the use of interrupted sutures, others the use of reabsorbable ones, with inconclusive data to support either technique. Attention must be paid to maintain adequate patency of the anastomosis without distortion of the ostium of the pulmonary veins (Figure 34.3A-C).

This approach, which involves a substantial displacement of the heart anteriorly and to the right, carries the potential for distortion of the atrium and confluence at the time of the repair and consequent postoperative stenosis. In order to avoid this problem, some centers advocate performing the posterior anastomosis across the roof of the left atrium between the SVC and the aortic root [53], so that the reciprocal position of the two chambers is left unchanged during the repair. Alternatively, the venous confluence behind the left atrium is accessed from the right following a leftward retraction of the heart. A transverse incision is conducted along the right atrium inferiorly across the Waterston groove and through the posterior wall of the left atrium. The confluence is exposed and incised longitudinally between the pulmonary vein ostia. The anastomosis is then performed starting at the leftward corner of the incision and moving rightward. The interatrial defect is closed with a patch of autologous pericardium and the repair completed [54]. This approach offers excellent visualization of the confluence without significant distortion while avoiding rightward retraction of the heart. Also this technique permits patch enlargement of the left atrium, which is usually small (Figure 34.3D-F).

Repair of the Cardiac Type

When the communicating vein is connected to the coronary sinus, access is obtained through a right atriotomy. The portion of the septum between the ostium of the coronary sinus and the fossa ovalis is incised and the Thebesian valve removed. The opening of the connecting vein is usually seen in the mid portion of the coronary sinus. The coronary sinus is then unroofed towards the left atrium. In cases in which the confluence is connected to the coronary sinus by an obstructed communication, this is also incised back to the confluence via the coronary sinus to provide unobstructed drainage of the pulmonary return. The resulting large interatrial defect is closed with a patch, normally of glutaraldehyde-treated autologous pericardium, leaving the coronary and the pulmonary venous drainage to the left of the reconstructed septum (Figure 34.4). In cases of TAPVC to the right atrium, the pulmonary drainage can be redirected into the left atrium with a baffle repair through the patent foramen ovale as in the case of a sinus venosus interatrial defect. Hiramatsu and colleagues have proposed use of posterior displacement of the interatrial septum: after its detachment from the posterior edge, the septum is reattached to the right, between the pulmonary veins and the venae cavae ostia, thus recreating the normal anatomical relationships [55].

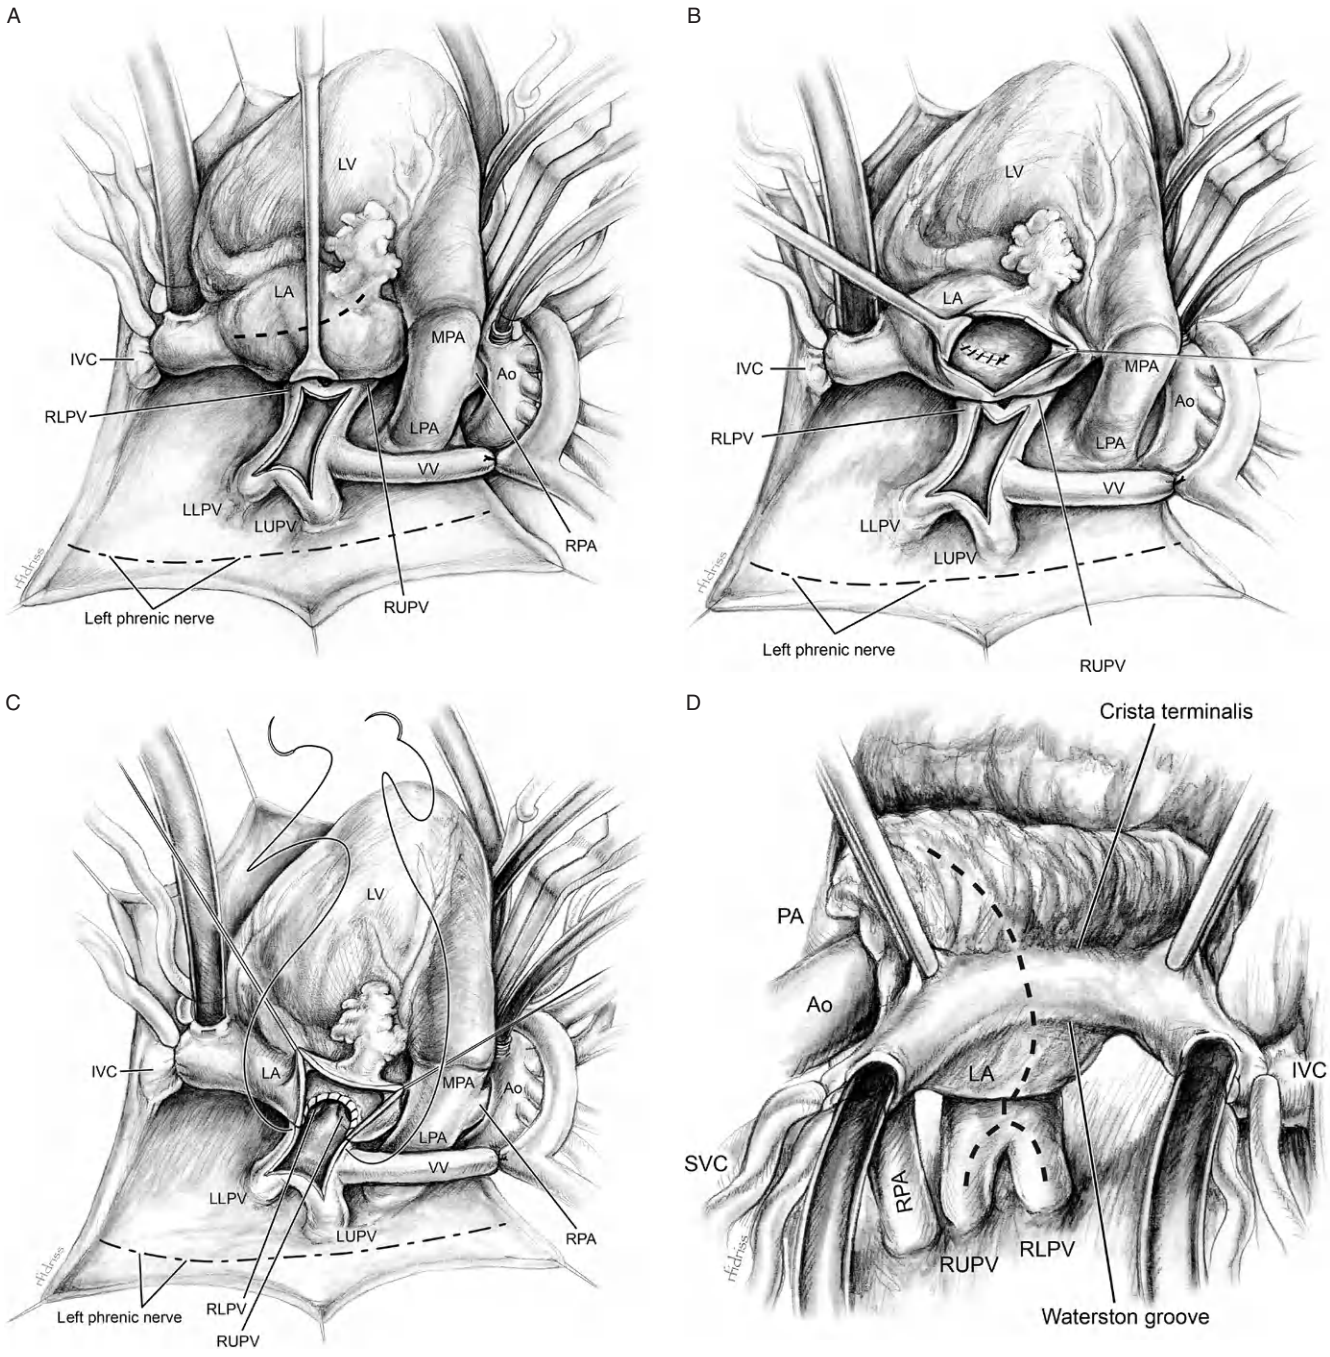

Figure 34.3 Repair of supracardiac total anomalous pulmonary venous connection with vertical vein (VV) connected to the innominate vein. **A,** The vertical vein is ligated next to its connection to the innominate, due to its accessibility in this point and the relative distance from the phrenic nerve. The incision into the confluence is extended into each of the pulmonary veins to increase the length of the anastomosis. An incision is made in the left atrial wall extending inferiorly from the base of the left atrial appendage to the inferior vena cava (IVC)-atrial junction. **B,** A secundum atrial septal defect is closed through the left atriotomy with a patch of autologous pericardium. **C,** The anastomosis between the left atrium (LA) and the venous confluence is started at the right corner and continued leftward on the superior and inferior rims as the heart is returned to its anatomic position. **D,** Alternatively, the venous confluence can be accessed from the right pericardial fossa. The LA is retracted and both atria are opened with a longitudinal incision crossing the Waterstone's groove and extending on the posterior wall of the left atrium. The pulmonary venous confluence is opened through a longitudinal incision extending from left to right. An incision is commenced in the right atrium and extended across the Waterstone groove into the left atrium. **E,** The anastomosis between the left atrial wall and the venous confluence is commenced at the left corner and is brought rightward. **F,** After completion of the anastomosis the interatrial septum is augmented with the interposition of a pericardial patch to augment the left atrial cavity. **G**, The right atrial wall is finally closed with primary suture and the addition of a second pericardial patch. (LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; LV, left ventricle; PA, pulmonary artery; RLPV, right lower pulmonary vein; RPA, right pulmonary artery; RUPV, right upper pulmonary vein; SVC, superior vena cava.)

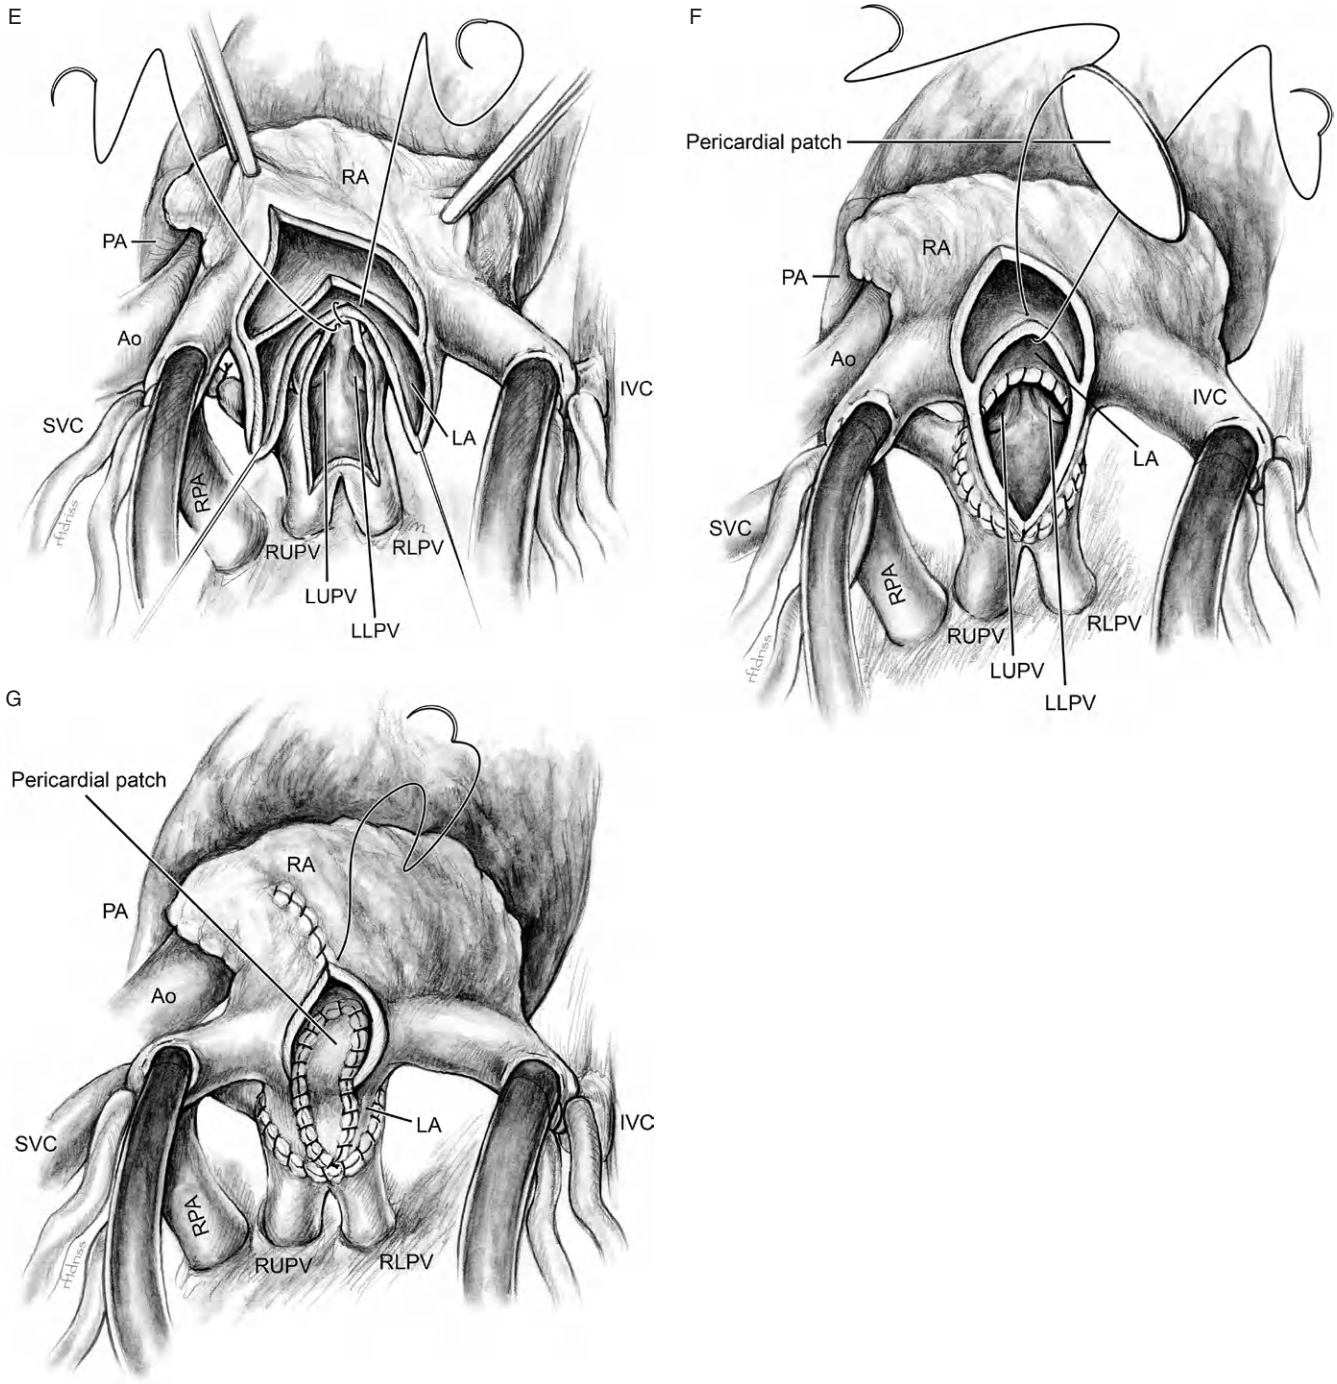

Figure 34.3 (*Continued*)

Repair of the Infracardiac Type

The vertical vein is typically extrapericardial, and descends to the abdominal cavity via the esophageal hiatus. The confluence is often aligned vertically in a Y-shape. Exposure can be obtained from a left approach retracting the heart anteriorly and to the right. Alternatively, access can be gained through a biatrial incision from the right side as described above. Once access to the confluence is obtained, the vertical vein can be ligated. As noted above, some authors recommend leaving the vertical vein intact to allow decompression of the small, non-compliant left atrium into the systemic venous system, and thereby diminish postoperative pulmonary venous hypertension [56]. Once the confluence has been opened with a vertical, Y-shaped incision, the repair is carried out as described previously

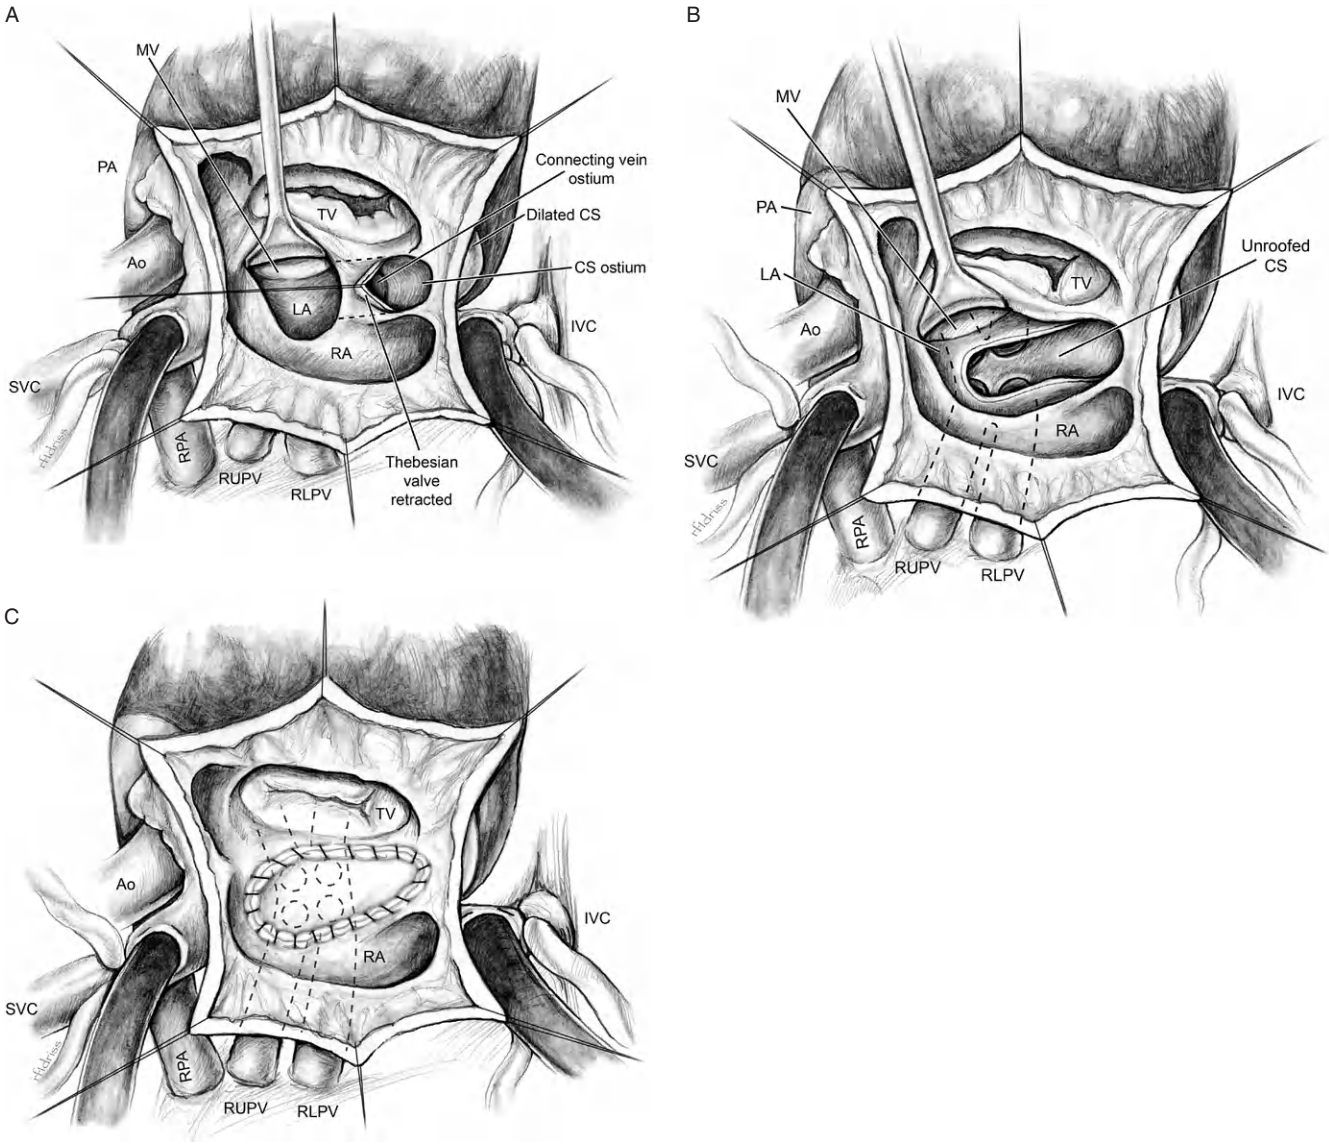

Figure 34.4 Repair of cardiac total anomalous pulmonary venous connection with connecting vein (CV) to the coronary sinus (CS). **A,** The CS is enlarged and the ostium of the CV is visualized near its ostium. A secundum atrial septal defect is retracted to permit visualization of the mitral valve (MV) in the left atrium. The pulmonary vein (PV) orifices are not present in the left atrium (LA). The CS is unroofed into the LA and the atrial septal defect thus enlarged (dotted lines). **B,** The PV confluence is inspected through the unroofed CS and all four vein ostia are inspected. **C,** The defect is then closed with a patch of autologous pericardium, leaving the unroofed CS draining to the reconstructed LA. (IVC, inferior vena cava; LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; LV, left ventricle; PA, pulmonary artery; RLPV, right lower pulmonary vein; RPA, right pulmonary artery; RUPV, right upper pulmonary vein; SVC, superior vena cava; TV, tricuspid valve.)

(Figure 34.5). The supradiaphragmatic portion of the vertical vein can be used to augment the anastomosis to the left atrium after its division (Figure 34.5) [57].

Repair of the Mixed Type

The commonest pattern of mixed TAPVC is three veins to a posterior confluence and one separately connecting to the systemic venous system. Repair often involves an anastomosis between the left atrium and the confluence as described previously and reimplantation of the fourth vein if possible. Single, unobstructed pulmonary veins can be left in situ to avoid postoperative restenosis. Imoto *et al*. have demonstrated that small residual left-to-right shunts from a single residual anomalous pulmonary vein in continuity with the systemic veins did not result in significant hemodynamic compromise [58]. More complex arrangements of the anomalous pulmonary veins may need repairs tailored to the patient's specific anatomy.

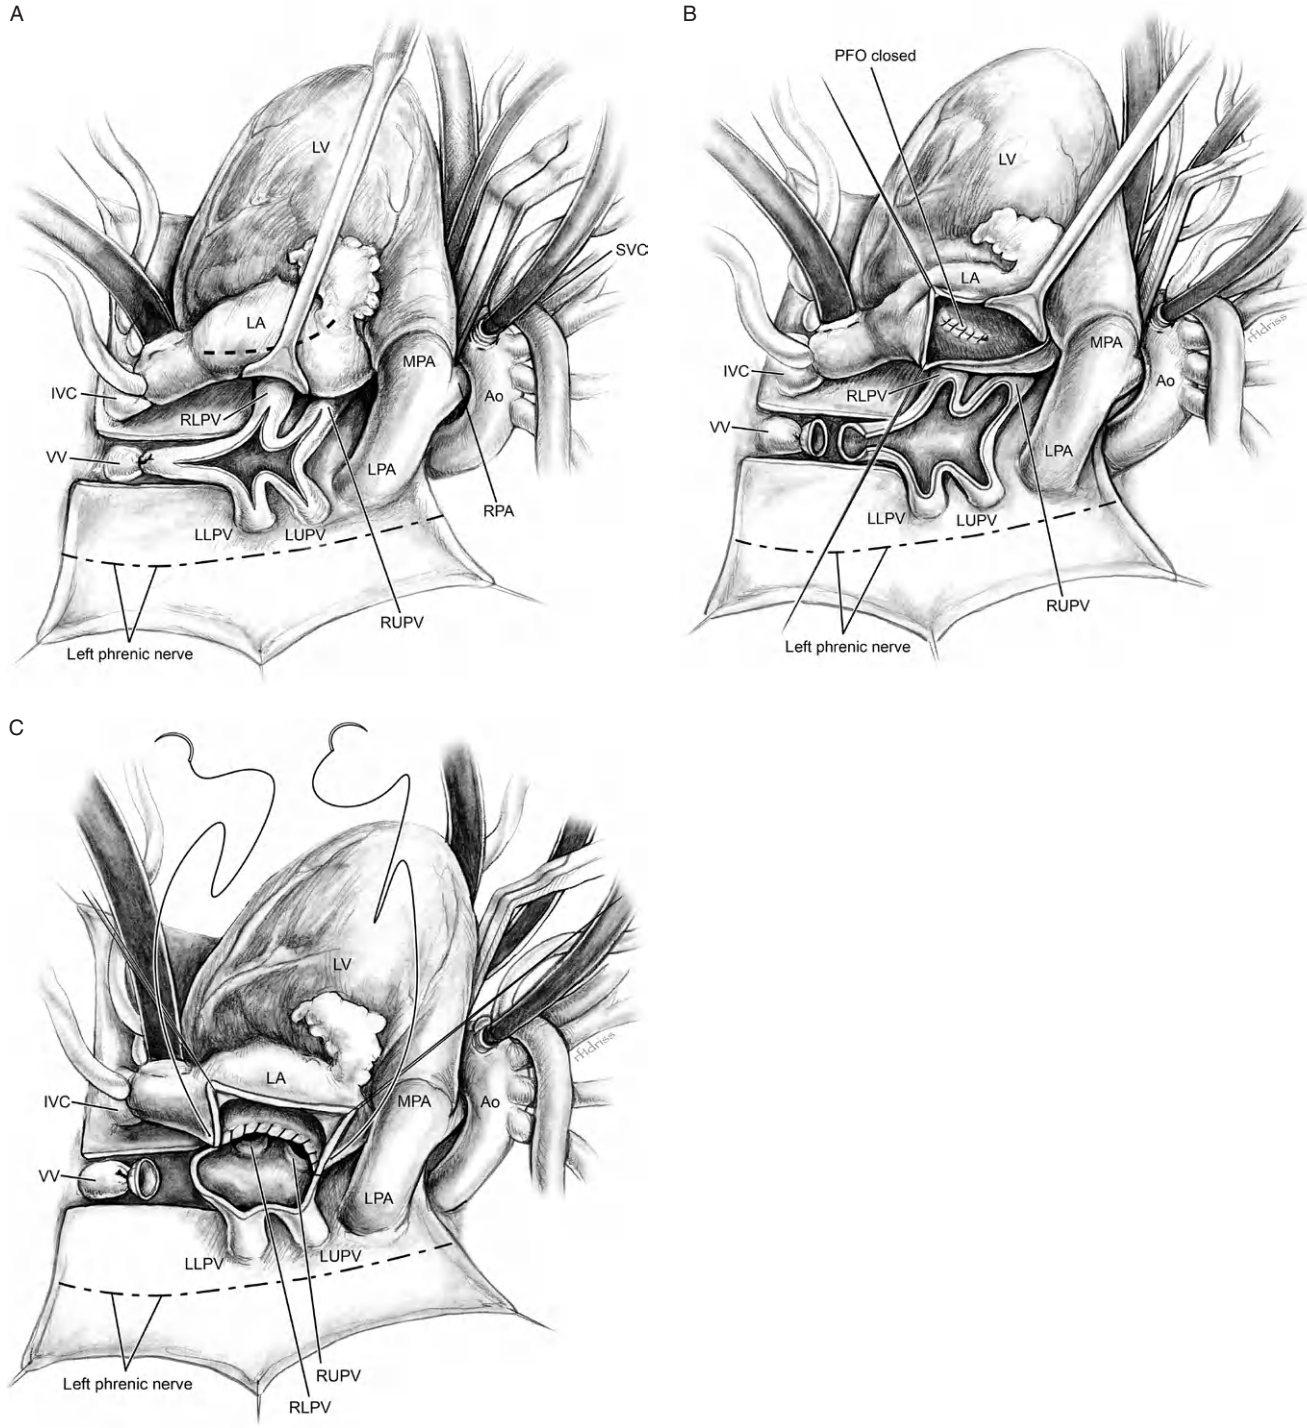

Figure 34.5 Repair of infracardiac total anomalous pulmonary venous connection with ligation of the vertical vein (VV). **A,** The VV is ligated at its emergence through the esophageal hiatus. The confluence is opened with a "Y" shaped incision. The left atrium is opened with an incision extending into the left atrial appendage (dotted line). **B,** The atrial septal defect is closed via the atriotomy. The VV is divided to increase the length of the anastomosis. **C,** The anastomosis is then completed. (IVC, inferior vena cava; LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; LV, left ventricle; MPA, main pulmonary artery; RLPV, right lower pulmonary vein; RPA, right pulmonary artery; RUPV, right upper pulmonary vein; SVC, superior vena cava.)

Results

In a large meta-analysis reviewing the published results for repair of simple TAPVC between 1966 and 1993, Clabby *et al*. showed the perioperative mortality rates dropping from 85% in the first series to less than 5% in the last decade [59]. According to the Pediatric Cardiac Care Consortium, which reported on 437 operations for anomalous pulmonary connections performed between 1985 and 1993, supracardiac connection was seen in 40% of the cases, cardiac in 17%, infracardiac in 22%, and mixed in 10%. In 11% of the cases the type of connection was unknown. The mortality per type of connection was 14.2%, 11.6%, 32.6%, 15.8%, and 36% respectively [59]. This distribution of connection types is in accordance with most published surgical and pathology series [7,10,13,16,21]. Recently published series from the Toronto and Boston groups have confirmed the trend toward improved survival and overall good operative outcome with acceptable long-term survival rates, especially in isolated TAPVC [60,61].

In an analysis of the impact of coexisting cardiac anomalies on survival after repair of TAPVC, multivariate analysis demonstrated that single-ventricle and associated cardiac lesions adversely affected perioperative mortality and long-term survival (Figure 34.6) [36]. Moreover, when comparing survival after repair of TAPVC in the presence of two- and single-ventricle hearts, survival was 70% at 15 years in the biventricular population compared with 20% survival at 5 years in the univentricular population [36]. The type of palliation in patients with single-ventricle physiology depends on whether the pulmonary antegrade blood flow is restricted as in pulmonary stenosis or atresia, or unrestricted. In single-ventricle patients with restricted pulmonary blood flow, the presence of obstructed pulmonary venous return may be unmasked by a palliative procedure designed to increase pulmonary perfusion (systemic-to-pulmonary shunts) [36,62]. Early palliation in single-ventricle neonates requiring repair of TAPVC and stabilization of pulmonary circulation at the same time has proven disappointing [59,62–65].

The long-term prognosis is influenced by the incidence of post-repair pulmonary vein stenosis, which occurs in 5–15% of cases. This complication has been attributed to anastomotic fibrotic stricture at the ostia of single pulmonary veins and/or to a poorly understood process of intimal hyperplasia often involving the whole length of the pulmonary veins [37,66–68]. The restenosis tends to appear within the first 6–12 months following the repair, and its hemodynamic effects can remain undetected until the degree of obstruction is severe. The occurrence of post-repair pulmonary vein stenosis is a significant risk factor for poor outcome (Figure 34.7) [37]. Several authors have found that poor prognosis is directly proportional to the number of pulmonary veins involved in the restenosis process [37,67–72]. Progressive shortness of breath has been consistently reported as the most common symptom. Chest radiographs often present congested lungs or severe pulmonary edema bilaterally or limited to the side of the obstructed veins. Lung perfusion scans show severe ventilation/perfusion mismatch with the affected side hypoperfused, but normally ventilated. Echocardiography and Doppler interrogation demonstrate turbulent or accelerated flow through the stenotic veins. However, Valsangiacomo *et al*. have shown that echocardiography was able to identify the pulmonary veins in only 89% of cases, whereas MRA visualized the central two-thirds of

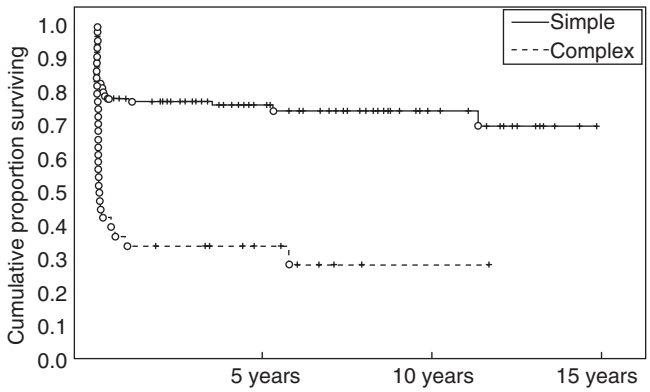

Figure 34.6 Actuarial survival stratified by the presence of simple total anomalous pulmonary venous connection (continuous line) versus total anomalous pulmonary venous connection associated with other complex cardiac anomalies (dotted line). (Reproduced with permission from Caldarone *et al.* [36].)

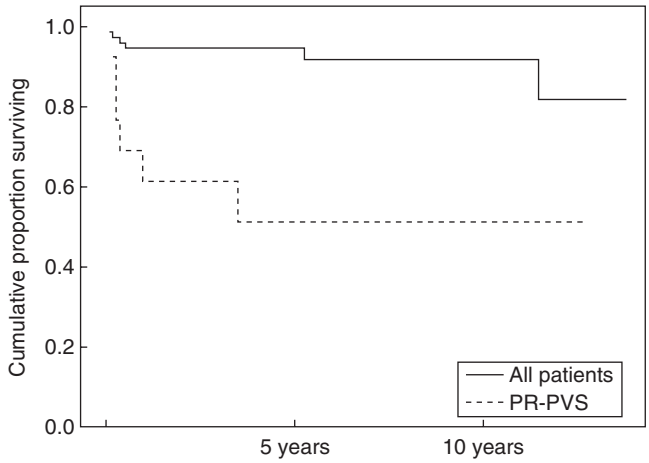

Figure 34.7 Survival after repair of total anomalous pulmonary venous drainage (<30 days mortality excluded) for all patients (continuous line) versus patients with post-repair pulmonary vein stenosis (PR-PVS; dotted line) ($p < 0.001$). (Reproduced with permission from Caldarone *et al.* [37].)

the pulmonary veins in 99% [33]. Phase-contrast MRA offers a functional evaluation and grading of the ensuing stenosis by demonstrating the type of blood flow as monophasic or biphasic. Contrast-enhanced MRA visualizes not only the stenotic lesion but also the collateral venous channels to the unobstructed pulmonary veins within the lung parenchyma [32,34]. Therefore, when pulmonary vein stenosis is suspected, we prefer to perform MRA as the initial sequence (Plate 34.2, see plate section opposite p. 594).

Almost invariably the occurrence of post-repair pulmonary vein stenosis requires surgical intervention. Conventional repair of pulmonary vein stenosis, such as resection of the anastomotic endocardial fibrotic overgrowth, patch venoplasty with or without endarterectomy, as well as percutaneous stenting techniques are associated with a high incidence of recurrent stenosis and poor prognosis [37,67,68,73].

Sutureless techniques to treat post-repair pulmonary vein stenosis have been reported by many groups. This technique avoids direct suture on the pulmonary veins, based on the assumption that this will reduce intimal hyperplasia. Cardiopulmonary bypass is instituted in the standard manner. The left atrium is incised along its posterior wall with the incision extending into the appendage to create the widest possible opening. The pulmonary veins are opened starting at the atrial junction and the incision is continued upstream until the secondary or tertiary branches are opened. The pericardium is breached below the phrenic nerve to avoid damaging it and to allow the incision of the vein below the reflection of the mediastinal pleura at the hilum of the lung. Any obstruction is then incised or resected. The atrial edge is sutured to the pericardium around the veins and to the reflection of the pericardium just below the phrenic nerve. The presence of adhesions in the posterior pericardium and hilar area contribute to hemostasis (Figure 34.8) [74]. Cine magnetic resonance imaging (MRI) studies have demonstrated favorable flow patterns and rare recurrent restenosis especially in patients with localized stenosis, and significantly lower transvenous

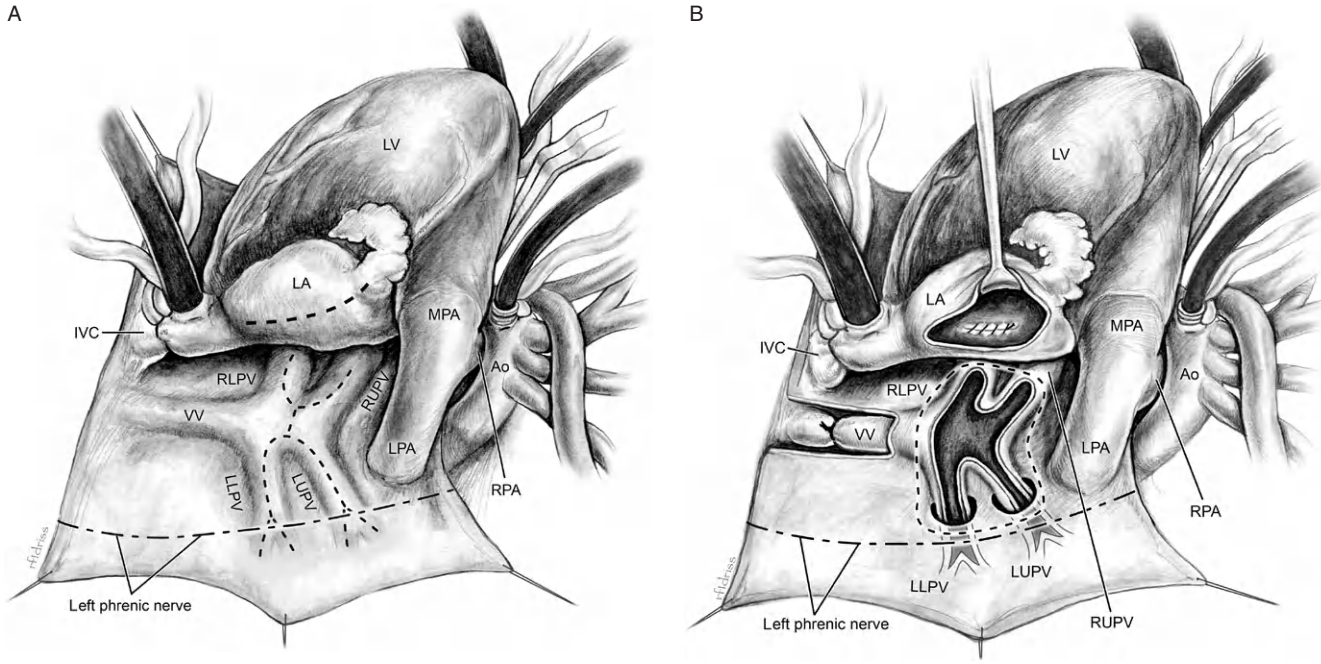

Figure 34.8 Repair of infracardiac total anomalous pulmonary venous connection with a sutureless technique. **A,** The venous confluence is retropericardial. The left atrium (LA) incision is extended into the appendage to create the widest possible opening. **B,** The posterior pericardium is breached and the descending vertical vein (VV) ligated (optional). The pulmonary veins are opened starting at the atrial junction and the incision is continued upstream until the secondary or tertiary branches are opened. **C,** The atrial edge is sutured to the pericardium along the dotted line, as indicated, avoiding direct suturing of the veins. The anastomosis is conducted from left to right. **D.** The pericardium is breached below the phrenic nerve to avoid damaging it and to allow the incision of the vein below the reflection of the mediastinal pleura at the hilum of the lung. Any obstruction is then incised or resected. The free edge of the left atrial wall is anastomosed to the pericardium below the phrenic bundle. The integrity of the mediastinal pleura and the presence of adhesions allow drainage of pulmonary venous blood inside the newly constructed atrium. (IVC, inferior vena cava; LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; LV, left ventricle; MPA, main pulmonary artery; RLPV, right lower pulmonary vein; RPA, right pulmonary artery; RUPV, right upper pulmonary vein; SVC, superior vena cava.)

gradients when compared to conventional repairs. These results have promoted the use of the sutureless technique as primary repair of TAPVC (Figure 34.9) [74].

In summary, TAPVC represents a broad spectrum of anomalies that can be isolated or associated with complex cardiac anomalies. Surgical results for repair in the isolated form have steadily improved over the last three decades and offer good long-term survival. Single ventricle circulation, severe associated anomalies, and recurrent diffuse pulmonary vein stenosis continue to represent a challenge. The sutureless technique offers significant benefit for post-repair pulmonary vein stenosis and may offer benefit for primary repair of TAPVC.

CHAPTER 35

Cor Triatriatum Sinister, Pulmonary Vein Stenosis, Atresia of the Common Pulmonary Vein, and Cor Triatriatum Dexter

Ralph E. Delius[1,2] and Henry L. Walters III[1,2]

[1]Children's Hospital of Michigan, Detroit, MI, USA
[2]Wayne State University School of Medicine, Detroit, MI, USA

Cor triatriatum sinister, atresia of the common pulmonary vein, and pulmonary vein stenosis are very uncommon but related congenital lesions that share similar morphogenesis. The embryological origins of these lesions are similar to total anomalous pulmonary venous connection (TAPVC), in that each of these lesions are related to abnormal incorporation of the common pulmonary vein into the left atrium during cardiac development. The pathophysiology of these lesions, usually involving some degree of obstruction to pulmonary venous drainage or a diversion of pulmonary venous return into the right atrium, is similar as well. Not surprisingly, the clinical presentation of patients with these defects may mimic each other. Cor triatriatum dexter, also referred to as divided right atrium, is unrelated developmentally and clinically and will be considered separately.

Embryology of Pulmonary Venous System

Morphogenesis of the pulmonary venous system is well understood, and a fundamental understanding of the pulmonary venous development can elucidate the development of cor triatriatum, atresia of the common pulmonary vein, and pulmonary vein stenosis. The primordial lung buds share the splanchnic plexus with other foregut derivatives, and drainage into the systemic circulation is through the paired cardinal and umbilicovitelline veins. At about 27–29 days of gestation, a primitive pulmonary vein develops as an evagination from the posterior wall of the left atrium (Figure 35.1A) [1]. At approximately 30 days gestation the nascent pulmonary vein engages the pulmonary portion of the splanchnic plexus and begins to drain blood from this region (Figure 35.1B) [1]. A common pulmonary vein develops, which is progressively incorporated into the posterior wall of the left atrium. After communication between the pulmonary portion of the splanchnic plexus and the heart is established, connections to the cardinal and umbilicovitelline systems involute (Figure 35.1C) [1]. Consequently, the common pulmonary vein is a transient anatomic structure. The normal left atrium is made of common pulmonary vein and primitive left atrium, with each making roughly comparable contributions to the fully developed left atrium.

Pathologic Anatomy

The morphology of pulmonary venous abnormalities is related to abnormalities of common pulmonary vein development. Timing of the development of the defect is important, as connections to systemic venous drainage are still present if the defect occurs early, while late development of common pulmonary vein abnormalities occurring after involution of the pulmonary–systemic venous connections may lead to a different congenital pulmonary venous anomaly. If the common pulmonary vein becomes atretic or fails to develop early, a connection to the splanchnic plexus and cardinal or umbilicovitelline veins is still present and can serve as collateral venous drainage, resulting in total anomalous pulmonary venous connection (TAPVC). Atresia of only the left or right portion of the common pulmonary vein leads to partial anomalous pulmonary venous return. If atresia of the common pulmonary vein occurs late, after involution of the connections to

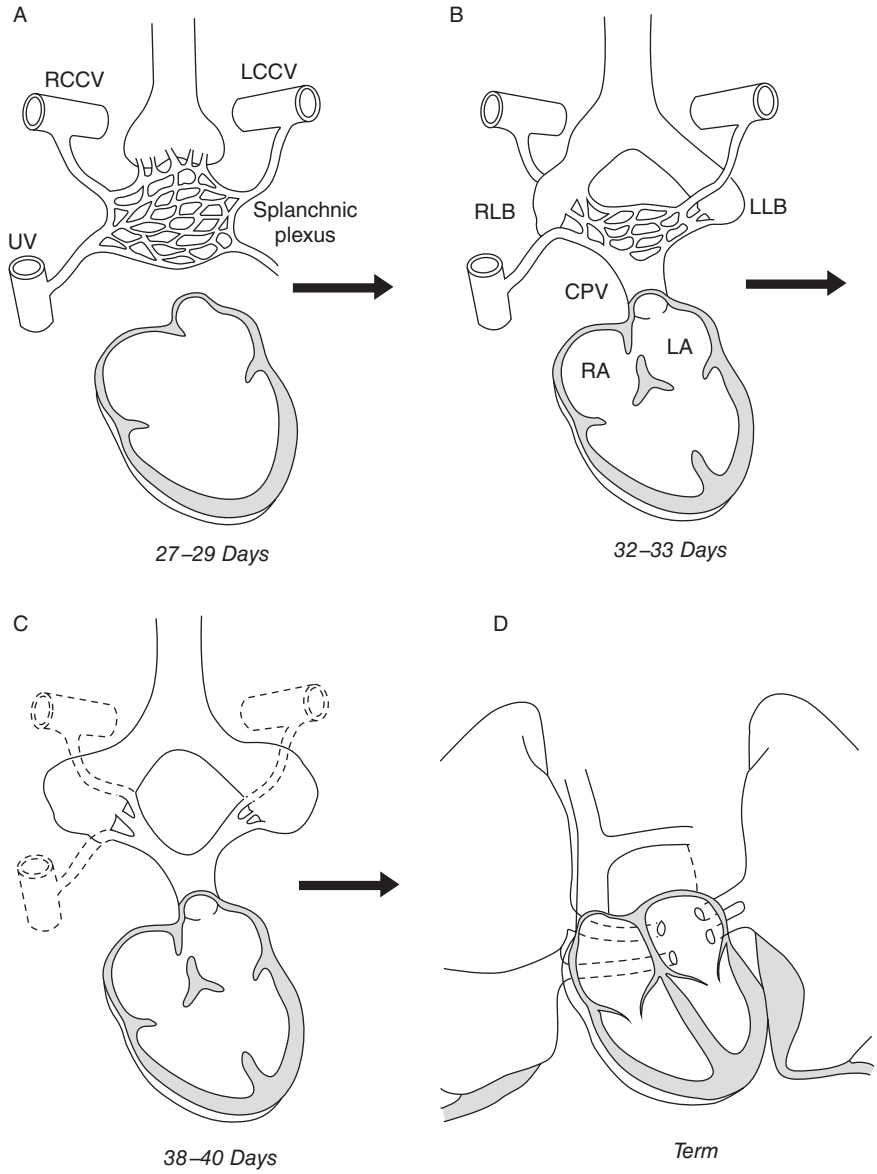

Figure 35.1 Development of the pulmonary veins. **A,** At 27–29 days of gestation, the primordial lung buds are enmeshed by the vascular plexus of the foregut (the splanchnic plexus). At this stage, there is no direct connection to the heart. Instead there are multiple connections to the umbilicovitelline and cardinal venous systems. A small evagination can be seen in the posterior wall of the left atrium (LA) to the left of the developing septum secundum. **B,** By the end of the first month of gestation, the common pulmonary vein (CPV) establishes a connection between the pulmonary venous plexus and the sinoatrial portion of the heart. At this time, the connections between the pulmonary venous plexus and the splanchnic venous plexus are still patent. **C,** Next, the connections between the pulmonary venous plexus and the splanchnic venous plexus involute. **D,** The common pulmonary vein incorporates into the left atrium so that the individual pulmonary veins connect separately and directly to the left atrium. (LCCV, left common cardinal vein; LLB, left lung bud; RA, right atrium; RCCV, right common cardinal vein; RLB, right lung bud; UV, umbilical vein.) (Reproduced with permission from Geva *et al.* [1].)

the systemic venous system, atresia of the common pulmonary vein develops, in which the pulmonary veins drain into a common pulmonary vein, which serves a blind cul-de-sac that has no connection to the left atrium or systemic venous drainage (Figure 35.2A) [1].

Stenosis of the common pulmonary vein leads to cor triatriatum sinister, giving the appearance of incomplete incorporation of the common pulmonary vein into the left atrium (Figure 35.2B) [1]. In most cases, the stenosis develops late, after involution of collateral venous connections.

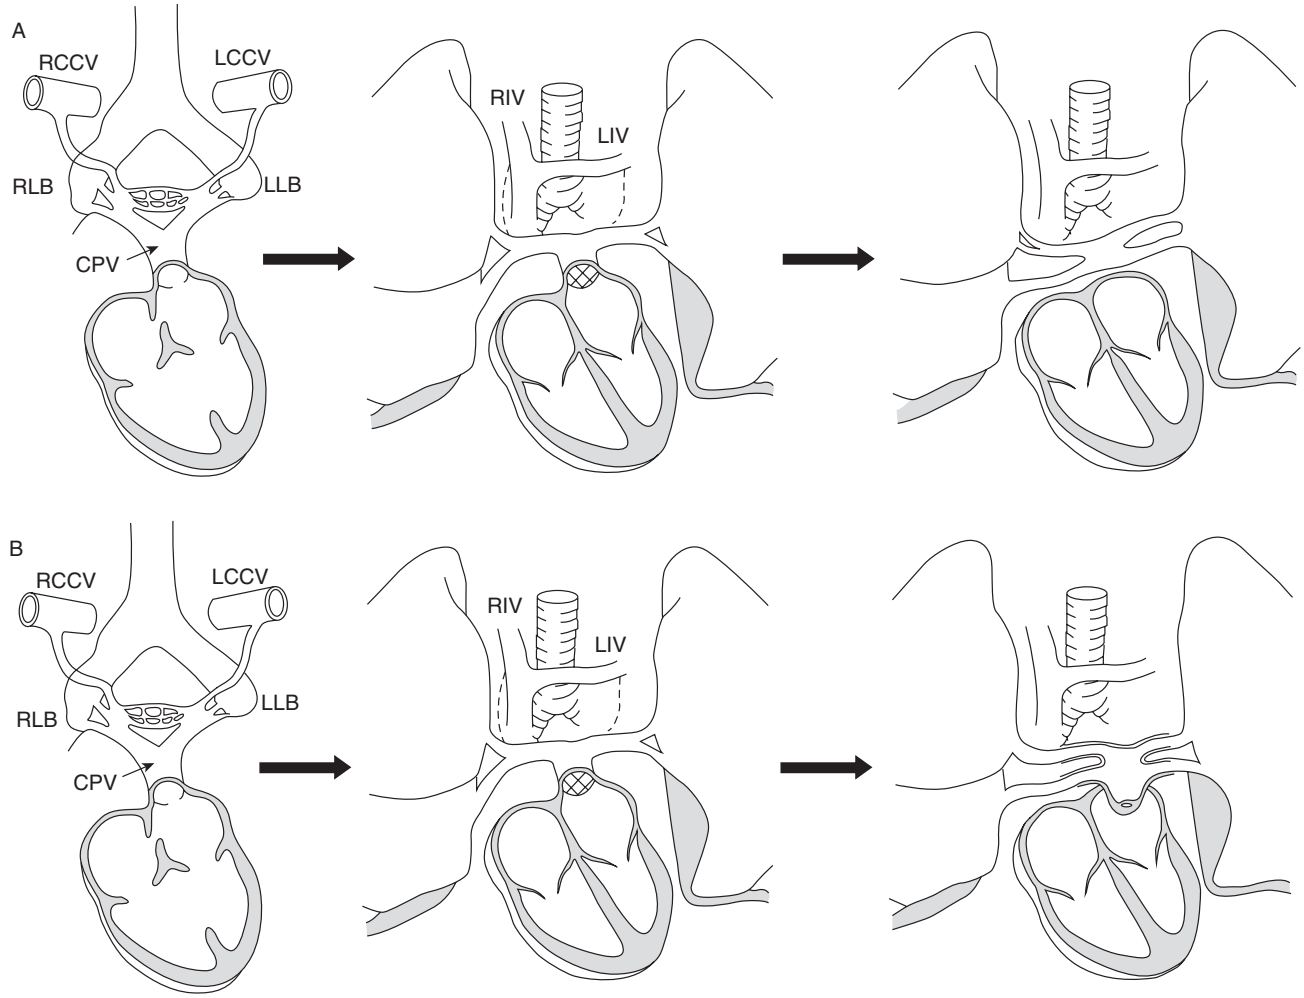

Figure 35.2 Embryologic basis of atresia of the common pulmonary vein and cor triatriatum. **A,** The common pulmonary vein (CPV) has established a connection with the left atrium and the primitive venous connections have regressed (middle panel). Normally, the connection between the common pulmonary vein and the left atrium enlarges. If the normal connection between the common pulmonary vein and the left atrium fails, the pulmonary veins drain into a blind cul de sac without a significant alternative egress for pulmonary venous blood (atresia of the common pulmonary vein). **B,** The connection between the common pulmonary vein and the left atrium is stenotic, and the common pulmonary vein dilates (cor triatriatum). (LCCV, left common cardinal vein; LIV, left innominate vein; LLB, left lung bud; RCCV, right common cardinal vein; RIV, right innominate vein; RLB, right lung bud.) (Reproduced with permission from Geva *et al.* [1].)

Early stenosis, however, can lead to cor triatriatum sinister with partial anomalous pulmonary venous connection, which suggests that collateral vessel channels were present at the time the stenosis developed.

Abnormal incorporation of the common pulmonary vein into the left atrium can lead to abnormal numbers of pulmonary veins, or stenosis of pulmonary veins at the junction with the left atrium.

Cor Triatriatum Sinister

Cor triatriatum sinister was initially described by Church in 1868, but Andral was the first to describe a heart with "three auricles" in 1829 [2,3]. This defect is rare, comprising approximately 0.1% of all congenital cardiac malformations. Males and females are equally affected. Initial surgical repair was accomplished separately in 1956 by two pioneers of early cardiac surgery, Drs John Lewis and Arthur Vineberg [4,5]. Additional cardiac defects can be seen in approximately 50% of patients with cor triatriatum sinister [6–11]. The incidence of coexisting lesions reported in postmortem series tends to be higher than the incidence seen in operative series [12].

Anatomy

The hallmark feature of cor triatriatum sinister is the drainage of pulmonary veins into an accessory chamber that is

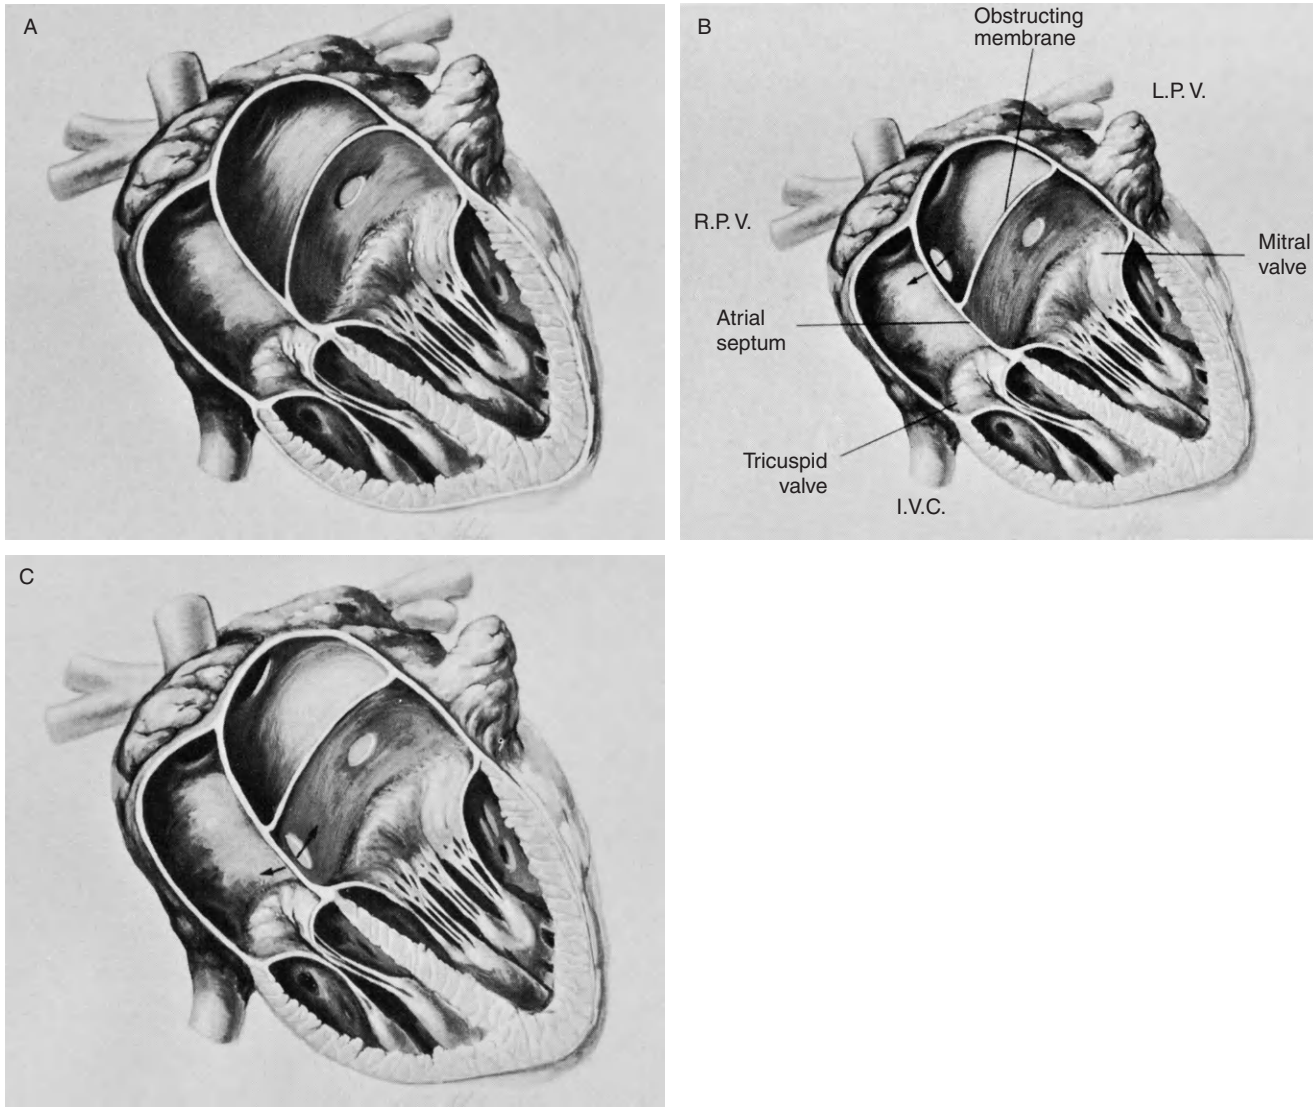

Figure 35.3 A, Cor triatriatum with intact atrial septum (type A). **B,** Cor triatriatum with atrial septal defect between the proximal left atrial chamber and the right atrium (type A_1). **C,** Triatrial heart, type A_2. The atrial septal defect connects the distal or true left atrium with the right atrium. IVC, inferior vena cava; LPV, left pulmonary vein; RPV, right pulmonary vein. (Reproduced with permission from Arciniegas *et al.* [14].)

adjacent and attached to the left atrium. This accessory chamber, in turn, drains into the left or right atrium. Failure of the common pulmonary vein to incorporate completely into the left atrium is the most commonly accepted theory of embryogenesis of cor triatriatum sinister. In most cases, the conjunction between the proximal accessory chamber and the left atrium consists of a fibromuscular membrane which is usually perforated. The size of the perforation establishes whether obstruction to pulmonary venous flow is present. In some cases, the membrane is imperforate and the accessory chamber drains directly or indirectly into the right atrium.

Several classification schemes have been developed, but none are comprehensive or universally accepted, probably due to the small number of patients in each series. The Lam classification is probably the most commonly referred to and is shown in Figure 35.3 [13,14]. Type A cor triatriatum consists of a proximal accessory chamber that receives all four pulmonary veins, with the true left atrium containing the left atrial appendage and mitral valve (Figure 35.3A) [14]. The two chambers communicate through a variable sized foramen in the membrane. Type A is further divided on the basis of the presence and location of an atrial septal defect. Subtype A1 has an atrial septal defect (ASD) communicating between the proximal chamber and the right atrium (Figure 35.3B) [14]. In Type A2 the ASD communicates between the right atrium and the true left atrium

Table 35.1 Anatomic classification of cor triatriatum. (Reproduced with permission from Geva *et al.* [1].)

I	Accessory atrial chamber receives all pulmonary veins and communicates with left atrium
	A. No other connections: classic cor triatriatum
	B. Other anomalous connections
	1. To right atrium directly
	2. With total anomalous pulmonary venous connection
II	Accessory atrial chamber receives all pulmonary veins and does not communicate with left atrium
	A. Anomalous connection to right atrium directly
	B. With total anomalous pulmonary venous connection
III	Subtotal cor triatriatum
	A. Accessory atrial chamber receives part of pulmonary veins and connects to left atrium
	1. Remaining pulmonary veins connect normally
	2. Remaining pulmonary veins connect anomalously
	B. Accessory atrial chamber receives part of pulmonary veins and connects to right atrium
	1. Remaining pulmonary veins connect normally

(Figure 35.3C) [14]. Type B hearts are those with coronary sinus receiving the pulmonary veins, which in fact is a form of TAPVC. Type C has no communication between the pulmonary veins and the proximal chamber. Type A is the most common, accounting for nearly two-thirds of all cases. The Lam classification scheme has many shortcomings, as type B is actually TAPVC and several anatomic variants are not included in this scheme, including unilateral cor triatriatum with partial anomalous venous return. The Lucas classification scheme, which is probably the most comprehensive nosology of cor triatriatum sinister, is outlined in Table 35.1 [1,15]. Type 1 consists of all four veins draining into the accessory chamber, which in turn communicates with the left atrium (Figure 35.4A–D) [1]. Subtypes are based on the presence or absence of other connections with the accessory chamber. Type 2 consists of the accessory chamber receiving all four pulmonary veins but does not communicate with the left atrium (Figure 35.4E) [1]. Type 3 includes subtotal cor triatriatum, with the various subtypes describing the various connections of the veins not connected to the accessory atrial chamber (Figure 35.4F–H) [1]. An even more comprehensive classification scheme including all pulmonary venous abnormalities has been proposed by Herlong *et al.* [16].

Pathophysiology

The pathophysiology of cor triatriatum sinister is determined by the size of the fenestration in the membrane between the accessory atrial chamber and the left atrium, by the size of communication, if present, with the right atrium, and by the effects of associated lesions. In defects in which all four veins drain into the accessory chamber, which in turn drains into the left atrium via the obstructing membrane, pulmonary venous obstruction with pulmonary hypertension will be present. A large fenestration in the membrane may be occasionally nonobstructive. The presence of an atrial septal defect between the accessory chamber and the right atrium leads to significant left-to-right shunting, with the pathophysiology being similar to TAPVC.

Clinical Presentation

The severity of symptoms and the age of presentation are dependent on the size of the communication between the pulmonary venous chamber and the left or right atrium. If the communication between the pulmonary venous chamber and left atrium is less than 3 mm, and no other communications are present, the age of presentation will be in the first year of life and the clinical picture will be of pulmonary venous obstruction with low cardiac output and severe pulmonary hypertension [8]. Tachypnea, failure to thrive, and outright respiratory failure can be presenting symptoms when pulmonary venous obstruction is present. Signs of pulmonary hypertension include a long pulmonary component of the second heart sound, right ventricular heave, and pulmonary systolic ejection click. Occasionally, a diastolic murmur is heard at the apex. Electrocardiogram shows evidence of right ventricular strain. Chest radiogram shows cardiac enlargement and ground glass appearance characteristic of pulmonary venous obstruction. A nonobstructive communication between the pulmonary venous chamber and left atrium may be clinically silent and may not present until adulthood [17]. Communication to the right atrium can result in right atrial and ventricular dilatation, and the clinical presentation can mimic TAPVC.

The diagnosis of cor triatriatum sinister can be established reliably by echocardiography. A curvilinear membrane, occasionally with a windsock appearance, can be seen in the left atrial cavity. During diastole, the membrane moves toward the mitral valve. The motion and appearance of the mitral valve are normal. The relationship of the left atrial appendage to the membrane distinguishes between cor triatriatum sinister and supravalvar mitral stenosis, with the membrane superior to the left atrial appendage in cor triatriatum sinister. Transesophageal echocardiography may provide more anatomic detail, and may be a useful adjunct if transthoracic echocardiography fails to provide clear definition of the lesion. Magnetic resonance imaging (MRI) can be used as well, but as of yet, use of MRI with this lesion is sporadic [18]. Cardiac catheterization is usually not needed unless hemodynamic features are thought to be necessary prior to intervention. The presence of cor triatriatum may be masked if associated lesions

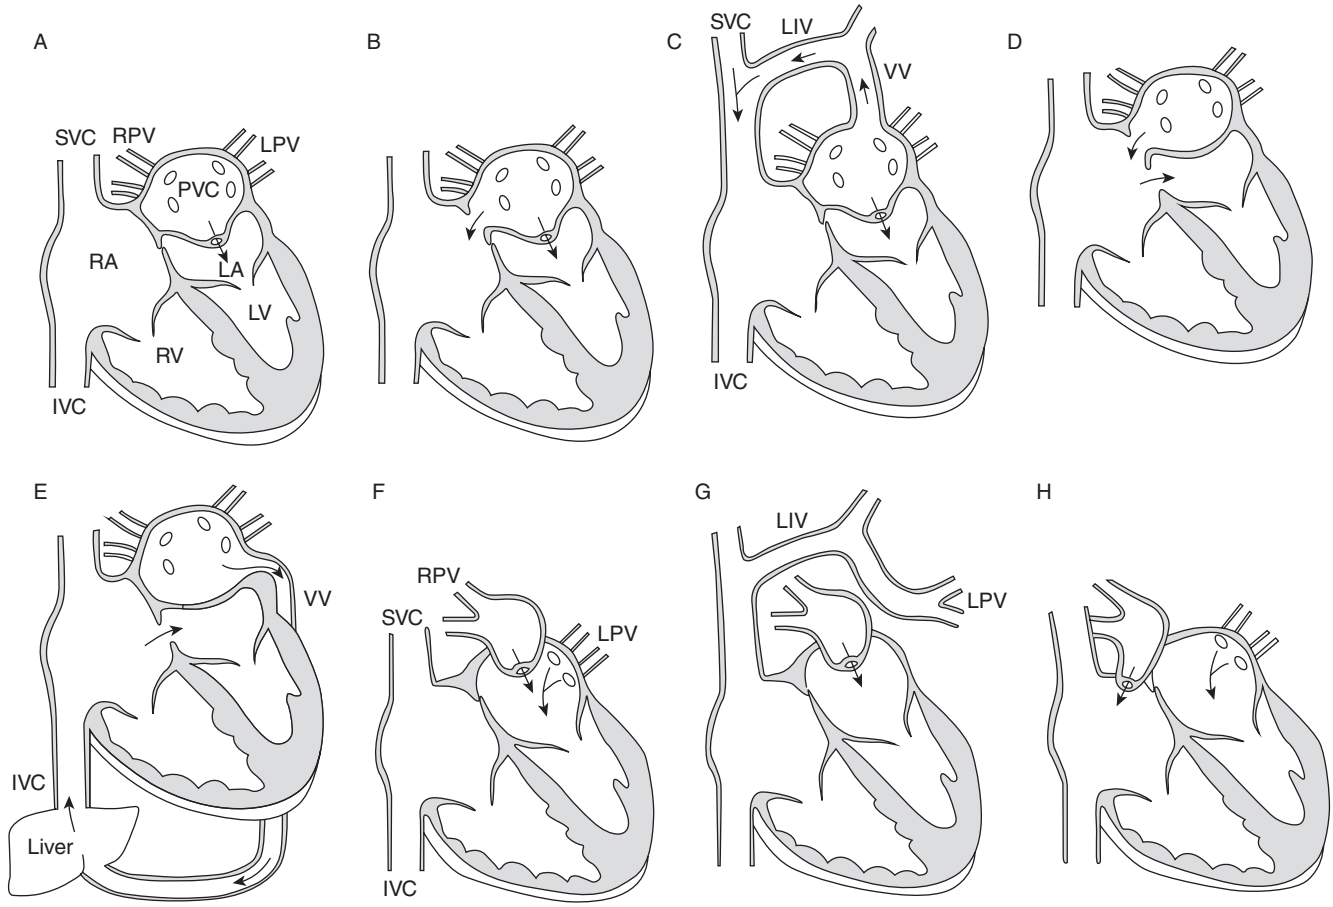

Figure 35.4 Diagram of variants of cor triatriatum. **A,** Classic cor triatriatum. The pulmonary venous chamber (PVC) receives the right and left pulmonary veins (RPV; LPV), and the only egress for pulmonary venous return is through the opening in the cor triatriatum membrane (arrow). **B,** Cor triatriatum with a communication between the PVC and the right atrium (RA). This communication allows decompression of the PVC. **C,** Cor triatriatum with an anomalous connection between the PVC and the left innominate vein (LIV). This anomalous connection (levoatrialcardinal vein) decompresses the PVC. The PVC does not communicate directly with the left atrium (LA). **D,** Pulmonary venous return reaches the right atrium (RA) through a communication between the PVC and the right atrium. Blood then reaches the left atrium via the foramen ovale. **E,** The PVC decompresses via a vertical vein to the portal vein. Subtotal cor triatriatum. **F,** The confluence of the right pulmonary veins communicates with the left atrium via a stenotic orifice. The left pulmonary veins connect normally to the left atrium. **G,** Subtotal cor triatriatum of the right pulmonary veins associated with partially anomalous pulmonary venous connection of the left pulmonary veins to the left innominate vein. **H,** Subtotal cor triatriatum of the right pulmonary veins to the right atrium via a stenotic orifice. The left pulmonary veins connect normally. This variant may be viewed as a restrictive sinus venosus defect with atresia of the orifice of the right pulmonary veins. (IVC, inferior vena cava; LV, left ventricle; RV, right ventricle.) (Reproduced with permission from Geva *et al.* [1].)

are present that feature reduced pulmonary blood flow, such as tetralogy of Fallot [19,20].

Treatment

Management of cor triatriatum sinister is surgical, although use of balloon dilation has been reported [21,22]. Experience with catheter-based intervention is limited, and long-term follow-up is lacking. The diagnosis of cor triatriatum sinister is, in itself, an indication for operation, since mortality in unoperated patients is 75%.

In virtually all cases, cardiopulmonary bypass is established through a median sternotomy, with hypothermia, aortic cross-clamping, and cardioplegia according to standard techniques. Bicaval cannulation is used for venous drainage. The cardiac exposure can be either through the right or left atrium, depending on the specific anatomic presentation and associated defects. Regardless of approach, the principles of surgical repair include complete resection of the membrane, identification of all pulmonary veins, and closure of all septal defects (Figure 35.5) [14]. Other lesions are addressed as needed.

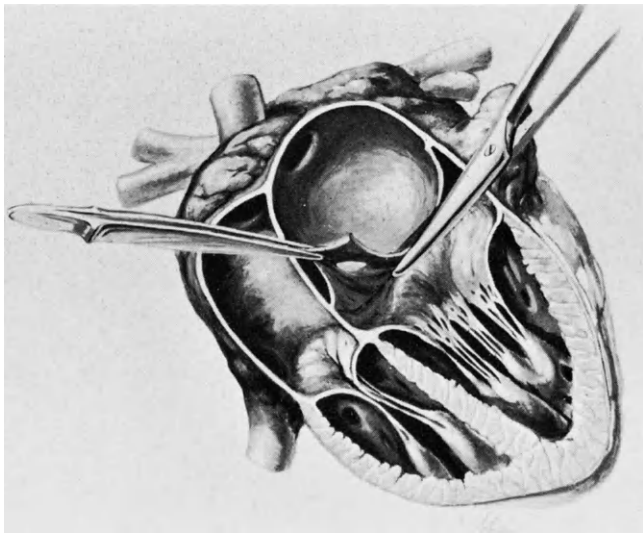

Figure 35.5 The obstructing membrane is resected; injury to the mitral valve and left atrial wall is avoided. (Reproduced with permission from Arciniegas *et al.* [14].)

Results of surgical repair of cor triatriatum sinister are good. Reported perioperative mortality is 4–25%, but mortality is largely dependent on the severity of illness at the time of presentation and associated cardiac and extracardiac anomalies [21,23–25]. The long-term prognosis after classic cor triatriatum sinister repair is excellent. The postoperative management strategy is dependent on the severity of preoperative pulmonary venous obstruction. Pulmonary vasodilators, such as nitric oxide may be necessary in patients with preoperative pulmonary hypertension. Patients who present without significant pulmonary venous obstruction typically have a benign postoperative course.

Atresia of the Common Pulmonary Vein

Atresia of the common pulmonary vein is an extremely rare malformation in which no communication exists between the pulmonary veins and left atrium. Moreover, there is no connection between the common pulmonary vein and any systemic veins. In essence, the common pulmonary vein is a blind pouch. The only drainage of common pulmonary venous flow is through small collateral connections, often bronchopulmonary veins, to the atria or systemic circulation. The clinical presentation is that of severe pulmonary venous obstruction, and patients are severely cyanotic and critically ill immediately after birth [25–27]. The differential diagnosis includes obstructed total anomalous pulmonary venous return. Diagnosis can usually be established by echocardiography; findings are similar to TAPVC, but Doppler flow studies fail to demonstrate outflow from the common pulmonary vein. Most patients are too ill for cardiac catheterizations, but if performed, they would demonstrate severe pulmonary hypertension and persistence of contrast in the pulmonary vasculature after right ventricular injection of contrast. Surgical intervention is emergent and consists of anastomosis between the posterior left atrium and the pulmonary venous confluence (Figure 35.6) [26]. Severe postoperative pulmonary hypertension can be anticipated; nitric oxide or extracorporeal membrane oxygenation (ECMO) may be needed [28]. The first successful surgical repair was reported by Khonsari in 1982 [26]. Reports of survivors have been sporadic. Long-term follow-up has not been reported to date.

Pulmonary Vein Stenosis

Stenosis of individual pulmonary veins, first reported by Reye in 1951 in an 8-year-old patient who died with severe stenosis of three veins and atresia of the fourth [29], is a rare malformation affecting one or more veins at the junction with the left atrium. Concomitant lesions are common, affecting 30–80% of patients with pulmonary venous stenosis [30]. Unilateral pulmonary vein stenosis is seen in approximately one half of patients with this diagnosis; in 30–35% all four veins are involved, with 10–15% having only a single stenotic vein. Stenosis of the pulmonary veins may appear as a relatively discrete shelf or web, as tubular hypoplasia at the junction of the pulmonary vein to the left atrium, or as diffuse hypoplasia of the pulmonary veins (Figure 35.7) [31,32]. Pulmonary vein stenosis is thought to develop from abnormal incorporation of the common pulmonary vein into the left atrium during the later stages of cardiac development. Microscopically, a fibrous intimal thickening is seen, with uniformly sized spindle cells with elongated nuclei and tapering cytoplasm [33]. The cells resemble myofibroblasts, which have the capacity to differentiate into either myocytes or fibroblasts. The rapid progression of pulmonary vein stenosis and the exuberant intimal growth and recurrent stenosis after surgical or catheter-based manipulations suggests a neoproliferative process may be responsible. Antiproliferative therapy, such as radiation or chemotherapy, has been proposed, but clinical data are lacking [33].

The clinical presentation of patients with pulmonary venous stenosis is dependent on a number of veins involved and the severity of the obstruction. Patients with bilateral involvement are more likely to present early [34]. Tachypnea and frequent respiratory infections are common presenting symptoms. Signs of pulmonary hypertension become increasingly prominent as pulmonary vein stenosis progresses. Hemoptysis can be seen in older patients. Physical examination reveals signs of pulmonary hypertension, including right ventricular lift and accentuation of

the pulmonary component of the second heart sound. A pulmonary systolic click may be heard. A chest X-ray shows a hazy ground glass appearance. Electrocardiogram shows right ventricular hypertrophy and strain.

Diagnosis is usually established by noninvasive imaging. All four veins can usually be identified by echocardiography if good acoustic windows are present. The presence of turbulent flow on color Doppler is suggestive of pulmonary venous stenosis. Monophasic flow or flow velocities greater than 1.6 m/s indicate potentially significant obstruction [30]. Transesophageal echocardiography can be useful and may provide better imaging of pulmonary veins. Magnetic resonance imagery and CT angiography have also been shown to be useful diagnostic techniques for imaging pulmonary veins [35].

Cardiac catheterization with angiography provides detailed views of the pulmonary veins and assessment of pulmonary hypertension. Injection of dye into the pulmonary arterial segments can selectively visualize individual pulmonary veins. Hemodynamic data show varying degrees of pulmonary hypertension, with elevated pulmonary artery wedge pressures. Left-sided obstructive lesions, such as mitral stenosis and left ventricular outflow tract obstruction can also be ruled out.

Prognosis of patients with pulmonary venous stenosis is very guarded, particularly if bilateral stenosis is present. Mortality rates of 80–100% have been reported in patients with involvement of all four veins [34,36]. Patients with only one or two veins involved have a more benign course [33]. The precise history of milder forms of pulmonary vein stenosis has not been clearly established.

Multiple surgical strategies have been applied to pulmonary venous stenosis, with varying degrees of success. Pericardial patch angioplasty is associated with a very high rate of pulmonary vein stenosis recurrence. Simple ring or web excision has had some success, but has also been associated with a high incidence of recurrence [37]. Another technique, in which surgical trauma to the pulmonary vein is minimized, has been advocated due to the notion that trauma to the veins can provide a stimulus for regrowth of obstructive tissue. An incision is made in the pulmonary vein and adjacent left atrium, and a pericardial pouch is created over these incisions, thereby avoiding suture lines in the pulmonary veins (Figure 35.8) [38]. Preliminary data are limited, but suggest improved outcomes over standard patch technique [39]. However, freedom from operation or death at 5 years is still only approximately 50% [30]. Lung transplantation has also been advocated for isolated pulmonary venous stenosis [40]. Catheter-based interventions have met with limited success. Immediate improvement is usually seen, but recurrent stenosis is nearly universal. Catheter intervention may be complementary to surgery, and can be repeated multiple times [30]. Stents have been disappointing, with a high frequency of recurrence. However, stents have been

successfully used for palliation in patients listed for lung transplantation [30].

Cor Triatriatum Dexter

Cor triatriatum dexter, first described by Von Rokitansky in 1875, is an extremely rare condition in which there is abnormal partitioning of the right atrium due to persistence of the right valve of the sinus venosus [41]. During embryologic development, the right horn of the sinus venosus is gradually incorporated into the right atrium to form the nontrabeculated posterior portion of the right atrium. The embryologic right atrium forms the trabeculated portion. The embryologic right atrium and the right horn of the sinus venosus join at the sinoatrial orifice, which has two folds on either side called the right and left venous valves. The left valve becomes part of the septum secundum, and the right valve divides the right atrium into two chambers (Figure 35.9) [42]. The right valve directs oxygenated blood from the inferior vena cava across the patent foramen ovale to the left side during fetal development. Normally the right valve regresses by 12 weeks, leaving the crista terminalis superiorly and the Eustachian valve of the inferior vena cava and Thebesian valve of the coronary sinus inferiorly. Persistence of the right valve results in separation of the smooth and trabeculated portions of the right atrium, resulting in cor triatriatum dexter.

Clinical manifestations of cor triatriatum dexter are dependent on the degree of septation of the right atrium. Mild septation is usually asymptomatic, and is usually found by routine echocardiography, at necropsy, or at operation for other lesions. More severe degrees of septation can mimic right heart failure, with an elevated central venous pressure and hepatomegaly. Supraventricular tachycardia has been reported in conjunction with this lesion [43]. Cyanosis may be present if an atrial septal defect is present.

The need for intervention is based entirely on the presence of symptoms. Surgical resection or percutaneous catheter disruption of the membrane has provided symptomatic relief [43,44]. Prognosis after intervention is excellent.

CHAPTER 36

Anomalous Systemic Venous Connections

Henry L. Walters III[1,2] and Ralph E. Delius[1,2]

[1]Children's Hospital of Michigan, Detroit, MI, USA
[2]Wayne State University School of Medicine, Detroit, MI, USA

Introduction

"Usual" systemic venous cardiac connections exist when a right-sided morphologically right atrium receives systemic venous blood from single right-sided superior and inferior vena cavae in addition to coronary venous return through the coronary sinus. The definition of "normal" systemic venous cardiac connections is more difficult and is perhaps controversial. For example, it can be argued that anatomically and physiologically "normal" connections can exist when the superior and inferior vena cavae and the coronary sinus connect to a morphologically right atrium whether this right atrium is in its usual right-sided (situs solitus) or unusual left-sided (situs inversus) position. However, cardiac surgeons consider both the mediastinal position of the superior and inferior vena cavae and the cardiac connection of these veins to be important factors in planning the conduct of surgical repair. For example, usual cannulation strategies must be altered to accommodate unusually positioned vena cavae. Hence, in this chapter, "abnormal" or "anomalous" systemic venous cardiac connections are classified as departures from the "usual" situation.

Anomalies of systemic venous connection (ASVC) are congenital disorders of the route or destination of the systemic venous return to the heart (Table 36.1) [1]. ASVC can be either partial, involving part of the systemic venous return, or total, involving all of the systemic venous return. In route abnormalities, the anomalous systemic venous return follows an abnormal pathway but eventually drains into the right-sided morphologically right atrium. Route abnormalities usually produce no physiologic sequelae. They become clinically important when they are associated with cardiac disorders requiring surgical repair. In disorders of destination, the anomalous systemic veins do not connect to the right-sided morphologically right atrium. Destination disorders, by default, must include obligatory route abnormalities as well.

While Table 36.1 [1] provides one possible classification for visualizing and categorizing ASVC, others have been proposed in the literature. One such classification is an anatomical scheme that is based upon three major categories: 1) superior vena cava (SVC); 2) inferior vena cava (IVC); and 3) hepatic veins [2]. A more physiological classification is based upon the ultimate destination of the venous drainage such as the left atrium, the right atrium, and both atria [3]. More recently the Society of Thoracic Surgeons Congenital Heart Surgery Database Committee has outlined a hierarchical scheme for classification of ASVC that is based upon abnormalities of the IVC, the SVC, and the hepatic veins [4].

History

The development of knowledge about ASVC is best illustrated by the history of its most common representative, the left superior vena cava (LSVC). In 1850, Marshall provided an embryological explanation for LSVC and he underscored its frequent association with other congenital cardiac lesions [5]. Winter [6] and Campbell's [7] descriptions of LSVC, both published in 1954, include thorough discussions of its anatomy, embryology, and relationships with other major systemic and pulmonary venous structures. While Helseth and Peterson first coined the term "unroofed coronary sinus" in 1974 [8], Raghib and colleagues made the first accurate description of the morphology of this syndrome in their classic paper of 1965 [9]. Hurwitt, in 1955, was the first to report successful ligation of an LSVC to the left atrium in a cyanotic patient [10]. In his report the LSVC was connected to the right superior

vena cava (RSVC) by a communicating vein. The first successful anatomic repair for common atrium and LSVC to the left atrium was performed at Mayo Clinic in 1965 and reported by Rastelli and colleagues. They decided upon an intracardiac baffle repair after temporary clamp occlusion of the LSVC resulted in a rise of the left internal jugular vein pressure from 8 to 25 mmHg [11]. These same authors reported a complete intracardiac repair of a very rare form of total anomalous systemic venous connection consisting of drainage of the LSVC and inferior vena cava (IVC) directly into the left atrium in the absence of an RSVC [12].

Incidence

In one large series, 100 cases of ASVC were found among 5127 patients undergoing open heart surgery between 1955 and 1974 [13]. The 2% incidence in this older series may underestimate the true occurrence of these anomalies since patients who underwent closed heart procedures were not included and since many very complex patients likely to have ASVC may never have been offered an operation during this early era.

Anatomy

Left Superior Vena Cava to Coronary Sinus without Coronary Sinus Ostial Atresia

Embryologically, LSVC to the coronary sinus is thought to be due to the persistence of the left anterior and common cardinal veins. The LSVC descends anterior to the aortic arch and left pulmonary hilum. It enters the pericardium and contacts the heart at the left posterior atrioventricular groove where it continues into the right atrium as the coronary sinus (Figure 36.1A) [1]. The right atrial orifice of the coronary sinus is usually dilated in proportion to the size of the LSVC. While the majority of patients also have an RSVC, the size of this contralateral vessel is usually inversely proportional to the size of the LSVC. For example, when the LSVC is large the RSVC is usually small and vice versa. In 24% of cases the RSVC is hypoplastic or even atretic (Figure 36.1B) [1,13–15]. In 75% of cases the left innominate vein is absent or severely hypoplastic [6]. When an adequately sized left innominate vein is present, it provides an important alternate pathway for LSVC flow to the right atrium in addition to the coronary sinus. LSVC to the coronary sinus can coexist with azygos continuation of the IVC to the RSVC (9%), hemiazygos continuation of the IVC to the LSVC (7%), and separate entrance of the IVC and hepatic veins into the right atrium (2%) [13]. While LSVC to the coronary sinus rarely can be an isolated anomaly, it is most commonly associated with septal defects (atrial septal defect [ASD], ventricular septal defect [VSD] or common atrium), tetralogy of Fallot, atrioventricular septal defects, transposition of the great arteries, and other more complex defects [13]. While the true incidence of this anomaly is not known, it may occur in as many as 3–10% of patients with congenital heart disease. It appears to occur in 0.1–0.5% of the general population [16].

Left Superior Vena Cava with Coronary Sinus Ostial Atresia

Coronary sinus ostial atresia with persistent LSVC is a rare cardiac anomaly with 35 total cases reported in the world literature. Of these reported cases, 11 were diagnosed in living patients either by angiography or intraoperatively and the remainder were identified at autopsy [17]. Anatomically these lesions consist of a membranous occlusion of the coronary sinus ostium, thereby disconnecting the usual direct drainage of the coronary sinus (and LSVC) to the right atrium (Figure 36.1C) [1]. The gap between the blind end of the coronary sinus and the right atrium can

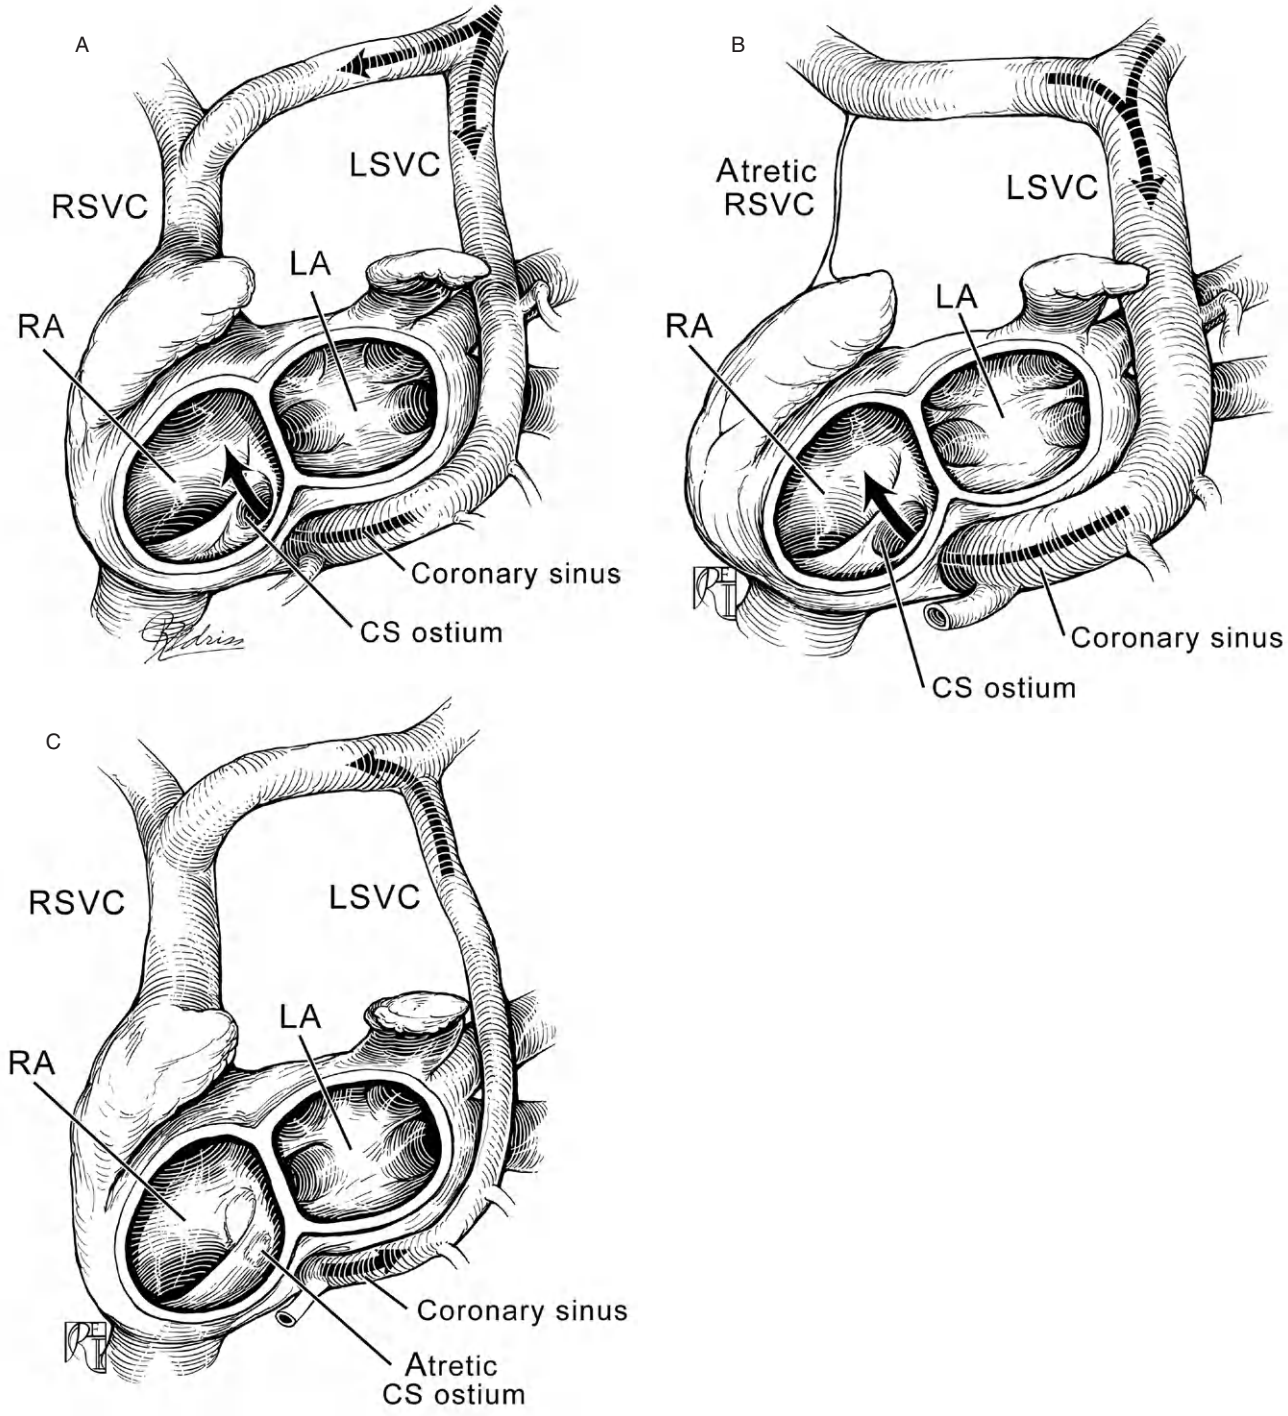

Figure 36.1 **A,** Left superior vena cava (LSVC) to the coronary sinus. **B,** Left superior vena cava to the coronary sinus with atretic right superior vena cava (RSVC). **C,** Coronary sinus ostial atresia with persistent LSVC. Arrows denote the retrograde flow of coronary sinus blood to the right atrium (RA). (CS, coronary sinus; LA, left atrium.)

be either a short- or a long-segment interruption [18]. The anomalous LSVC provides the major route for venous drainage from the coronary sinus; however, there can be small communicating veins between the coronary sinus and the right atrium [19]. Retrograde flow from the coronary sinus to the LSVC and across the innominate vein to the RSVC is most commonly found (Figure 36.1C) [1]. Other venous connections, however, can exist between the LSVC and the RSVC. For example, the LSVC can drain into the RSVC through a hemiazygos–azygos connection. Other

cardiac malformations coexist in 56% of the reported cases of coronary sinus ostial atresia [17].

Unroofed Coronary Sinus Syndrome

Unroofed coronary sinus syndrome (UCSS) is a spectrum of congenital cardiac anomalies consisting of partial or complete absence of the partition between the coronary sinus and the left atrium. All patients have an interatrial communication. An LSVC is usually present but is not a requirement for UCSS. Since the coronary sinus itself is a systemic vein, UCSS should be considered a subset of ASVC regardless of whether an LSVC coexists.

Persistence of the left anterior and common cardinal veins draining into the left sinus horn with failure of the normal invagination process that separates the left sinus horn (future coronary sinus) from the left atrium is a possible embryological mechanism for development of the UCSS [9,12,20].

UCSS can consist of either complete or partial unroofing [21,22]. In complete unroofing the entire length of the partition between the coronary sinus and the left atrium is absent. An LSVC is usually present but can be absent. In partial unroofing only a segment of the partition between the coronary sinus and the left atrium is absent. This partial unroofing can occur in the midportion or the distal portion (right atrial end) of the coronary sinus.

Complete Unroofing with Left Superior Vena Cava

The LSVC forms as the confluence of the left internal jugular vein and the left subclavian vein. Its vertical descent is anterior to the distal transverse left-sided aortic arch and the left pulmonary hilum. The LSVC terminates in the superior left aspect of the left atrium (Figure 36.2A) [1]. The position of its left atrial orifice appears to be relatively constant with the left superior pulmonary vein orifice located posteriorly and inferiorly and the orifice of the left atrial appendage located anteriorly. There can be a valve like structure or a ridge near the LSVC ostium. The hemiazygos vein joins the LSVC after arching superiorly and anteriorly over the left mainstem bronchus. The left innominate vein is absent in 80–90% of cases. The RSVC is usually smaller than the LSVC, or it can be absent with the right internal jugular and subclavian veins draining into the LSVC through a right innominate vein. There may be hemiazygos continuation of the IVC to the LSVC. In this situation the hepatic veins enter the inferior right atrium separately. Occasionally the hepatic veins may enter the left atrium posterior to the interatrial septum. This, in combination with an LSVC and hemiazygos continuation of the IVC, produces total anomalous systemic venous connection.

A coronary sinus atrial septal defect (ASD) is located posteriorly and inferiorly in the interatrial septum in the position usually occupied by the right atrial orifice of the coronary sinus. When the interatrial communication is an isolated coronary sinus defect, it is separated from the atrioventricular valve annulus by an anterior remnant of interatrial septal tissue. It is also bounded superiorly and inferiorly by interatrial septal tissue and posteriorly by the posterior atrial free wall. There may be an associated secundum ASD separated from the coronary sinus ASD by interatrial septal tissue. Alternatively, the coronary sinus ASD may be confluent with a secundum and/or primum ASD. When a primum ASD coexists in confluence with the coronary sinus ASD, the anterior leaflet of the mitral valve is frequently cleft. Occasionally the complete absence of interatrial tissue creates a common atrium (Figure 36.2B) [1,9,21–24].

In the presence of complete unroofing of the coronary sinus with an LSVC, the pulmonary veins can enter the left atrium more superiorly than usual. This can create an apparent narrowing between the area of the left atrium into which the pulmonary veins enter and the portion of the left atrium to which the LSVC, left atrial appendage, and mitral valve are attached [21].

Complete Unroofing without Left Superior Vena Cava

In this case complete unroofing of the coronary sinus exists in the presence of a coronary sinus type ASD but without an LSVC (Figure 36.2C) [1].

Partially Unroofed Coronary Sinus with or without Left Superior Vena Cava

Partial absence of the partition between the coronary sinus and the left atrium can occur in the middle (Figure 36.2D) [1,25,26] or the distal [21,22] coronary sinus with or without an LSVC. Distal unroofing of the coronary sinus occurs most commonly in the presence of atrioventricular canal defects. In this situation the distal coronary sinus, including its right atrial orifice, can be unroofed resulting in a displacement of the distal opening of the coronary sinus into the left atrium (Figure 36.2E) [1].Conversely, the distal coronary sinus may be unroofed just prior to its right atrial orifice resulting in a coronary sinus ASD (Figure 36.2F) [1,22,26].

While situs solitus of the atria and viscera with levocardia are usually present, anomalies that can coexist with UCSS include dextrocardia, situs inversus, and atrial appendage isomerism with asplenia or polysplenia. UCSS has been reported in association with partial atrioventricular canal defect, complete atrioventricular canal defect, common atrium, tetralogy of Fallot, double-outlet right ventricle, pulmonary stenosis, total anomalous pulmonary venous connection, and hypoplastic left ventricle [21,22].

Right Superior Vena Cava to the Left Atrium

An RSVC draining to the left atrium is very rare as an isolated lesion, and was first reported by Kirsch and

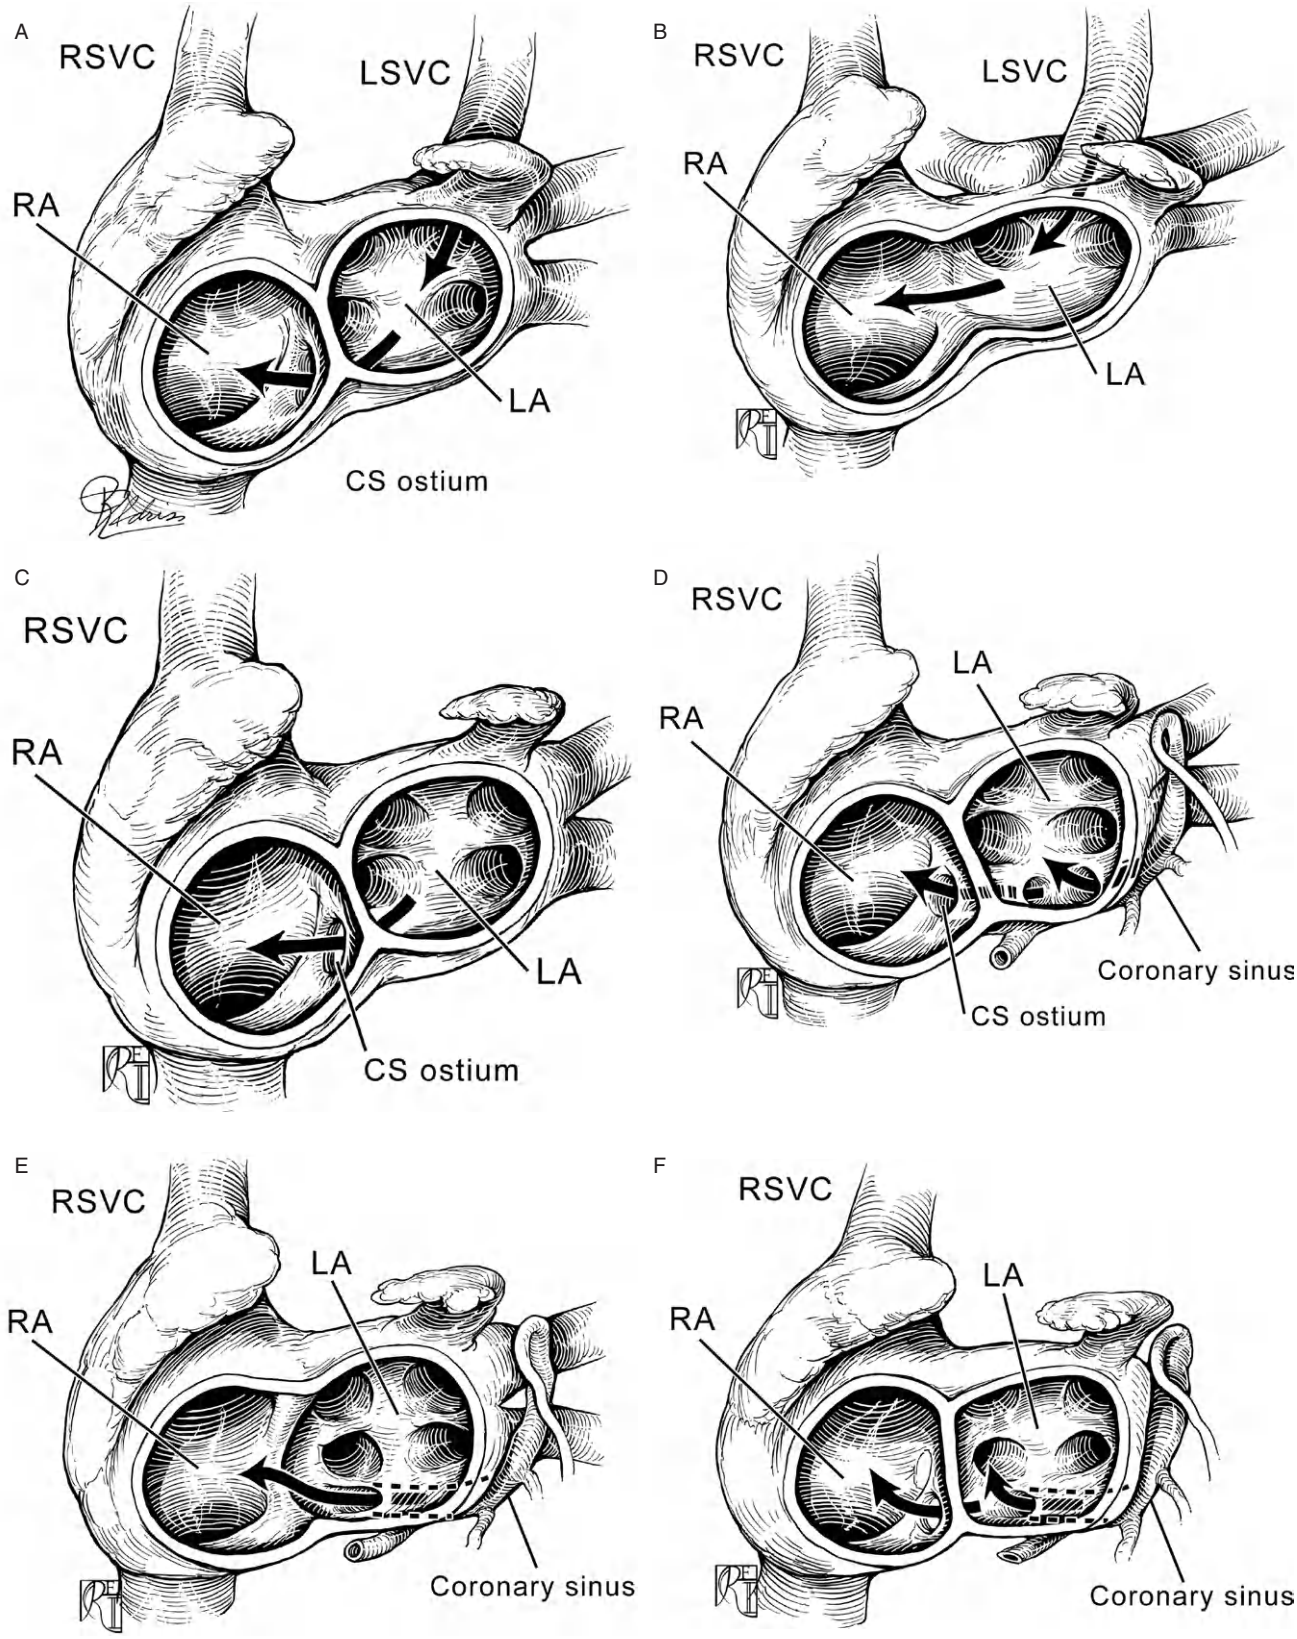

Figure 36.2 Unroofed coronary sinus syndrome. **A,** Left superior vena cava (LSVC) to the left atrium (LA) with complete unroofing of the coronary sinus and coronary sinus atrial septal defect (ASD). **B,** Left superior vena cava to the LA with complete unroofing of the coronary sinus and absence of the interatrial septum (common atrium). **C,** Complete unroofing of the coronary sinus without LSVC. **D,** Partial unroofing of the midportion of the coronary sinus with a coronary sinus ASD, absence of an LSVC. **E,** Partial unroofing of the distal portion of the coronary sinus with partial atrioventricular septal defect coexisting in confluence with coronary sinus ASD, absence of an LSVC. **F,** Partial unroofing of the distal portion of the coronary sinus with intact right atrial coronary sinus orifice with coronary sinus ASD, absence of an LSVC. (IVC, inferior vena cava; LA, left atrium; RA, right atrium; RSVC, right superior vena cava.)

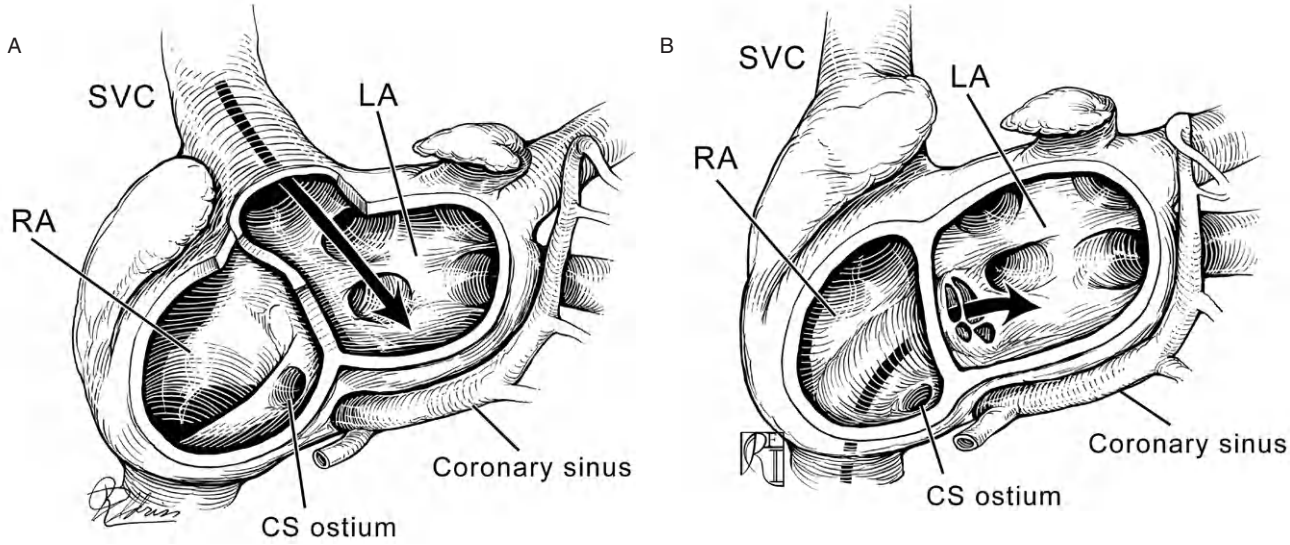

Figure 36.3 A, Right superior vena cava (SVC) to the left atrium (LA). **B,** Inferior vena cava (IVC) with fenestrated opening into the LA. (CS, coronary sinus; RA, right atrium.)

colleagues (Figure 36.3A) [1,27].True cases must be differentiated from the sinus venosus type of ASD with an SVC overriding the interatrial septum.

Direct Inferior Vena Caval Connections

The IVC normally receives the hepatic veins and then connects directly to the inferior aspect of the right-sided morphological right atrium. Very rarely the IVC connects to the right atrium through the coronary sinus. This latter anomaly has been reported in a patient with an LSVC to the coronary sinus, absent RSVC, left-sided hypoplasia (small left ventricle, parachute mitral valve, bicuspid aortic valve, hypoplastic arch, and coarctation of the aorta), primum ASD, and secundum ASD. [28] Direct connection of the IVC to the left-sided morphologically left atrium can occur either as an isolated lesion or in association with other cardiac anomalies (Figure 36.3B) [1,29–33]. One very unusual case of left-sided superior and inferior vena cavae draining into the left atrium in association with normal right superior and inferior vena cavae and an atrial septal defect has been reported [34].

Indirect Inferior Vena Caval Connections

Indirect inferior vena caval connections exist when the IVC does not connect to the atrium from below but rather "continues" as an extension of either the azygos or hemiazygos veins. In azygos continuation the IVC passes up the right paravertebral gutter and arches over to join the RSVC as a dilated azygos vein (Figure 36.4A) [1]. In hemiazygos continuation the IVC courses up the left paravertebral gutter to join the LSVC as a dilated hemiazygos vein (Figure 36.4B) [1]. Both azygos and hemiazygos continuation have been collectively referred to as "anomalous IVC with azygos continuation" or "infrahepatic interruption of the IVC" [35]. When there is azygos or hemiazygos continuation of the IVC, the hepatic veins always connect directly to the atrial mass and never via the anomalous IVC.

The incidence of indirect IVC connections is 0.6% of patients with congenital heart defects. Its incidence in patients without congenital heart defects is probably much less than the 0.3% incidence quoted for LSVC under the same circumstances [35].

Although indirect IVC connections can rarely be found in individuals with otherwise normal hearts [36], the vast majority of them occur in association with other congenital cardiac abnormalities such as atrial appendage isomerism, atrioventricular canal defect, anomalous pulmonary venous connection, double-outlet right ventricle, common atrium, pulmonary atresia, SVC anomalies (especially bilateral SVC), and others.

Atrial (Appendage) Isomerism

Heterotaxy (Greek: *heteros* – other than, and *taxis* – arrangement) is synonymous with the terms "visceral heterotaxy" and "heterotaxy syndrome." It is literally defined as a pattern of anatomic organization of the thoracic and the abdominal organs which is neither situs solitus (the usual or normal arrangement) nor complete situs inversus (the unusual or mirror image arrangement of normal) [37]. If asymmetry of the thoracic and abdominal viscera is the usual or normal situation, then the heterotaxy syndrome includes patients with an unusual degree of thoracic and abdominal visceral symmetry. Admittedly, this broad term

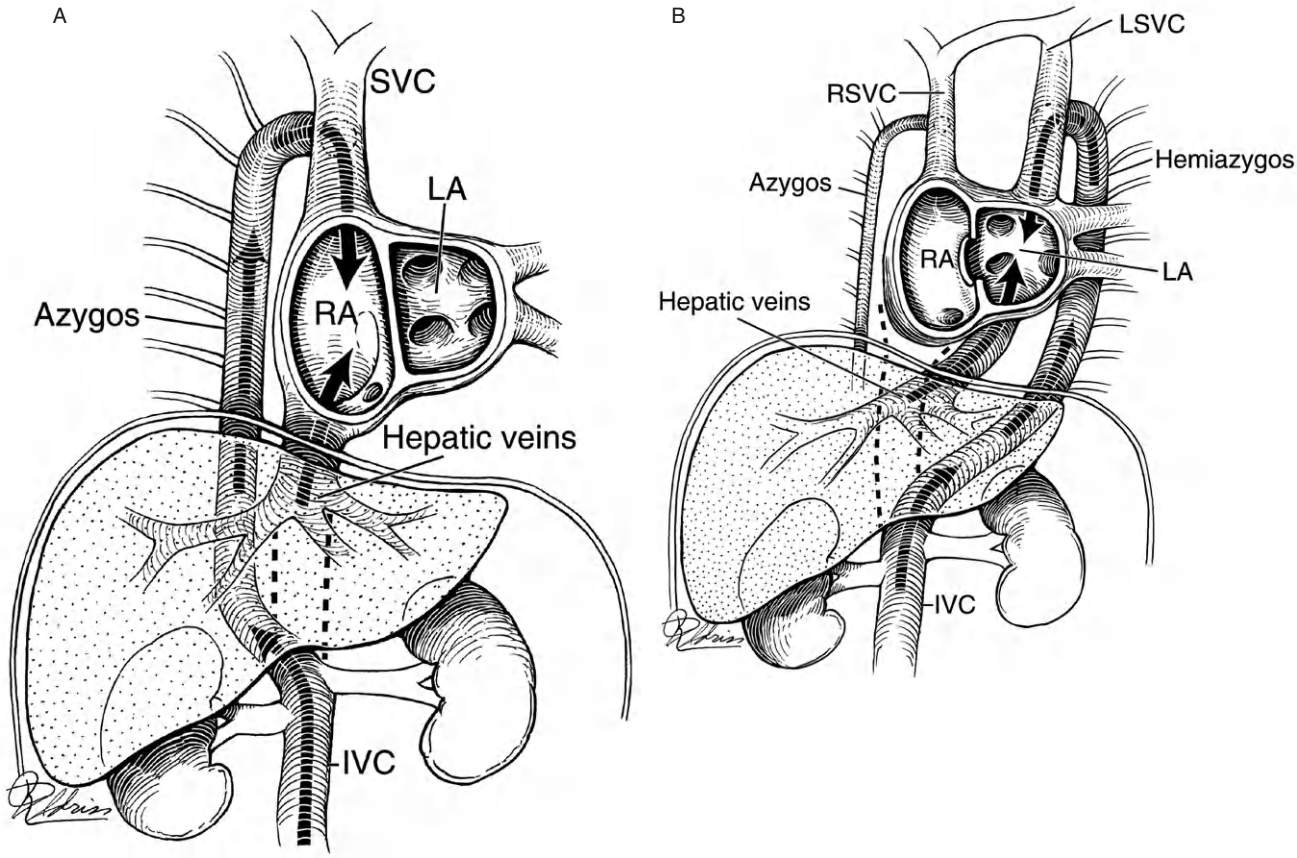

Figure 36.4 A, Azygos continuation of the inferior vena cava (IVC) to the right superior vena cava (SVC). **B,** Hemiazygos continuation of the IVC to the left superior vena cava (LSVC). Single hepatic venous trunk connects to the left atrium (LA). Secundum atrial septal defect present. (RA, right atrium; RSVC, right superior vena cava.)

includes patients with a wide variety of very complex cardiac lesions and is a term that has generated confusion and controversy in the literature. The definition of heterotaxy which currently enjoys the greatest consensus in the literature is "an abnormality where the internal thoracoabdominal organs demonstrate abnormal arrangement across the left-right axis of the body. By convention, heterotaxy does not include patients with either the expected usual or normal arrangement of the internal organs along the left-right axis, also known as 'situs solitus', nor patients with complete mirror-imaged arrangement of the internal organs along the left-right axis also known as 'situs inversus'" [38]. One way to impose order upon this diverse group of cardiac lesions is to stratify them according to the morphology of the atrial appendages [39]. This is accomplished by applying the chemistry term, isomerism, to congenital cardiac morphology. Isomerism, in the context of the congenitally malformed heart, is defined as a situation where some paired structures on opposite sides of the left–right axis of the body are, in morphologic terms, symmetrical mirror images of each other [38]. In atrial appendage isomerism, both atrial appendages are similar rather than displaying their usual distinctive right and left morphology. Right or left atrial appendage isomerism exists when both atria have right or left atrial appendage morphologic characteristics, respectively. Right atrial appendage isomerism is frequently, but not always, associated with bilaterally tri-lobed lungs (each with short bronchi) and asplenia. Left atrial appendage isomerism is frequently, but not always, associated with bilaterally bi-lobed lungs (each with long bronchi) and polysplenia.

ASVC are the rule in patients with heterotaxy syndrome. Up to 70% of patients have bilateral SVCs. In patients with right atrial appendage isomerism the superior vena cavae typically enter the atrial roof with the coronary sinus being universally absent. Also, in heterotaxy syndrome the inferior vena caval connections can be either direct or indirect. Direct communications are most commonly to the right-sided atrium but may be left-sided or, rarely, to the midline of the atrial mass. Indirect inferior vena caval connections exist when there is azygos or hemiazygos continuation. While the IVC typically connects directly to the atrium in

right atrial appendage isomerism, it is usually interrupted with azygos/hemiazygos continuation in patients with left atrial appendage isomerism. Up to 30% of heterotaxy patients also have anomalous hepatic venous drainage. The hepatic veins always connect to an atrium from below, either normally, via the IVC, or by a separate and direct connection of their own. When the hepatic veins connect separately, they can do so to either atrium or to both atria. When the IVC enters the atrial mass from below, the hepatic veins can connect to the atrium either via this IVC or separately from it [40].

Diagnosis

Physical examination is neither sensitive nor specific for the diagnosis ASVC. The chest radiograph and electrocardiogram may be normal, consistent with left- and/or right-sided cardiac enlargement or characteristic of any dominant associated cardiac malformation. ASVC can be diagnosed by a number of methods. The accuracy of these methods depends upon the constant maintenance of a high index of suspicion and a high level of interest in discovering these abnormalities. Echocardiography (transthoracic and/or transesophageal) is an extremely specific and highly sensitive method for making the diagnosis of ASVC [41–43]. Prenatal echocardiography is less accurate than postnatal studies because of the limitations imposed by fetal size, movement, and position as well as shadowing by ribs or other structures. Fetal inferior vena caval anatomy is more reliably predicted than are superior vena caval connections [44]. Radionuclide angiocardiography with injection of technetium-99m pertechnetate into the left arm and the determination of differential right-to-left shunting after injection of labeled albumin microspheres into the left and right arms have been reported to accurately diagnose LSVC to the left atrium but this technique is not used currently [45]. While computer-assisted tomography with intravenous contrast administration can identify mediastinal venous anomalies [46], magnetic resonance imaging (MRI) may be more accurate without the need for the radiation and contrast exposure. Prospective studies have shown that the diagnostic yield of cardiac MRI is superior to echocardiography and, often, to cardiac angiography in defining systemic (and pulmonary) venous anatomy and its relationship to surrounding mediastinal structures [47]. Cardiac MRI is especially effective and efficient in identifying the arrangements and abnormalities of the thoracic and abdominal organs in heterotaxy syndrome, with its many visceral and cardiovascular abnormalities [40,48–50]. In the current era, noninvasive imaging, such as echocardiography and cardiac MRI, has largely replaced cardiac angiography to establish the cardiac anatomy of patients with congenital heart disease. This trend is just as apparent in patients with ASVC and heterotaxy syndrome as it is in other forms of congenital heart disease. Cardiac catheterization and angiography may need to be performed to supplement or clarify anatomical information obtained by noninvasive methods or to document hemodynamics, especially in patients with heterotaxy syndrome who may need to undergo staged Fontan palliation.

Pathophysiology and Natural History

Isolated systemic venous route abnormalities (i.e., LSVC to the coronary sinus) are asymptomatic and physiologically innocuous. When other important congenital cardiac malformations accompany systemic venous route abnormalities, the pathophysiology and natural history are determined by the associated lesion(s).

Abnormalities of systemic venous destination can produce a right-to-left shunt that results in varying degrees of cyanosis. Progressive cyanosis can produce all of the sequelae of polycythemia including cerebral embolization and abscess formation [22,51]. Since an atrial septal defect is frequently associated with ASVC, a left-to-right shunt can coexist with the right-to-left shunt producing mild-to-moderate cyanosis and right ventricular dilatation with pulmonary overcirculation. When additional important cardiac malformations are coupled with systemic venous destination anomalies, the physiologic burden of the associated cardiac lesion(s) is additive and further complicates the presentation, clinical course, and natural history.

In partially unroofed midportion of the coronary sinus there can be a left-to-right or a right-to-left shunt depending upon the relative ventricular compliances and the right atrial pressure. When this lesion is isolated, a large left-to-right shunt exists at the atrial level and dictates the clinical presentation and natural history [25,26]. When partially unroofed midportion of the coronary sinus coexists with tricuspid atresia, significant right-to-left shunting has been reported after a Fontan repair that incorporates the coronary sinus into the systemic venous pathway [52–54].

Surgical Management of Systemic Venous Route Abnormalities

Venous route abnormalities not associated with other cardiac lesions do not require surgical treatment because they are physiologically benign. When venous route abnormalities exist with associated cardiac lesions, the conduct of the cardiac surgical repair must accommodate the abnormal venous anatomy.

Left Superior Vena Cava with Coronary Sinus Ostial Atresia

Even though LSVC with coronary sinus ostial atresia is physiologically benign, this lesion can pose a grave hazard

for the cardiac surgeon if it is not recognized before or at the time of cardiac surgical intervention for associated cardiac lesions. Permanent or even temporary intraoperative occlusion or vigorous manipulation of the LSVC can lead to acute obstruction of the coronary venous system causing myocardial congestion and ischemia [55]. When an LSVC (especially a small one) to the coronary sinus exists, patency of the coronary sinus orifice should be sought preoperatively or intraoperatively. If coronary sinus ostial atresia is confirmed and the only route for decompression of the LSVC is retrograde to the RSVC through the left innominate vein or through another venous connection, the LSVC should never be occluded, even temporarily. This will avoid the possibility of intraoperative or postoperative coronary venous congestion and myocardial ischemia [17].

Left Superior Vena Cava to the Coronary Sinus without Coronary Sinus Ostial Atresia

If a large left innominate vein is present between the LSVC and the RSVC, a tourniquet can be used to temporarily occlude the LSVC below the left innominate vein during the intracardiac portion of the surgical repair.

At the time of cardiac catheterization of a patient with an LSVC to the coronary sinus and a small or absent left innominate vein, an end-hole balloon catheter can be threaded retrograde through the coronary sinus into the LSVC. The balloon is inflated low in the LSVC with complete occlusion confirmed by contrast injection through the end hole. The LSVC pressure is monitored for 20 minutes [56]. Conversely, the LSVC pressure can be measured intraoperatively using an indwelling left internal jugular vein catheter or by direct venous puncture during a trial of LSVC occlusion. Occlusion pressures consistently less than 18 mmHg suggest the presence of an adequately sized left innominate vein or of adequate venous collaterals. Under these circumstances the LSVC, at surgery, can be temporarily occluded with little risk of central nervous system complications. The LSVC should not be temporarily occluded if the results are equivocal or if the pressure is consistently greater than 18 mmHg. These conservative guidelines are arbitrary since no rigorously derived LSVC pressure data exist upon which to formulate a strict policy.

When temporary occlusion of the LSVC is not advisable, the LSVC is cannulated directly [1]. After the institution of cardiopulmonary bypass with standard cannulation of the RSVC and IVC, a third angled venous cannula is placed directly into the LSVC. This technique affords optimal control, visualization, and ease of insertion during cannulation of the relatively inaccessible LSVC. Alternatively, a flexible venous cannula can be inserted retrograde through the coronary sinus into the LSVC after opening the right atrium [1]. This technique is relatively simple but has the disadvantage of placing a cannula in the area of the surgical repair. Barring the use of either of these cannulation techniques, the exuberant coronary sinus effluent can be recovered during the repair with a cardiotomy sucker. This technique may be associated with poor visualization due to escaped blood and the physical presence of the cardiotomy sucker in the surgical field. Furthermore, myocardial protection could be compromised by the continual flow of the relatively warm LSVC effluent through the coronary sinus.

Finally, in neonates and small infants, the use of a single right atrial venous cannula with profound hypothermia and total circulatory arrest may be advisable because of the logistical problems associated with the use of multiple cannulae in these patients.

Azygos or Hemiazygos Continuation of the Inferior Vena Cava

When azygos continuation of the IVC to a RSVC is found at the time of cardiac surgery for an associated cardiac lesion, the RSVC is typically dilated and should be directly cannulated with a large venous cannula well below the IVC (azygos) insertion. The SVC cannula should be positioned to avoid obstructing the IVC (azygos) orifice. With hemiazygos continuation of the IVC to the LSVC, the dilated LSVC is directly cannulated with a large venous cannula below the IVC (hemiazygos) entrance.

Separate Connection of Hepatic Veins into the Right Atrium

Typically, hepatic veins that connect from below to the right atrium can be directly cannulated with a small angled venous cannula as one might cannulate a small IVC. To promote optimal venous drainage, the venous cannula should not be advanced too far into the common hepatic venous trunk. If the hepatic veins enter the right atrium from below by small and separate venous branches, profound hypothermia with low flow and recovery of the hepatic venous return with the cardiotomy sucker or the use of profound hypothermia with total circulatory arrest is necessary.

Surgical Management of Systemic Venous Destination Abnormalities

Left Superior Vena Cava to the Left Atrium without a Coronary Sinus

The preoperative and intraoperative methods for determining the LSVC pressure with a trial of occlusion are the same as those described previously for LSVC to the coronary sinus. If there is a significant innominate vein between the LSVC and an RSVC and if the trial occlusion pressure

is acceptable, the LSVC may be ligated below the innominate vein [57,58]. Any associated cardiac defects are then repaired.

If ligation is not an option, the LSVC to the left atrium must be routed to the correct destination (right atrium). This must be coordinated with the repair of any associated cardiac abnormalities. The cannulation strategy is identical to that for LSVC to the coronary sinus.

Repositioning the Atrial Septum

A surgical technique that is especially useful when common atrium is part of the associated cardiac pathology, is repositioning of the interatrial septum. The interatrial septum, if present, is completely excised except for the anterior limbus. A piece of autologous pericardium or other patch material is used to reposition the interatrial septum so that the systemic venous orifices lie on the right atrial side of the new interatrial septum while leaving the pulmonary venous orifices on the left atrial side (Figure 36.5) [1,59,60]. Excision of all of the native interatrial septum prior to septal repositioning allows optimal baffle placement to avoid systemic or pulmonary venous obstruction [59,60]. Repositioning of the interatrial septum can be performed in neonates with very complex forms of ASVC associated with LSVC but the operative risk and the hazard of postoperative obstructive complications is probably higher in this age group [61].

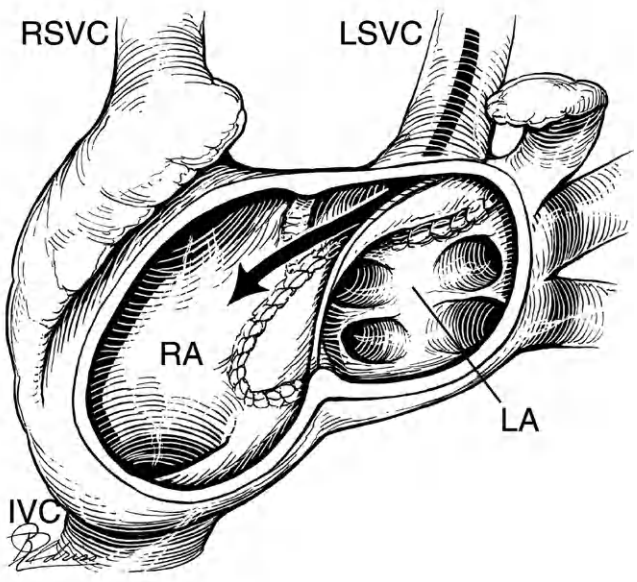

Figure 36.5 Repair of a left superior vena cava (LSVC) to the left atrium by repositioning the atrial septum. Excision of all the native interatrial septum before septal repositioning allows optimal baffle placement to avoid systemic or pulmonary venous obstruction. (IVC, inferior vena cava, RA, right atrium; RSVC, right superior vena cava.)

Superior Atrial Approach

If there is a significant amount of interatrial tissue, it is incised superiorly from the coronary sinus toward the RSVC orifice. The interatrial septum is then incised anteriorly thereby creating a medially hinged interatrial flap. Pericardium or prosthetic material is used to create a tunnel from the LSVC orifice along the superior left atrium toward the right atrium. Care is taken to avoid obstructing the left superior pulmonary vein. The remaining interatrial communication is closed with the interatrial flap. When not enough tissue exists to create an autologous interatrial flap, the interatrial communication is closed with autologous pericardium or other patch material (Figure 36.6) [1,62].

Left Superior Vena Cava Translocation with Interatrial Septal Repositioning

The placement of an interatrial baffle to separate the pulmonary and systemic venous orifices sometimes threatens to obstruct the left-sided pulmonary veins. In this circumstance, the LSVC can be detached from the left atrium and reimplanted into the roof of the left atrium closer to the plane of the native interatrial septum. The native interatrial septum is then excised and repositioned, with pericardium or other patch material, to direct all of the systemic venous flow to the pulmonary atrioventricular valve [51].

Bidirectional Cavopulmonary Connection

When the intracardiac anatomy precludes the placement of an interatrial baffle, an extracardiac repair technique can be used. The LSVC is detached from the heart and its cardiac end is oversewn. The LSVC is then sutured to an incision in the superior aspect of the left pulmonary artery [63–65]. Physiologic factors limiting the application of this technique are similar to those limiting the application of a bidirectional cavopulmonary connection to a patient with a variant of functionally single ventricle.

Roofing the Coronary Sinus

The coronary sinus can be "roofed" with autologous pericardium or by plication of the atrial wall over a stent. This roofing procedure starts at the left atrial LSVC internal orifice and continues to the level of the inferior aspect of the interatrial septum at the region normally occupied by the right atrial coronary sinus ostium [11,22]. Patch closure of the interatrial septum is performed around the new coronary sinus orifice (Figure 36.7) [1]. This technique is rarely used because of the possibility of left pulmonary vein and atrioventricular valve obstruction, injury to the conduction system, and early or late tunnel stenosis [62].

Translocation of the Left Superior Vena Cava to the Right Atrium

Although not commonly used, some have advocated detachment of the LSVC from the left atrium with implantation into the right atrium (Figure 36.8) [1]. When there

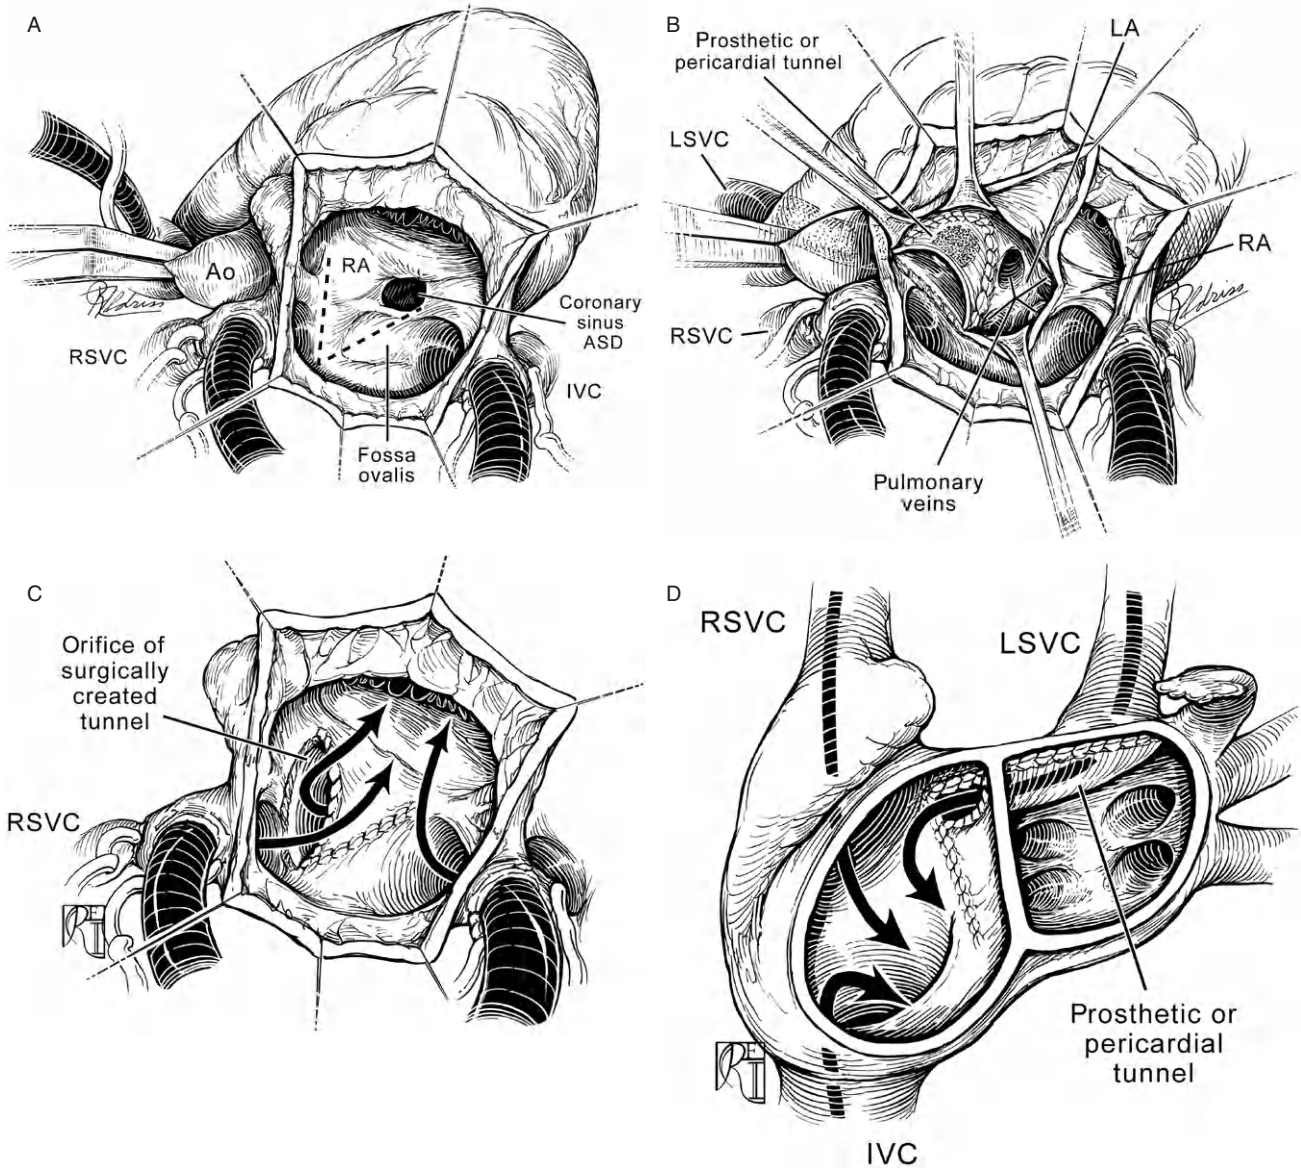

Figure 36.6 Superior atrial approach to repair a left superior vena cava (LSVC) to the left atrium (LA) with a coronary sinus atrial septal defect (ASD). **A,** Line of incision for creation of the medially hinged interatrial flap. **B,** Construction of the medially hinged interatrial flap. Pericardial or prosthetic tunnel is constructed along the superior aspect of the left atrium to connect the left superior vena caval orifice to the plane of the interatrial septum. **C,** Remaining interatrial defect is closed with autologous interatrial tissue flap (pericardium or prosthetic material may be used if there is inadequate autogenous tissue). **D,** Schematic representation of a completed superior atrial repair of a left superior vena cava to the left atrium. (Ao, aorta; IVC, inferior vena cava; RSVC, right superior vena cava; RA, right atrium.)

appears to be insufficient LSVC length to achieve a tension-free anastomosis to the right atrium, the LSVC can be divided along with a generous flap of left atrial tissue. This left atrial flap is sutured into a tubular extension to lengthen the LSVC. The LSVC is then sutured to the right atrium without tension (Figure 36.9A) [1]. If further length is needed to reach the right atrium without tension, a superiorly based right atrial flap can be fashioned into a tubular right atrial extension. This is sutured to the lengthened LSVC (Figure 36.9B) [1,24]. The technique of LSVC extension has also been adapted to implantation of the lengthened LSVC into the RSVC [66]. Successful connection of the LSVC to the right atrium with an interposition PTFE graft has also been reported [67]. The major limitation of these techniques is the possibility of stenosis or occlusion of the rerouted LSVC.

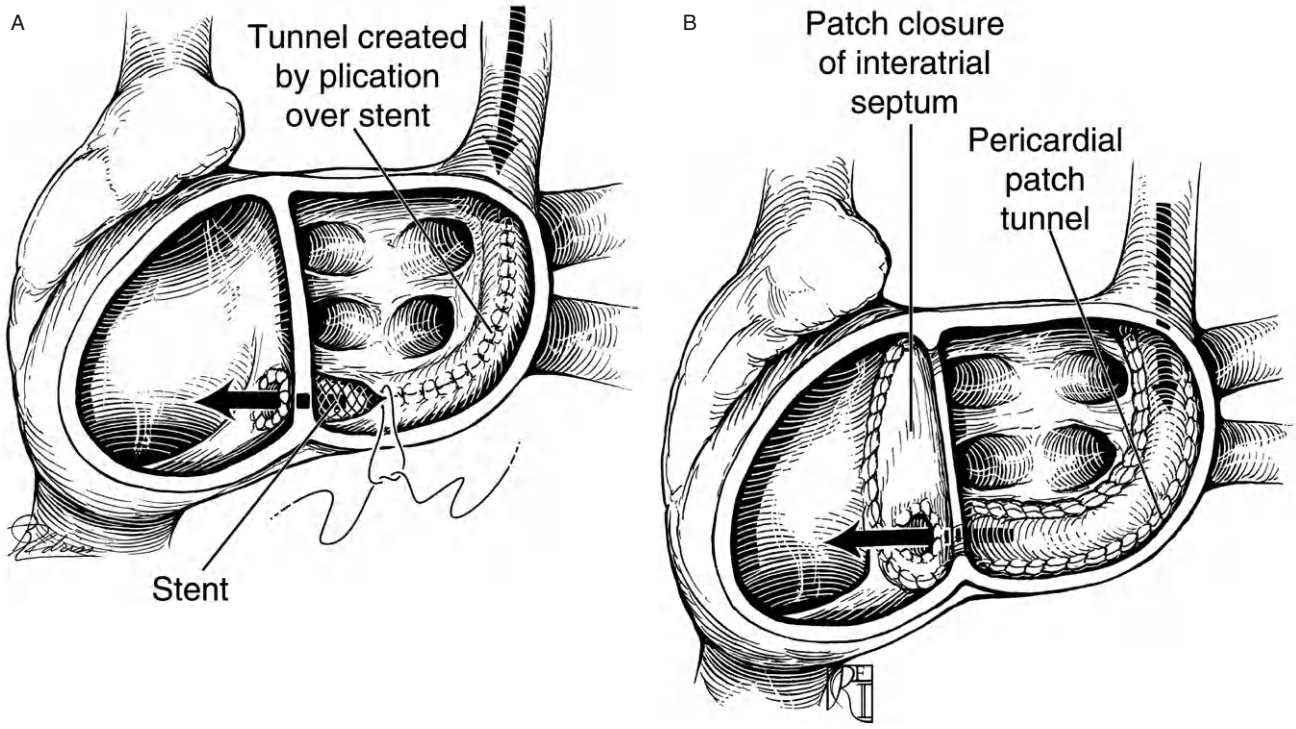

Figure 36.7 Roofing of the coronary sinus for repair of left superior vena cava to the left atrium with complete unroofing of the coronary sinus. **A,** Tunnel made by plication over stent on posterior wall of the left atrium. **B,** Tunnel made with pericardial patch: patch closure of interatrial septum.

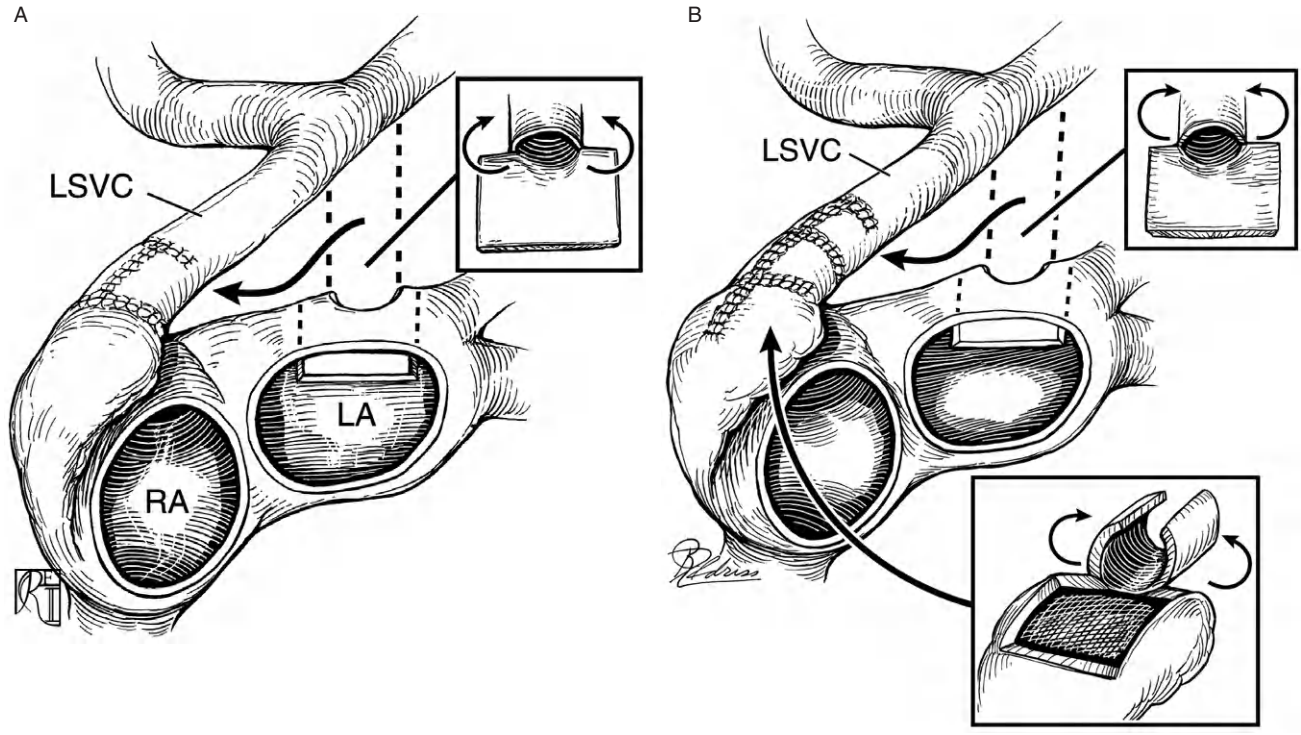

Figure 36.9 Extracardiac repair of left superior vena cava (LSVC) to the left atrium (LA). **A,** Translocation of the LSVC to the right atrium (RA) with extension of the LSVC using a tubular left atrial flap. The LSVC is detached from the LA with a flap of surrounding left atrial tissue (inset). The LSVC is lengthened by suturing the left atrial flap into a tubular extension. The lengthened LSVC is sutured to the right atrium. **B,** Translocation of the LSVC to the right atrium with right and left atrial flap extensions. The dotted lines mark the area of construction of the left atrial flap. The right atrial flap is formed into a right atrial tubular extension. The left atrial flap is formed into an LSVC extension. The lengthened LSVC is sutured to the right atrial tubular extension.

Partially Unroofed Midportion of the Coronary Sinus

If the diagnosis has not been made preoperatively, this lesion can easily be overlooked in the operating room without a high index of suspicion. The diagnosis is confirmed by passing a probe into the coronary sinus orifice, through the unroofed portion of the coronary sinus and into the left atrium. The communication with the left atrium through the defect in the roof of the coronary sinus can be confirmed by viewing the defect through a separate incision in the interatrial septum. When an LSVC is present, three potential repairs can be performed (Figure 36.10) [1]. If the LSVC can be ligated, the unroofed portion of the coronary sinus can be closed primarily or with a patch either through the mouth of the dilated coronary sinus or through an incision in the interatrial septum. A more straightforward repair consists of LSVC ligation with simple patch closure of the coronary sinus orifice. This leaves a negligible right-to-left shunt secondary to coronary sinus return to the left atrium. If the LSVC cannot be ligated, the defect in the roof of the coronary sinus must be repaired primarily or with a patch. When an LSVC is not present, the unroofed portion of the coronary sinus can be repaired or the coronary sinus orifice closed with a patch [58].

Inferior Vena Cava to the Left Atrium

Repair of drainage of the IVC to the left atrium involves excision of the interatrial septum with baffling of the IVC orifice to the right side using autologous pericardium or other patch material (Figure 36.11) [1].

Total Anomalous Systemic Venous Drainage

Repair of total anomalous systemic venous connection is accomplished by excising all of the interatrial septum, if one exists, except for the anterior limbus. The atrial mass is then partitioned with pericardium or other patch material so that the systemic venous orifices are baffled to the pulmonary atrioventricular valve and the pulmonary venous orifices are baffled to the systemic atrioventricular valve [68–71].

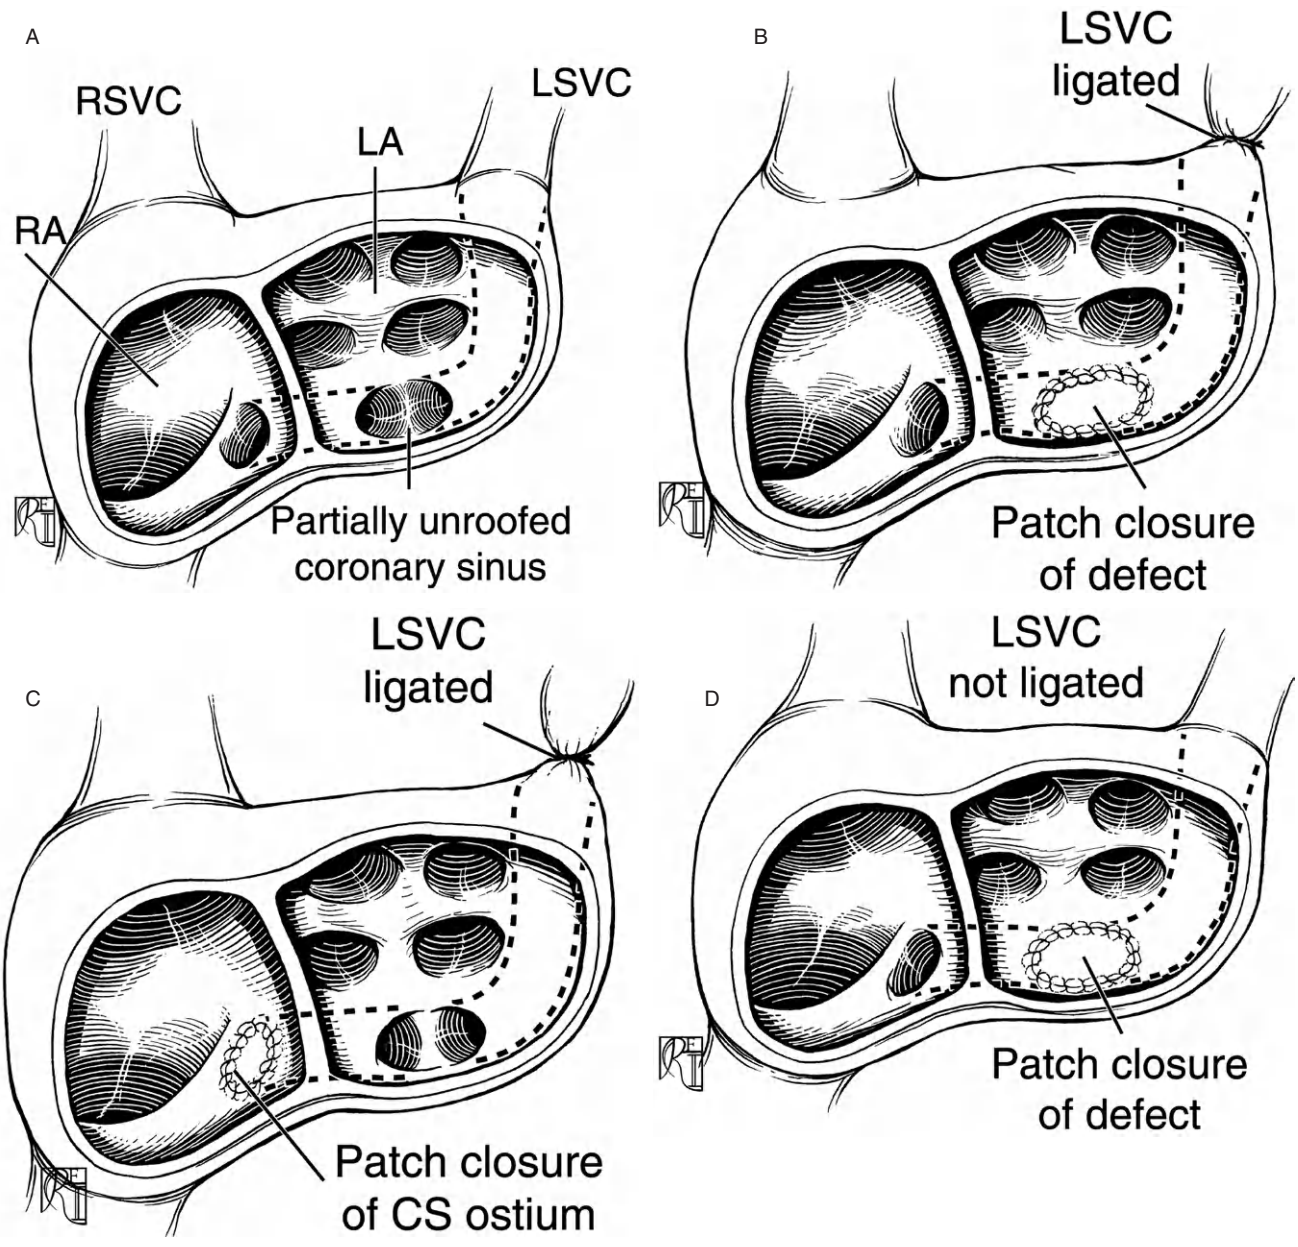

Figure 36.10 A, Repair of partially unroofed midportion of the coronary sinus with left superior vena cava (LSVC). **B,** Ligation of the LSVC and primary or patch closure of the unroofed portion of the dilated coronary sinus (CS). **C,** Ligation of the LSVC and primary or patch closure of the dilated coronary sinus right atrial orifice. **D,** Primary or patch closure of the unroofed portion of the dilated coronary sinus in a situation in which the LSVC cannot be ligated. (LA, left atrium; RA, right atrium; RSVC, right superior vena cava.)

Right Superior Vena Cava to the Left Atrium

Because of the uniqueness of this lesion nothing is known about the results of surgical treatment in the current era. Based upon one successful case report of a closed repair technique translocating the RSVC to the right atrium [27], it should be possible to improve upon this approach using cardiopulmonary bypass. Alternatively, excision of the superior interatrial septum with repositioning of the septum to the left side of the RSVC orifice using pericardium or a prosthetic patch is reasonable (Figure 36.12) [1].

Results

The mortality for repair of ASVC in isolation or associated with simple cardiac lesions is low. Survival primarily depends upon the patient's preoperative condition and the severity of the associated cardiac defects. Because these

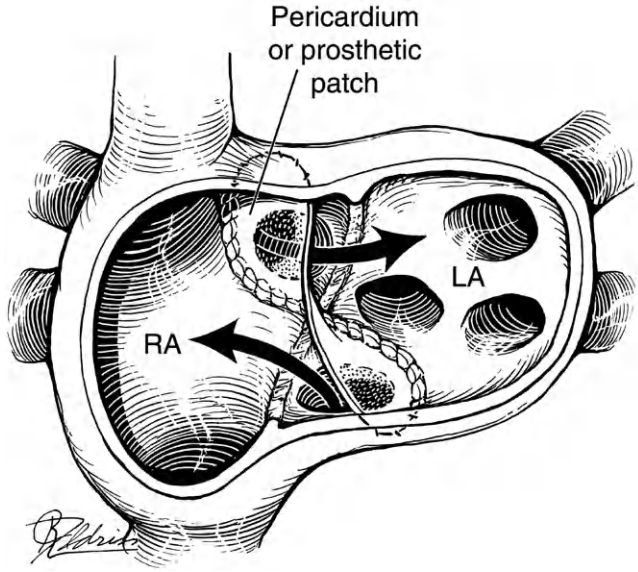

Figure 36.11 Baffle repair of inferior vena cava to the left atrium (LA) in association with partial anomalous pulmonary venous connection. The interatrial septum has been excised and pericardial or prosthetic patch is used to baffle the inferior vena cava into the right atrium (RA) and the right superior pulmonary veins into the LA.

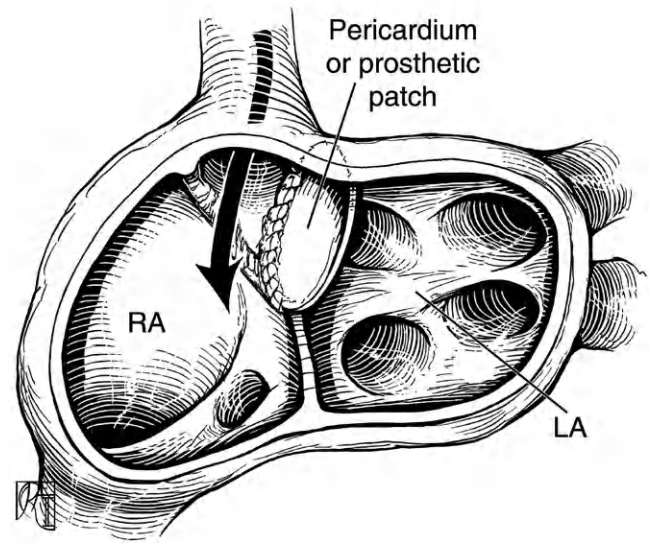

Figure 36.12 Baffle repair of right superior vena cava to the left atrium (LA). (RA, right atrium.)

anomalies are associated with a wide variety of cardiac malformations, it is difficult to determine morbidity and mortality rates directly attributable to the venous abnormalities per se.

Special Situations

Heart Transplantation in Patients with Anomalies of Systemic Venous Connection

The only absolute anatomic contraindication to heart transplantation is absence or marked hypoplasia of the central pulmonary arteries and absence or markedly diminutive pulmonary veins. ASVC increases the complexity of orthotopic cardiac transplantation and can potentially increase the operative risk. However, proper recipient selection, en bloc harvest of all donor vein and artery needed for complete reconstruction, harvesting of donor autologous pericardium, meticulous myocardial protection, and the use of profound hypothermia with low flow and intermittent total circulatory arrest are keys to a successful result [72].

During orthotopic cardiac transplantation, an LSVC to the left atrium can be reconstructed using external or internal techniques. The donor innominate vein can be harvested en bloc with the superior vena cava. The recipient LSVC is divided near its entrance into the left atrium during the recipient cardiectomy. The distal transected end of the recipient LSVC is then sutured end-to-end to the donor left innominate vein [73]. Conversely, the distal transected end of the recipient LSVC is sutured end-to-end to a length of harvested donor descending aorta. The opposite end of this fresh, homograft interposition graft is then sutured to an incision in the roof of the donor right atrium [74]. Finally, the internal techniques of inferior or superior roofing with fresh pericardium can be used. After the recipient cardiectomy has been performed, a defect is created in the inferior aspect of the recipient interatrial septum. Inferior roofing is performed by creating a left atrial tunnel anterior to and leftward of the recipient left pulmonary veins from the LSVC orifice down to the surgically created interatrial defect (Figure 36.13) [1]. In superior roofing a defect is created in the superior aspect of the recipient interatrial septum. The superior wall of the left atrium is used as a flap to create a left atrial tunnel from the LSVC orifice to the interatrial defect (Figure 36.13) [1,75,76].

Other ASVC, such as left atrial insertion of the hepatic veins can be corrected, after recipient cardiectomy, by performing a resection of the recipient interatrial septum and creating a new interatrial septum that baffles the anomalous hepatic vein orifices to the right atrial side. This same baffle technique can be used in combination with superior or inferior roofing techniques to address transplant situations in which an LSVC and left-sided hepatic veins coexist [75,76]. In situs inversus, the left-sided morphologic right atrium can be used as a flap to construct a composite tunnel on the pericardial surface of the diaphragm from the hepatic vein orifices across the midline to the right side. The right-sided opening of this composite tunnel is sutured to the inferior vena caval orifice of the donor heart (Figure 36.14) [1,77].

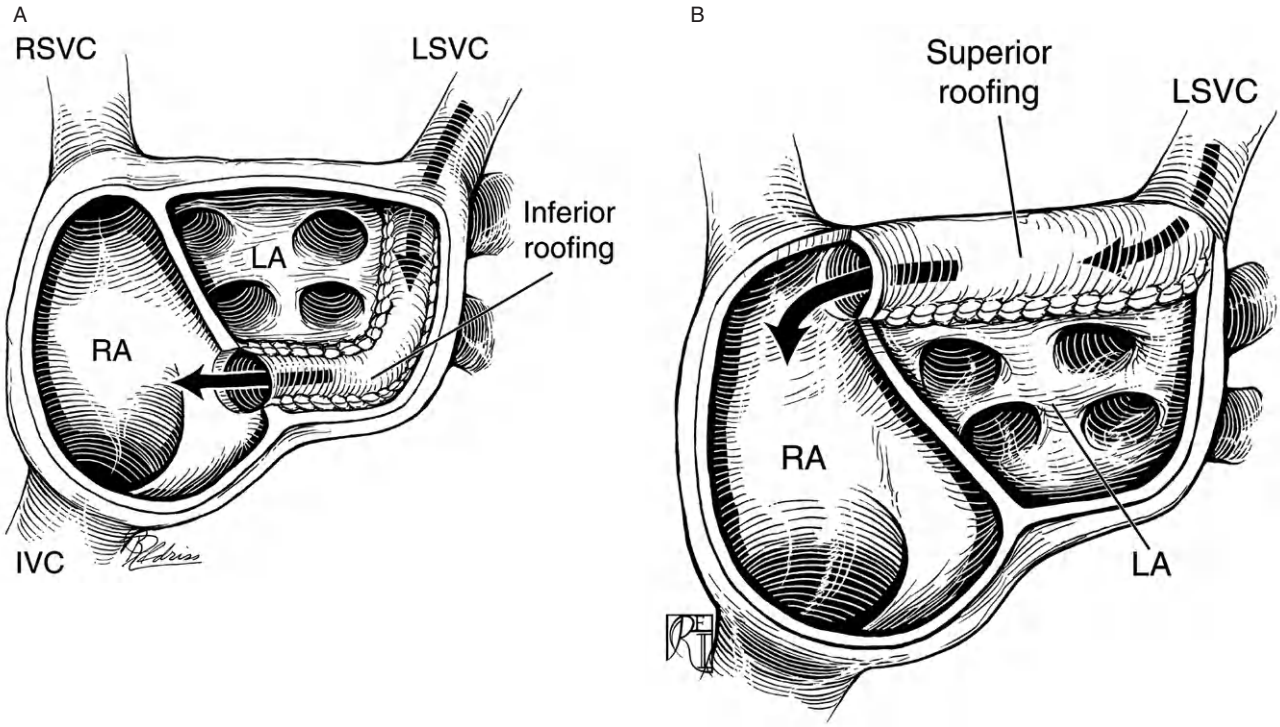

Figure 36.13 Orthotopic cardiac transplantation in a recipient with a left superior vena cava (LSVC) to the left atrium (LA) with completely unroofed coronary sinus. **A,** Pericardium or prosthetic material is used to form inferior roofing. **B,** Pericardium or prosthetic material is used to form superior roofing. (IVC, inferior vena cava; RA, right atrium; RSVC, right superior vena cava.)

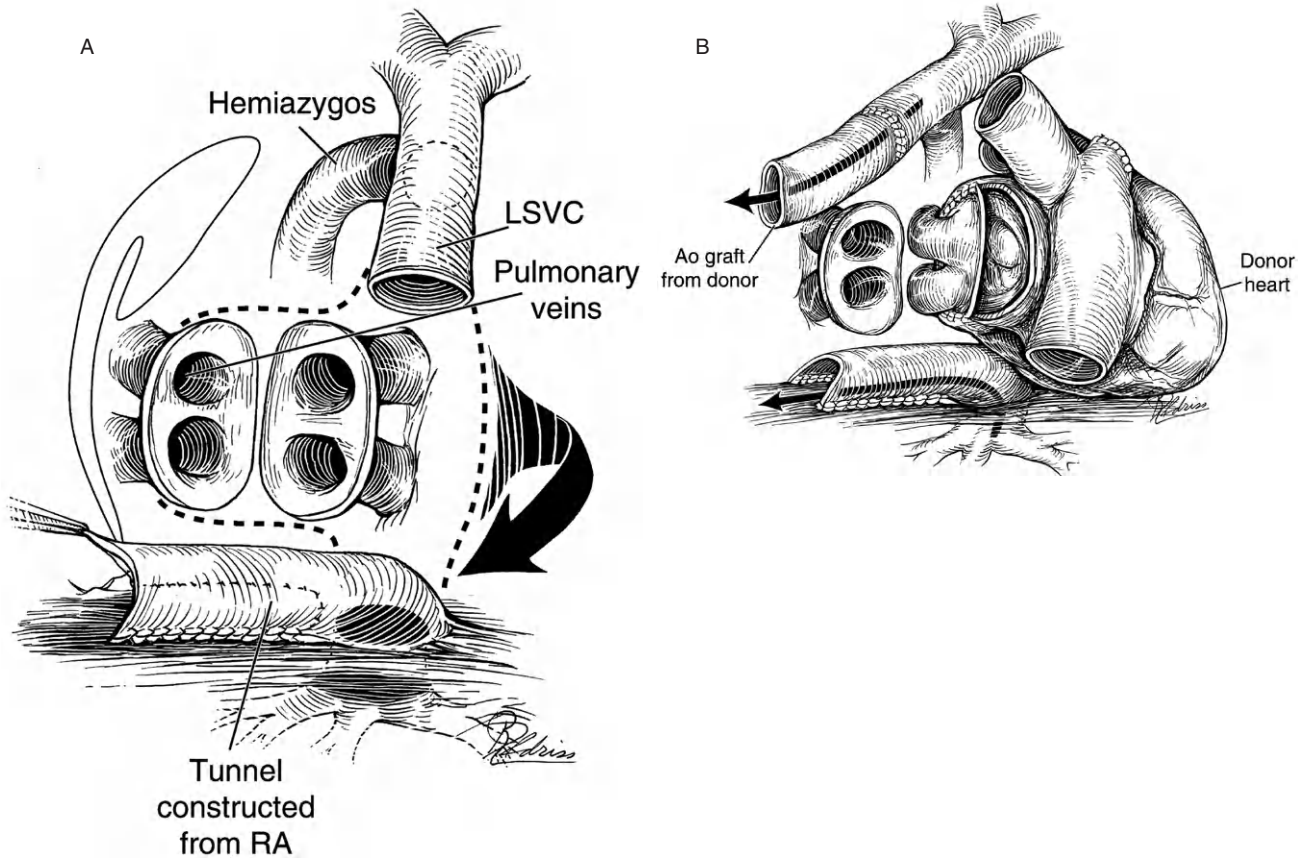

Figure 36.14 Orthotopic cardiac transplantation in a recipient with situs inversus with hemiazygos continuation of the inferior vena cava to the left superior vena cava. **A,** The left superior vena cava (LSVC) is divided. The right atrium and the left atrium are divided at the septum along the dotted line. The right and left pulmonary veins are separated and mobilized with generous cuffs of atrial tissue. The right atrium is devoted to the construction of a composite tunnel from the left-sided hepatic vein ostia, along the diaphragm and across the midline to the right side. **B,** The recipient right and left pulmonary venous cuffs are separately sutured to the donor left atrium. The ostium of the donor inferior vena cava is anastomosed to the orifice of the composite tunnel. The recipient LSVC with hemiazygos continuation is connected to the donor right atrium with donor descending thoracic aorta as an interposition graft. **C,** Completed repair. (Ao, aortic; RA, right atrium.)

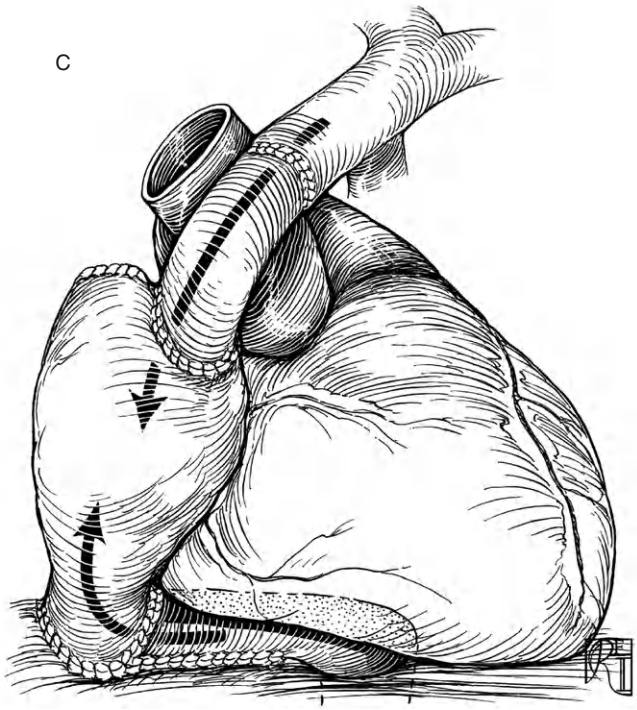

Figure 36.14 (*Continued*)

Cavopulmonary Connections in Patients with Complex Functionally Single Ventricle

Bidirectional cavopulmonary and total cavopulmonary connections are now commonly performed in patients with a variety of forms of complex functionally single ventricle. When the systemic venous return is normal, a staged approach to total cavopulmonary connection is undertaken in the usual manner. Many of these patients, however, have anomalies of systemic and pulmonary venous return. Among these patients visceral heterotaxy syndrome with atrial appendage isomerism is common. In the presence of bilateral SVCs, with or without azygos or hemiazygos continuation of the IVC, a bilateral bidirectional cavopulmonary connection is performed at 6 months of age. Intracardiac or extracardiac techniques of performing the completion total cavopulmonary connection are typically performed 1–2 years later. While the standard internal lateral tunnel technique may be used under certain circumstances, it is sometimes necessary to resort to an intracardiac tube graft to avoid pulmonary venous obstruction. In the presence of complex intracardiac anatomy and/or positional cardiac anomalies, an extracardiac tunnel or tube graft can also result in a satisfactory total cavopulmonary connection without interfering with pulmonary venous return [78–81].

CHAPTER 37

Sinus of Valsalva Aneurysm

W. Steves Ring
Children's Medical Center of Dallas, Dallas, TX, USA

Introduction

Definition

The sinus of Valsalva is defined as that portion of the aortic root bounded by the aortic cusp, the aortic valve annulus, and the sinotubular ridge. A congenital sinus of Valsalva aneurysm is a thin-walled enlargement or outpouching of the aortic wall, often appearing like a windsock that arises from the base of a single aortic sinus. Less frequently, it may appear as a simple fistulous communication between an aortic sinus and an adjacent structure. It usually originates from either the right sinus or the anterior aspect of the noncoronary sinus of Valsalva and penetrates the base of the heart into an adjacent low-pressure chamber. Rarely, it may present extracardiac or rupture freely into the pericardium. The aneurysm becomes clinically apparent when it ruptures into the adjacent low-pressure chamber creating an aortocardiac fistula, develops endocarditis, compresses or obstructs adjacent structures, or occasionally causes arrhythmias or thromboemboli. Other diseases such as endocarditis, syphilis, Marfan's syndrome, cystic medial necrosis, atherosclerosis, and trauma may involve the aortic root and cause aneurysms or fistulae of one or more sinuses of Valsalva. However, these acquired sinus of Valsalva aneurysms tend to be more evenly distributed among the three sinuses, more commonly involve multiple sinuses, are rarely associated with other congenital heart defects, and more commonly rupture outside the heart. Dilation of multiple sinuses as occurs in Marfan's syndrome or other connective tissue defects is generally considered to be an aortic root aneurysm and not an isolated sinus of Valsalva aneurysm.

History

The first description (1989) of a sinus of Valsalva aneurysm with intracardiac rupture is attributed to Hope [1]. One year later, Thurnam [2] described a series of six sinus of Valsalva aneurysms including Hope's case with five additional cases. Along with her many other anatomic descriptions of congenital heart defects, Maude Abbott [3] was one of the first to note the congenital etiology for many sinus of Valsalva aneurysms. Jones and Langley [4] also emphasized a distinction between acquired and congenital sinus of Valsalva aneurysms. In 1954, Brown [5] was the first to attempt surgical repair of a ruptured sinus of Valsalva aneurysm with endocarditis using deep hypothermia and inflow occlusion without cardiopulmonary bypass. Unfortunately, the patient expired 14 days after surgery from staphylococcal sepsis and aortic insufficiency. Lillehei [6,7] was the first to successfully use cardiopulmonary bypass to surgically correct a right sinus of Valsalva aneurysm that had ruptured into the right ventricular outflow tract. This was accomplished with primary suture closure in an 11-year-old girl on May 2, 1956 using cardiopulmonary bypass, aortic cross-clamping, and retrograde coronary sinus perfusion. Several other surgical teams accomplished and reported similar results over the next year [8–10].

Epidemiology

Congenital aneurysm of the sinus of Valsalva is a rare defect of the aortic root. The true incidence is unknown. It was reported as occurring in only 0.09% in a large autopsy series from 1914 [11], but this series did not distinguish between congenital and acquired aneurysms. The

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

incidence of ruptured sinus of Valsalva aneurysms in large cardiac surgical series is 0.14–0.37% of western surgical series [12–16], 0.46–3.57% of surgical series in Asia [17–27], and 0.51–1.5% in Chinese series [20–22,27]. However, because the application of cardiac surgery is quite different among these regions, the relative incidence in overall cardiac surgical series may be misleading. Surgical series only of procedures for congenital heart disease may be more representative. According to this criterion, the incidence of sinus of Valsalva aneurysms was 0.26% in one western series [16], 1.37–1.5% in a series from India [23,26], and 2.0–3.57% in a series in Japan [24,25].

On the basis of collected surgical series of 361 patients, Chu *et al*. [20] estimated that the incidence of sinus of Valsalva aneurysms among Asians is up to five times higher than in western populations. Other important differences noted by Chu *et al*. include a higher incidence of right sinus of Valsalva aneurysms (86% vs. 68%), more common penetration into the right ventricle (73% vs. 60%), a higher association with ventricular septal defects (52% vs. 38%), and an equal frequency of associated aortic insufficiency (34% vs. 33%). The reason for these differences is uncertain but parallels the higher incidence of supracristal or subarterial ventricular septal defects found in Asians [28].

Congenital sinus of Valsalva aneurysms occur more frequently in men with a male to female ratio of approximately 2:1 [15,27,29–31]. There does not appear to be any familial or hereditary association [20]. Although they can occur at any age, aneurysms most commonly (50–60%) present in the third or fourth decades of life [20,30]. The mean age in most surgical series of ruptured sinus of Valsalva aneurysms is 25–40 years. Fewer than 15% of cases occur before the age of 20 years [20], although ruptured aneurysms have occurred even in neonates [32,33].

Anatomy

Knowledge of the anatomic relations between the aortic sinuses and the adjacent cardiac structures is essential for understanding the pathological anatomy, pathophysiology, and surgical treatment of sinus of Valsalva aneurysms (Figure 37.1) [34]. Aneurysms originate most commonly from the right sinus in 65–70% of western series (Figure 37.2A) [15,16,20,29–31,35], and 80–90% of Asian series (Figure 37.2B) [17,18,20,24,25,27,31]. The noncoronary sinus is less commonly involved in 20–35% of western series and 10–20% of Asian series. The left sinus is involved in fewer than 5% of western series and fewer than 1% of Asian series. Aortic pressure causes gradual enlargement of the aneurysm into an adjacent low-pressure chamber; the result is rupture with formation of an aortocardiac fistula or, less commonly, compression, obstruction, endocarditis, or free rupture into the pericardium (Figure 37.3) [20,34]. Aneurysms of the right coronary sinus tend to rupture into the right ventricle (70–90%) or right atrium (5–20%) with rare rupture into the septum, left ventricle, pulmonary artery, or pericardium (<1–2%), and never into the left

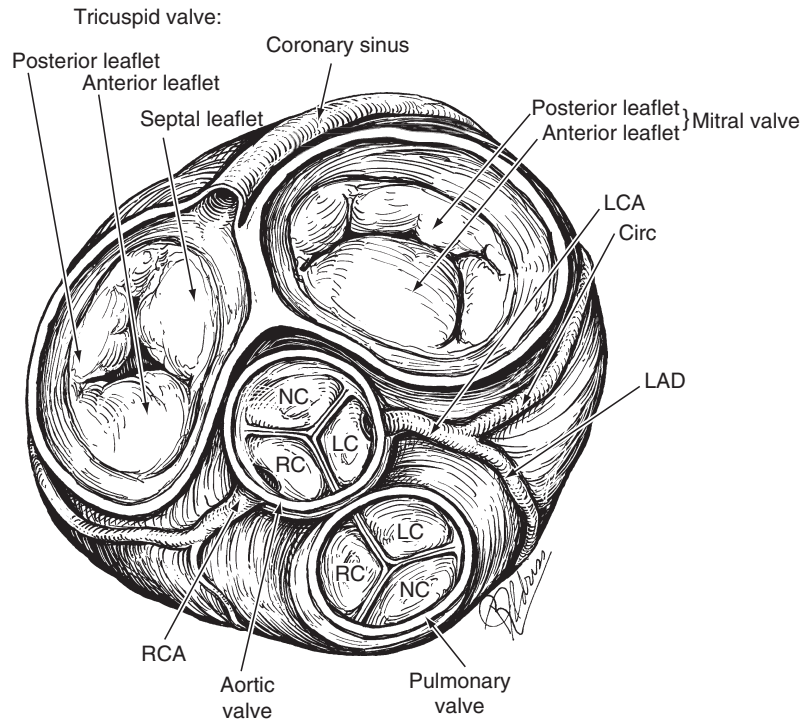

Figure 37.1 Coronal section through the base of the heart shows the aortic root, the sinuses of Valsalva, and their relations. (Circ, circumflex coronary artery; LAD, left anterior descending coronary artery; LC, left coronary cusp; LCA, left coronary artery; NC, noncoronary cusp; RC, right coronary cusp; RCA, right coronary artery.)

atrium. Noncoronary sinus of Valsalva aneurysms rupture most commonly into the right atrium (70–85%) or right ventricle (10–25%), rarely into the left atrium, left ventricle, or pericardium (<4%), and never into the pulmonary artery. Aneurysms of the left coronary sinus are rare and may rupture with variable frequencies into the right or left atrium, the right or left ventricle, the pericardium, or the pulmonary artery.

Embryology and Histology

Abbott [3] first postulated that the fundamental defect in congenital aneurysm of the sinus of Valsalva is a defective development of the bulbar septum. This concept was expanded by Jones and Langley [4] who emphasized the importance of fusion of the aortopulmonary septum with the bulboventricular septum to form the base for the right and the noncoronary sinuses, the location of most sinus of Valsalva aneurysms. They also noted the rarity of aneurysms arising from the left sinus of Valsalva, which is unrelated to the bulbar septum, and the frequent association of ventricular septal defects and bicuspid aortic valves, both related to imperfect septation of the bulbus cordis. The discontinuity or lack of fusion between the annulus fibrosus and the aortic media was later confirmed histologically by Edwards and Burchell [36,37]. However, Angelini [38] has questioned this theory due to the lack of association of sinus of Valsalva aneurysms with other conotruncal defects. He has also correctly questioned the inclusion of aortic leaflet prolapse and subarterial ventricular septal defects with sinus of Valsalva aneurysms.

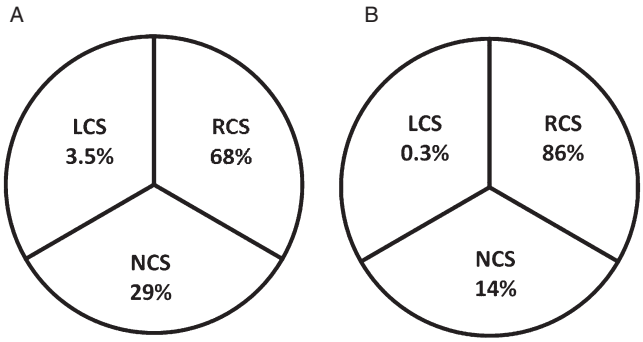

Figure 37.2 Racial differences in the location sinus of Valsalva aneurysm sites of origin. **A,** Western series (n = 395). **B,** Asian series (n = 654). (LCS, left coronary sinus; NCS, noncoronary sinus; RCS, right coronary sinus.) (Adapted from Wang [31].)

Classification

Sakakibara and Konno [39–42] proposed the first classification system for congenital sinus of Valsalva aneurysms. Their proposed classification includes only those aneurysms originating from the posterior, middle, or anterior third of the right sinus (types I, II, and IIIa or IIIv respectively) or the anterior third of the noncoronary sinus (type IV). The classification allows penetration of types I, II, and IIIv only into the right ventricle (v), and types IIIa and IV only into the right atrium (a). Subclassification is based on the presence or absence of a ventricular septal defect (e.g., type II VSD). Although it includes the most common types of congenital sinus of Valsalva aneurysms, this classification scheme does not account for all three possible sinuses of origin and does not account for the variety of intracardiac and extracardiac sites of penetration.

A new classification scheme based on anatomy (sinus of origin and chamber of penetration), and acuity (ruptured versus nonruptured), with a modifier added for etiology (atherosclerotic, congenital, connective tissue defects, inflammatory, infection, and trauma) has been proposed by the STS Congenital Heart Surgery Nomenclature Database

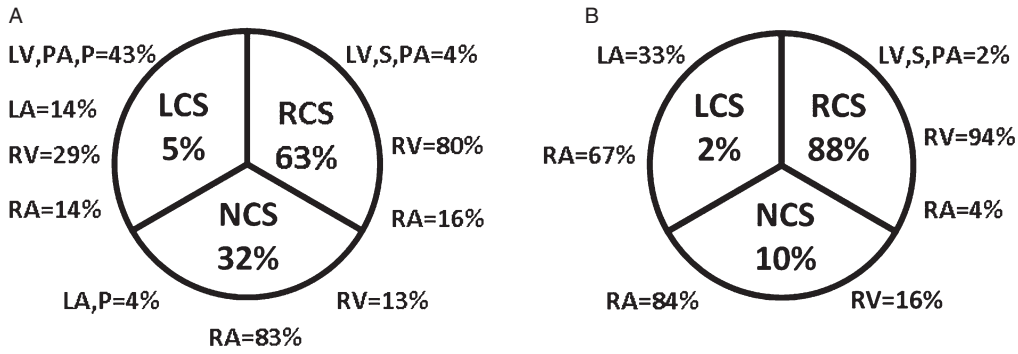

Figure 37.3 Racial differences in the location of sinus of Valsalva aneurysm chamber of penetration. **A,** Western Series (n = 151). **B,** Asian Series (n = 181). (LA, left atrium; LCS, left coronary sinuses; LV, left ventricle; P, pericardium; PA, pulmonary artery; RCS, right coronary sinuses; NCS, noncoronary sinuses; RA, right atrium; RV, right ventricle; S, ventricular septum.) (Adapted from Chu [20] and Ring [34].)

Project [43]. However, this classification scheme is new and has not yet been widely adopted.

Associated Defects

Approximately one-half of all patients with sinus of Valsalva aneurysms have associated defects. Ventricular septal defect is the most commonly associated defect, occurring in approximately 40–60% of Asian and 35–40% of western series [20,27,29–31]. These defects are found in 60–70% of cases with right sinus of Valsalva aneurysms but in only 10% of those with noncoronary sinus of Valsalva aneurysms. Aortic insufficiency occurs in 25–40% of patients, without significant differences between Asian and western series [20,31]. Other associated defects include bicuspid aortic valve (5–10%), pulmonary stenosis (5%), atrial septal defect (2–5%), patent ductus arteriosus (1–2%), and coarctation (1–2%). Rare isolated cases of associations with tetralogy of Fallot, subaortic stenosis, and other congenital defects are likely only chance occurrences, without true association.

Natural History

There is little information about the natural history of sinus of Valsalva aneurysms. However, Sakakibara and Konno [39] noted that the majority of patients with ruptured sinus of Valsalva aneurysm died within 1 year of diagnosis if not repaired surgically, with the exception of one patient followed for 17 years after the diagnosis. Adams and Sawyers [44] also reported an average survival of only 3.9 years after diagnosis, but the survival period decreased to less than 1 year when two patients who survived for 10 and 15 years were excluded. Based on these observations, most authors believe surgical repair is indicated for all patients with ruptured sinus of Valsalva aneurysm and for any patient with symptomatic nonruptured sinus of Valsalva aneurysm [45,46]. The natural history of unruptured sinus of Valsalva aneurysm is unknown because most are asymptomatic and remain undetected. Therefore, the role of surgery for asymptomatic nonruptured aneurysms remains controversial.

Diagnosis

Clinical Presentation

Unruptured sinus of Valsalva aneurysm usually is asymptomatic and often found incidentally at the time of cardiac evaluation for some other heart condition. However, when it enlarges, it may cause symptoms by distorting or compressing adjacent structures. This condition can manifest as aortic insufficiency from annular dilation or a prolapsing cusp [35,47], right ventricular outflow tract obstruction [48–55], coronary artery compression with myocardial ischemia or infarction [56–64], conduction disturbances with septal penetration [65–72], malignant arrhythmias [73,74], or a mediastinal mass [75]. Other initial manifestations include endocarditis [15,29,30] and thromboembolism [76–78].

Rupture of a sinus of Valsalva aneurysm occurs into one of the adjacent cardiac chambers, the interventricular septum, or the pericardium. Free rupture into the pericardium usually is fatal [79,80], although successful surgical repair has been reported [81,82]. Rupture or dissection into the interventricular septum results in conduction abnormalities and aortic insufficiency [83,84] or eventually free rupture into the right or left ventricle [84]. Intracardiac rupture usually occurs into one of the adjacent right cardiac chambers causing a left-to-right shunt with biventricular volume overload. Approximately 25–35% of patients with ruptured sinus of Valsalva aneurysms will develop the acute onset of dyspnea and substernal or epigastric chest pain. More commonly, about 45–50% of patients develop more gradual symptoms of congestive heart failure with dyspnea, fatigue, chest pain, and peripheral edema. Remarkably, 15–20% of patients with ruptured sinus of Valsalva aneurysms are asymptomatic [19,27,29,30].

Physical Examination

In examinations of patients who have a ruptured sinus of Valsalva aneurysm, the most notable physical finding (85–95% of cases) is a loud, continuous murmur along the left sternal border [27,30]. The differential diagnosis of this characteristic murmur includes patent ductus arteriosus, aortopulmonary window, coronary arteriovenous fistula, pulmonary arteriovenous malformation, and ventricular septal defect with associated aortic insufficiency. When the murmur is absent, pulmonary hypertension or rupture into the left ventricle should be suspected. Approximately 80% of patients have a thrill, bounding peripheral pulses, and widened pulse pressure, characteristic of aortic runoff lesions.

Diagnostic Testing

Chest radiographs usually show signs of cardiac enlargement and pulmonary overcirculation [26,27,30]. The electrocardiogram often is abnormal but nonspecific with evidence of ventricular hypertrophy, conduction disturbance, or in rare instances ischemia if a coronary artery is compromised by the aneurysm [18].

Diagnostic imaging is required in all cases with the objectives of defining: 1) the sinus of origin; 2) the chamber of penetration or perforation; 3) the presence and location of an associated ventricular septal defect; 4) the presence and degree of aortic insufficiency; and 5) the coronary

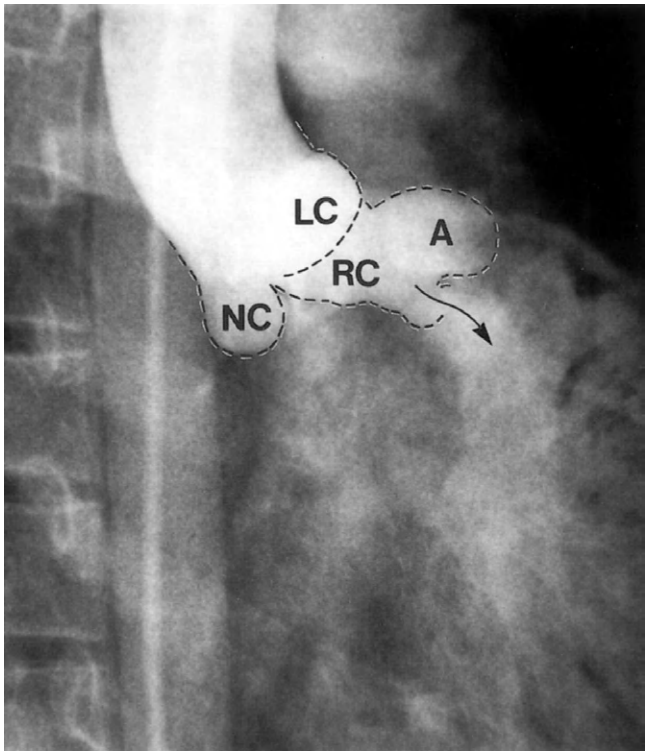

Figure 37.4 Cineangiogram in the right anterior oblique projection of a right sinus of Valsalva aneurysm ruptured into the right ventricle. (A, aneurysm; LC, left coronary sinus; NC, noncoronary sinus; RC, right coronary sinus.)

anatomy. Historically, angiography (Figure 37.4) [34] has been the "gold standard" for the evaluation of sinus of Valsalva aneurysm because it clarifies the anatomy of the root and the sinus of Valsalva aneurysm, the extent of aortic insufficiency, the coronary arteries, and most associated defects. However, angiography is not very accurate for the diagnosis of a ventricular septal defect, missing 16% of ventricular septal defects in one series [18], and nearly one-half in another [19].

Echocardiography was first used to diagnose a sinus of Valsalva aneurysm in 1974 [85,86]. Improvements in two-dimensional imaging and color flow mapping have made it the diagnostic procedure of choice [27,31,87–92]. The use of transesophageal echocardiography gives even better anatomic and functional characterization of the defect and allows better visualization when inadequate transthoracic windows compromise image quality [93–95]. However, adequate visualization of coronary anatomy may not always be achieved, and an associated ventricular septal defect may be missed because of occlusion of the ventricular septal defect by either the aneurysmal sac or the prolapsing aortic cusp [19,87]. Some authors [88,90,96] have advocated surgical correction based on echocardiography alone, and this may be possible in many cases. However, if the surgeon is uncomfortable about any aspect of the anatomy, particularly the coronary anatomy, angiography is advised. Because an associated ventricular septal defect also is frequently missed by angiography, this is not an indication for catheterization. It is best approached by careful inspection and repair when found at the time of surgery.

The role of magnetic resonance imaging is not clearly defined [97]. However, it may provide additional anatomic information in select cases [98–102], and has even been proposed as the sole diagnostic procedure before surgical correction [100,102].

Treatment

Surgical Technique

Sinus of Valsalva aneurysms are generally repaired surgically through a median sternotomy using cardiopulmonary bypass, bicaval cannulation, and left ventricular venting (Figure 37.5) [34]. Operative transesophageal echocardiography is useful for further delineation of the relation of the aneurysm or fistula to the adjacent structures, the status of the aortic valve, and ventricular function. The aortic root is palpated for a thrill, and the external structure is inspected, looking for external evidence of aortic sinus dilation or an aortoventricular tunnel that typically arises at or above the sinotubular ridge. Hypothermic cardiopulmonary bypass is begun, and the aorta is cross-clamped before ventricular fibrillation to avoid cardiac distension either from the fistula or from aortic insufficiency. A left ventricular vent is usually placed through the right superior pulmonary vein.

Because of the degree of aortic runoff through the fistula or regurgitant aortic valve, the technique of administering cardioplegia solution must be adjusted as for cases of aortic insufficiency or ruptured sinus of Valsalva aneurysm. We believe the aorta should be opened in all cases and therefore favor direct antegrade coronary cardioplegia followed by intermittent retrograde coronary sinus cardioplegia or retrograde cardioplegia alone. Aortic root cardioplegic arrest may be used if there is no fistula or aortic insufficiency; however, aortic root cardioplegia with digital compression of the fistula is discouraged owing to unreliable occlusion of the fistula and possible impairment of delivery to the coronary artery in the compressed sinus.

Three approaches to repair of the aneurysm or fistula have been used: 1) through the chamber of origin (aorta) (Figure 37.5A) [34]; 2) through the chamber of termination (atrium [Figure 37.5B], ventricle [Figure 37.5C], or pulmonary artery [Figure 37.5D] [34]); or 3) both [34]. Although the approach in each case should be individualized, the combined approach is currently most favored [11–13,16,18,

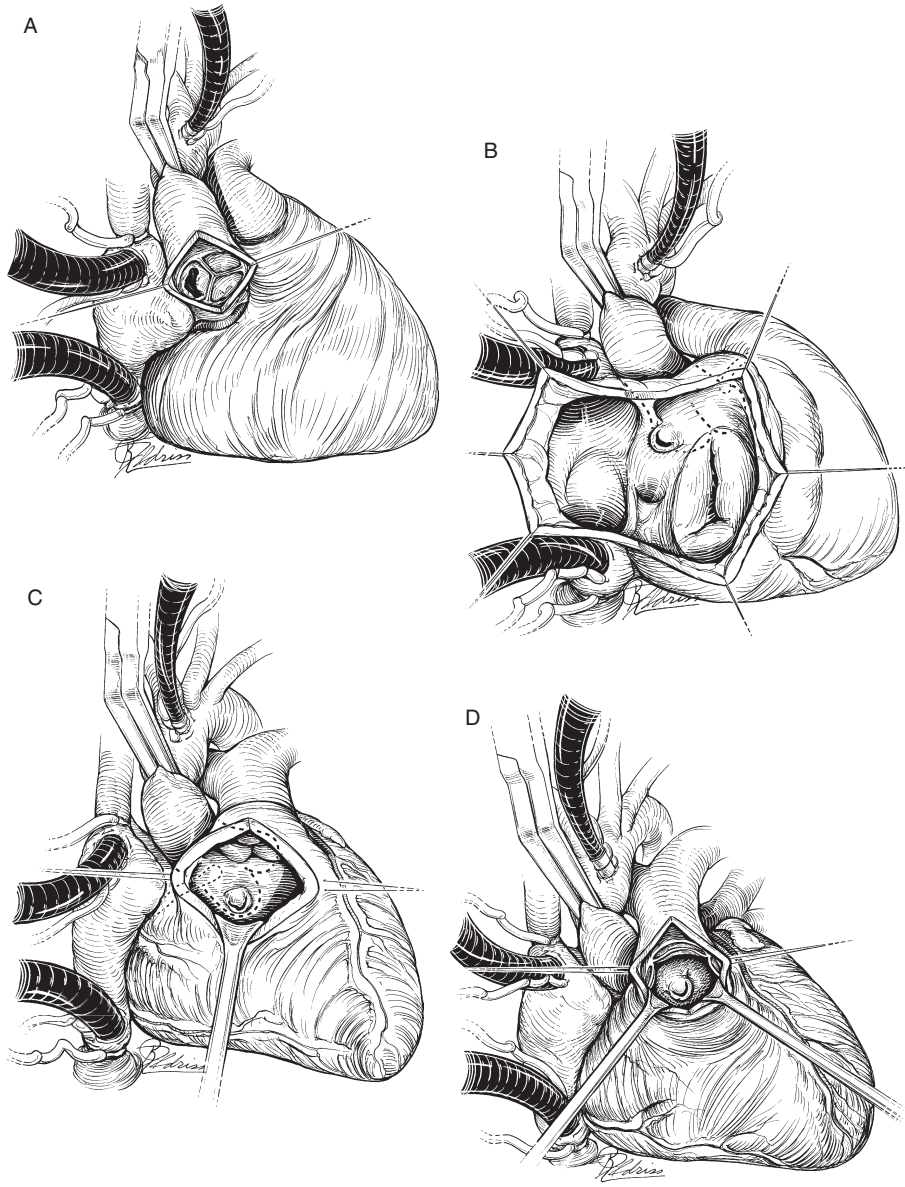

Figure 37.5 Surgical exposures for repair of sinus of Valsalva aneurysms. **A,** Initial exposure of sinus of Valsalva aneurysm through transverse aortotomy shows the relation of the aneurysm (shown here in noncoronary sinus) to the leaflets and the coronary arteries. **B,** Right atrial approach to aneurysm resection and patch repair. **C,** Presentation of aneurysm into the right ventricle exposed for repair through right ventriculotomy. **D,** Subpulmonic aneurysm with or without a ventricular septal defect exposed for repair through pulmonary arteriotomy.

23,31,35,41–43,63,103,104]. Approaching the defect only through the chamber has been advocated selectively when there is no coexisting ventricular septal defect or significant aortic insufficiency [27,105].

With either approach, the aorta is first opened for direct coronary cardioplegia delivery and to determine the anatomy of the root. This method also provides direct vision of the aneurysm orifice to prevent injury or distortion of the aortic leaflet, annulus, or coronary ostium, allows inspection for an associated ventricular septal defect, and allows repair or replacement of the aortic valve when indicated. Careful inspection for an associated ventricular septal defect is essential, because this lesion is frequently missed at angiography or echocardiography [19,20].

Nonruptured aneurysms involving the noncoronary sinus without penetration into an adjacent chamber, the rare case involving the left sinus, or those penetrating the ventricular septum [66,67] can be repaired through an aortic approach alone. However, ruptured aneurysms involving the right or noncoronary sinus or nonruptured aneurysms

with extensive penetration into an adjacent chamber are best repaired with a combined approach through the aorta and the chamber of penetration. The chamber of penetration is opened to facilitate resection of the aneurysmal sac and to reinforce the repair with a patch without injuring the conduction system. Aneurysms penetrating into the right atrium or membranous septum from the posterior third of the right sinus or from the noncoronary sinus can be approached through the right atrium. Those penetrating into the right ventricular outflow tract can usually be approached from the pulmonary artery, through the pulmonary valve. Right ventriculotomy usually is not necessary and avoided whenever possible. It is needed only for the occasional case in which the aneurysm arises from the middle third of the right sinus penetrating the region of the crista and cannot be adequately visualized through either the right atrium or the pulmonary artery.

Although a small aneurysm without associated ventricular septal defect can be closed primarily, this has been associated with a higher recurrence rate [6,8,11,16,35,39,41,63,106,107]. Therefore, after resection of the aneurysmal sac, primary closure of the sinus defect or closure with a pericardial patch should be reinforced with a separate synthetic patch through the chamber of penetration to buttress the weakened aortic sinus and reduce the risk of recurrence. Leaving the closed neck of the aneurysm as the floor of the reconstructed sinus, and buttressing it with a nonelastic patch of Dacron, polytetrafluoroethylene, or other material forms a double layer between the aortic lumen and the right-sided chamber and reduces the risk of residual fistulous connection or recurrence. An associated ventricular septal defect may be closed through the right side either with a single patch or with a separate patch. Closure of an associated ventricular septal defect through the right side reduces the risk of conduction system injury.

Moderate or severe aortic valve insufficiency should be corrected after the sinus of Valsalva and ventricular septal defect repair to avoid distortion of the aortic valve repair. Mild aortic insufficiency rarely necessitates correction but should be carefully followed long-term, owing to a small but significant risk of progression [16,35,108]. Closure of an associated ventricular septal defect, particularly of the subarterial type below the posterior third of the right sinus, may be sufficient to prevent aortic insufficiency. However, additional aortic valvuloplasty or annuloplasty by the techniques of Trusler [109], Carpentier [110], Cosgrove [111], or Schafers [112] may be necessary. Aortic valve replacement may be necessary when there is a severely deformed insufficient or stenotic bicuspid valve, endocarditis, or failure of a repair. Complete aortic root replacement with a valved conduit and coronary reimplantation is rarely indicated unless multiple sinuses are involved. Multiple sinus involvement is rarely seen with isolated congenital sinus of Valsalva aneurysm, but is usually associated with a connective tissue abnormality (e.g., Marfan's or Ehlers–Danlos), or extensive endocarditis.

Intraoperative transesophageal echocardiography is strongly recommended for evaluation of the sinus of Valsalva aneurysm, the aortic valve, and associated anomalies such as a ventricular septal defect. More importantly, it is essential to evaluate the effectiveness of repair, including residual fistulous communications, ventricular septal defect, aortic insufficiency, tricuspid or pulmonary valve function, ventricular function, and the adequacy of de-airing.

Percutaneous transcatheter closure of a ruptured right sinus of Valsalva aneurysm was first reported in 1994 using a Rashkind umbrella device [113]. Several recent series have also reported excellent early results using an Amplatzer duct occluder device [114] or an Amplatzer septal occluder device [115] for transcatheter closure of small ruptured sinus of Valsalva aneurysms. However, follow-up has been limited, and concerns remain regarding the increased risk of endocarditis and hemolysis associated with incomplete closure. Device closure is not appropriate for cases with significant aortic insufficiency or ventricular septal defect [116].

Results

The results of surgical repair for congenital sinus of Valsalva aneurysms, without complicating factors such as endocarditis, are excellent using modern techniques of cardiopulmonary bypass and myocardial preservation. Several contemporary surgical series have had no operative mortality even when repair of a ventricular septal defect or aortic valve replacement has been necessary [18,29,31,35,105,108]. Most other surgical series, even those extending back into the 1960s, report operative mortality of less than 5% [12,15–17,19–21,23,27,29,63,103,107,117]. The long-term results are also excellent with actuarial 10-year survival rates of 90–100% in recent western series [16,29,35], and 85–94% in Asian series [17,18,27,108]. The long-term functional results are quite acceptable with 90–100% of patients staying in New York Heart Association class I or II [19,21,27,29]. Although generally infrequent (<5%), the recurrence rate of fistula or ventricular septal defect seems to be higher when simple suture without patch repair is employed [6,8,11,16,17,35,39,41,63,106,107]. Late problems with prosthetic aortic valves or progressive native aortic insufficiency may necessitate reoperation in up to 30% of patients [16,18,27,31,35,105,108]. Progressive or recurrent native aortic insufficiency has been attributed to coexistent ventricular septal defect [16,118], coexistent bicuspid aortic valve [35], suture rather than patch repair [107,119], and the surgical approach [16,105].

The role of surgery for asymptomatic nonruptured sinus of Valsalva aneurysms remains controversial [45,46].

The wider use of echocardiography, computerized tomography, and magnetic resonance imaging for a wide variety of noncardiac conditions has resulted in more frequent detection of asymptomatic sinus of Valsalva aneurysm with unknown natural history. Rare case reports of prolonged survival [120] have prompted some authors to recommend medical follow-up evaluation of patients with asymptomatic nonruptured sinus of Valsalva aneurysms [46,121]. However, the results of repair in most experienced centers are excellent with operative mortality rates approaching zero. Meanwhile, reports of acute myocardial infarction [56,60], thromboembolism [76–78], complete heart block [65,70,83], malignant arrhythmias [74], and sudden death due to rupture [79,80] have been reported in association with previously unruptured sinus of Valsalva aneurysms. In addition, secondary bacterial endocarditis or progressive enlargement [57,122] can create a much riskier procedure at the time of repair. Therefore, we agree with most other authors that repair of a sinus of Valsalva aneurysm in adults should be undertaken at the time of diagnosis to prevent the numerous complications associated with lesions that are not repaired [29,31]. This recommendation is made with acknowledgment of the lack of good natural history studies, but these are unlikely to be performed. However, close follow-up care can be considered for children with small nonruptured aneurysms because of the risk of asymmetric distortion of the aortic valve caused by limiting growth of the affected sinus with patch material.

Introduction

Congenital and acquired anomalies of the coronary arteries can be generally characterized as deviations from the standard anatomy of two patent and separately arising right and left arterial blood vessels. The arteries are the first branches of the ascending aorta, arise from their respective sinuses of Valsalva, and gradually branch distally in a gradual and centrifugal fashion. Anomalies may be schematically summarized by a lack of origin, abnormal origin, anomalous course, lack of patency, abnormal connections, and/or abnormal drainage of the coronary vessels. Congenital and acquired coronary artery anomalies are associated with significant morbidity and mortality owing to patterns of ischemia, infarction, and fistulous connections, which can lead to cardiac failure.

The spectrum of congenital coronary artery malformations includes 1) anomalous left or right coronary artery (RCA) arising from the pulmonary artery (PA); 2) anomalous aortic origin of the left main or right coronary arteries with or without obstructing intramural stenotic courses and acute angulation; 3) single coronary artery with or without anomalous course between the aorta and PA; 4) congenital atresia/stenosis of the left main coronary artery (LMCA); 5) coronary artery fistulas; and 6) coronary artery bridging. The spectrum of acquired coronary lesions includes 1) coronary artery aneurysms and stenoses associated with Kawasaki disease; 2) iatrogenic injuries caused by transcutaneous invasive procedures or surgical mishaps; and 3) the rare instances of sharp or blunt trauma.

These anomalies are described in hearts with concordant atrioventricular and ventriculoarterial connections. The multiple coronary artery variations in complex heart diseases, such as transposition of the great arteries, truncus arteriosus, and pulmonary atresia with intact ventricular septum, among others, will be discussed in the chapters dedicated to that subject.

The incidence of coronary anomalies in the general population is 0.2–1.2%. Various anomalies have been described since the 17th century, both clinically and on the basis of postmortem pathologic studies. The first landmark article, to which most authors refer, is attributed to Ogden [1], who in 1969 attempted a comprehensive classification from which the many modifications of nomenclature are derived (Table 38.1) [1]. This classification includes major, minor, and secondary anomalies, determined purely on the basis of anatomic considerations (e.g., minor is a coronary arising directly from aorta with a normal distal distribution; major is an abnormal coronary origin from the PA or abnormal communications of the coronary arteries with intracardiac structures). In light of the clinical and surgical significance of these lesions, it is debatable whether minor and major are appropriate terms in the current era. In this chapter, regarding all further classifications for coronary artery anomalies, the inclusive nomenclature system of the Society of Thoracic Surgeons (STS) Congenital Heart Surgery Nomenclature and Database Project, including all possible variations, will be referred to and used [2].

Diagnostic modalities for congenital cardiac abnormalities have evolved rapidly over the last years, and a thorough review is beyond the scope of this chapter. Although a physical examination, electrocardiogram (ECG) and chest radiograph remain integral components of the diagnostic work-up, these are undeniably complemented and almost supplanted by color flow mapping and tomographic cross-sectional imaging echocardiography. More recently,

Minor coronary variations
High take-off
Multiple ostia
Anomalous circumflex artery origin
Anomalous anterior descending artery origin
Absent proximal ostium/single ostium in other aortic sinus
Hypoplastic proximal coronary artery
Congenital proximal coronary artery
Congenital distal stenosis
Coronary artery from the posterior aortic sinus
Ventricular origin of an accessory coronary artery
Major coronary anomalies
Coronary "arteriovenous" fistula
Anomalous origin from the pulmonary artery
Left coronary artery
Right coronary artery
Both coronary arteries
Secondary coronary anomalies
Secondary coronary "arteriovenous" fistula
Variations in transposition of the great vessels
Variations in truncus arteriosus
Variations in tetralogy of Fallot
Ectasia of coronary arteries in supravalvar aortic stenosis
Mural coronary artery

noninvasive magnetic resonance imaging (MRI) and computed tomography (CT) angiogram with ECG have gained increasing popularity and are the methods of choice as opposed to cardiac catheterization and coronary angiography in many leading centers [3,4], because the rate of erroneous diagnosis with conventional coronary angiography is reported to be as high as 50% in patients with coronary anomalies. Transverse sections of MRI or CT not only give the precise origin and proximal course in relation to the great vessels, but also assess the effect of coronary artery flow, with evaluation of the myocardial function, regional perfusion defects from associated ischemia, and coronary flow reserve. Indications for MR angiography include 1) uncertainty at conventional catheterization if this was performed as the primary investigation; 2) total proximal occlusion or suspicion of congenital absence of an epicardial coronary artery; 3) primary investigation for angina, arrhythmia, or syncope on exertion in young or adolescent patients; 4) evaluation before cardiac surgery to avoid intraoperative trauma, if there is an uncertain course of a known anomalous coronary; and 5) screening in highly competitive athletes to avoid increased risk of sudden death. The limitations of MR angiography are dependence on a regular heart rhythm (arrhythmias can distort the image) and the necessity for a calm and cooperative patient with apnea during approximately 16 cardiac cycles. In babies and small children, this practically often means the need for intubation and mechanical ventilation. The usual contraindications to MRI are valid (e.g., pacemaker, intracranial clip, intraocular metal debris, claustrophobia). Compared with MRI, CT angiogram has the advantage of faster acquisition of high spatial resolution images and patient comfort. However, drawbacks of CT scanning include the exposure to radiation and iodinated contrast medium, which require strict adherence to CT voltage, amperage principles, and patient weight-adjustment to minimize radiation risk [3]. Coronary angiography is still considered by many as a first-line diagnostic tool, and certainly is useful when potential interventional measures may be anticipated (transcatheter embolization or coil occlusion). Angiography is particularly useful when diagnosing anomalies of connections to other vessels (bronchial or mediastinal), and in delineating coronary fistula [3].

Anomalous Left Coronary Artery from Pulmonary Artery

Anomalous left coronary artery originating from the pulmonary artery (ALCAPA) is a rare congenital anomaly first described by Brooks [5] in 1885. It is present in 1 of 300 000 live births (0.25–0.5%). It is the most common of the abnormal origins of coronary arteries and is the most common cause of myocardial ischemia and infarction in children [6]. This anomaly may cause myocardial ischemia or infarction, mitral insufficiency, congestive heart failure, and death in early infancy if not treated. In 1933, Bland, White, and Garland [7] described the full clinical spectrum including angina and myocardial ischemia resulting from abnormal coronary flow, and the syndrome bearing their name is synonymous to ALCAPA.

Pathophysiology

Edwards [8] is credited with the first pathophysiological explanation of coronary flow patterns in patients with ALCAPA. The onset of symptoms and the degree of myocardial ischemia depend on a balance between the rapidity of ductus closure, maintenance of pulmonary hypertension, and development of intercoronary collateral vessels to provide retrograde perfusion from the RCA to the ALCAPA [8]. This pathophysiologic concept historically led to a division of ALCAPA patients into two groups, infantile and adult, according to their coronary circulation patterns [8]. The infantile type of circulation has little or no intercoronary collateral development. The result is early onset of symptoms—days to weeks after birth. Severe myocardial ischemia, left ventricular dysfunction and dilatation, mitral regurgitation from papillary muscle ischemia,

and rapid death can occur. Adult-type circulation accounts for 10–15% of cases with Bland-White-Garland syndrome and depends on intercoronary collateral vessels from the RCA that provide adequate flow into the anomalous left coronary artery. These patients may have no symptoms for decades and may have only mild to moderate myocardial damage. Survival to adulthood is conditionally possible in the presence of a large dominant RCA and a restrictive opening between the anomalous left coronary artery and the PA. This subset of patients has an estimated 80–90% incidence of sudden death at a mean age of 35 years [9]. This incidence indicates the severity of the process even in patients who do not have symptoms and thereby justifies surgical therapy as soon as the diagnosis is made. In addition to the infantile and adult categorization, a descriptive classification proposed in 1989 by Smith and associates [10] delineates various patterns of origin and their possible surgical implications. Regarding a classification, ALCAPA is an anomalous pulmonary origin of a coronary artery (APOCA) (Table 38.2) [2]; as it is the most common of all abnormal origins of coronary arteries, it is treated separately in this chapter. Incorporating Smith's classification, an inclusive nomenclature system including all possible variations of ALCAPA origin is described in the STS Congenital Heart Surgery Nomenclature and Database Project (Figure 38.1) [2].

Table 38.2 Proposed and accepted classification of anomalous pulmonary origins of coronary arteries. (Reproduced with permission from Dodge-Khatami *et al.* [2].)

Type 1 Anomalous origin of the left main coronary artery from the pulmonary artery
From right-hand sinus (sinus 1)
From nonfacing pulmonary sinus
From left-hand sinus (sinus 2)
From commissure between sinus 1 and nonfacing sinus
From commissure between sinus 2 and nonfacing sinus
From commissure between sinus 1 and sinus 2
High takeoff from left or right pulmonary arteries
Type 2 Anomalous origin of the right coronary artery
Type 3 Anomalous origin of circumflex coronary artery from pulmonary artery
Type 4 Anomalous right and left coronary arteries from the pulmonary artery (both)

Convention: Sinus of pulmonary valve designated right hand (no. 1), and left hand (no. 2) as viewed from nonfacing sinus of the pulmonary trunk toward the aorta. Thus sinus 1 of the aorta faces sinus 2 of pulmonary trunk and vice versa. Both nonfacing sinuses are at the two extremities.

Clinical Features

The clinical features of ALCAPA are sweating, dyspnea, failure to thrive, and atypical angina. Most patients have moderate to severe congestive heart failure with cardiomegaly on chest radiograph, ischemic signs on ECG, and a murmur of mitral insufficiency on auscultation. Left-axis deviation on the ECG is synonymous with a significant RCA-dominant circulation [11]. The diagnosis can be made with two-dimensional echocardiography alone (Figures 38.2, 38.3) [12]. Images show the enlarged, dilated RCA and a grossly hypokinetic and dilated left ventricle. Pulsed and color-flow Doppler ultrasonography can demonstrate reversal of flow from the anomalous left coronary artery into the PA that constitutes a left-to-right shunt. When necessary, MRI, CT angiography, or cardiac catheterization are used to exclude another coronary anomaly responsible for myocardial ischemia [13,14], to define coexisting intracardiac defects or to definitely exclude ALCAPA before settling for the diagnosis of idiopathic dilated cardiomyopathy [6]. They show the coronary anatomy in full detail, including the typically enlarged RCA, delayed passage of contrast medium, and the characteristic blush from the anomalous left coronary artery into the PA, as well as associated mitral valve regurgitation (Figure 38.4) [12]. Myocardial viability studies such as dobutamine echocardiography, thallium CT myocardial perfusion imaging, or positron emission tomography (PET) scans may be used to assess hibernating myocardium. However, they are only relevant to influencing surgical strategy in patients with massive infarction or aneurysmal tissue, whereby coronary revascularization techniques would not be expected to improve myocardial function [6]. Documented absence of

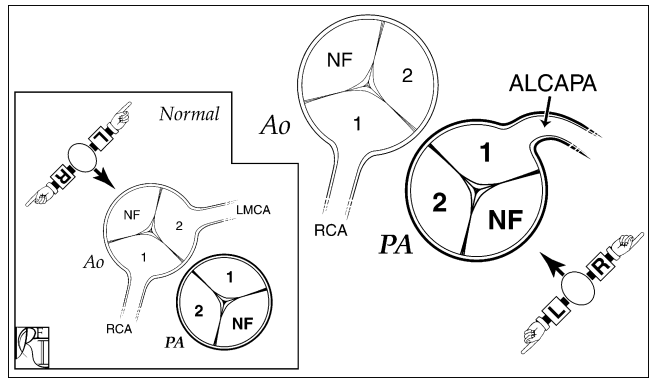

Figure 38.1 Diagram shows aortic and pulmonary artery origins of the left main coronary artery in normal and anomalous conditions. Cephalic views depict a person in the nonfacing sinus with the right hand always signifying sinus 1 and the left hand always signifying sinus 2. (Reproduced with permission from Dodge-Khatami *et al.* [2].)

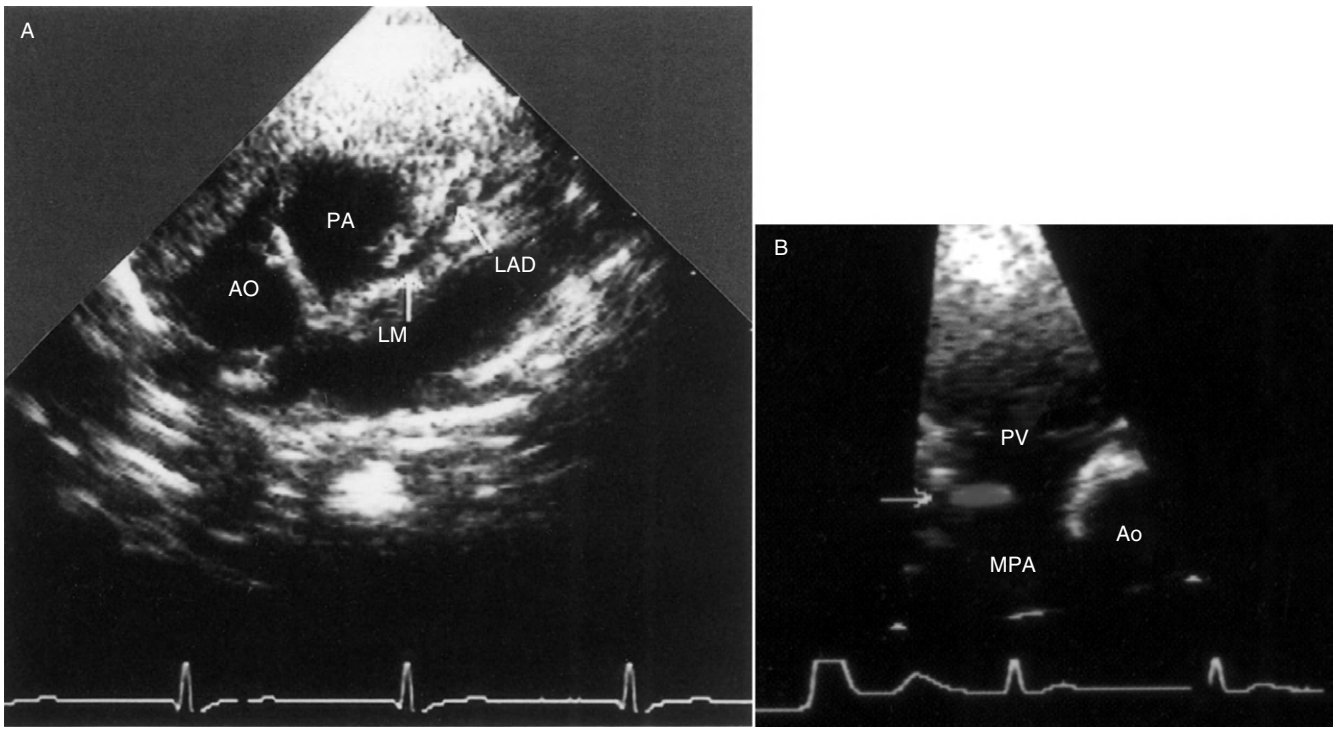

Figure 38.2 Anomalous origin of left coronary artery. **A,** Two-dimensional echocardiographic parasternal short-axis view shows origin of left main coronary artery (LM) with the left anterior descending (LAD) coronary artery from the pulmonary trunk. **B,** Color-flow Doppler echocardiogram shows turbulent flow from the left coronary artery entering the pulmonary artery trunk. (Ao, aorta; MPA, main pulmonary artery; PA, pulmonary artery; PV, pulmonary valve.)

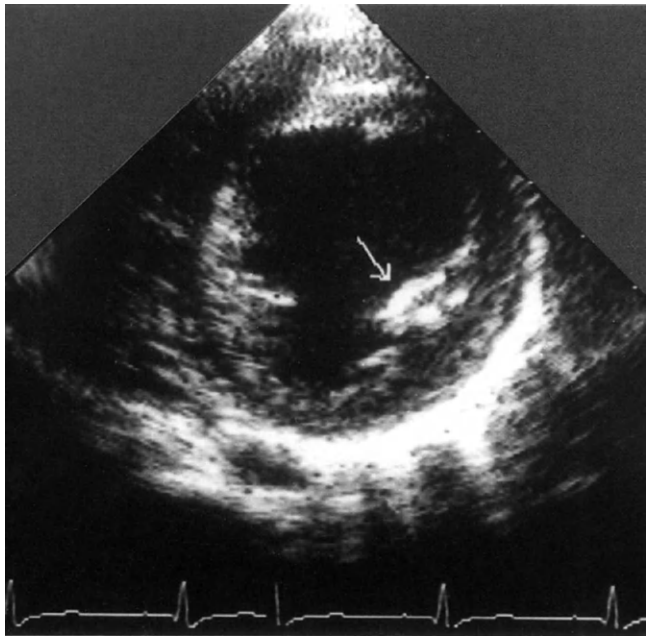

Figure 38.3 Anomalous origin of left coronary artery. Parasternal short-axis echocardiogram of the left ventricle shows bright echodensity of the papillary muscles of the mitral valve (arrow) that denotes papillary muscle ischemia.

viable tissue would be the only indication to consider heart transplantation over myocardial reperfusion [15].

Surgical Management

Attempts at medical therapy are associated with dismal survival and have no place in the current era of management for ALCAPA. Potts was the first to attempt surgical repair, creating an aortopulmonary anastomosis to increase PA blood flow and oxygen saturation in the anomalous coronary artery [16]. In 1953, Mustard [17] performed left common carotid-to-ALCAPA end-to-end anastomosis. The first successful nonpalliative operation was performed in 1959 by Sabiston [18], who ligated the ALCAPA at its origin. Cooley and associates [19] performed the first saphenous vein graft to the ALCAPA in 1960. Meyer *et al*. [20] used the left subclavian artery to bypass the origin of the ALCAPA. Already in 1974, Neches *et al*. [21] were the first to describe the direct reimplantation of the anomalous left coronary into the aorta, transferring it with a button of PA. This is the current ideal option toward achieving a definitive two-coronary artery anatomy and physiology (Figures 38.5, 38.6) [13]. In 1979, Takeuchi *et al*. [22] devised an operation for cases in which direct implantation is not

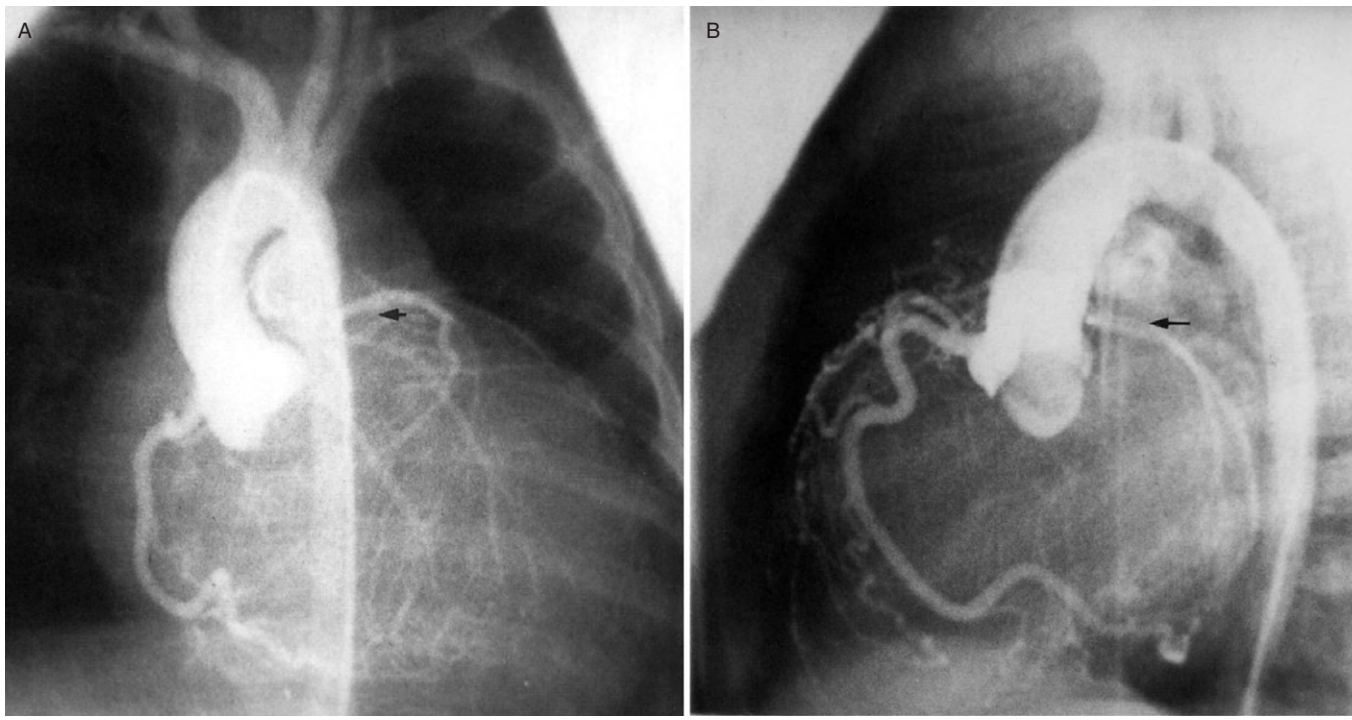

Figure 38.4 Anomalous origin of the left coronary artery. Retrograde aortogram (right [**A**] and left anterior oblique [**B**] views) shows prompt opacification of the enlarged right coronary artery and filling of the left coronary artery by collateral vessels. Arrow indicates origin of the left coronary artery from the pulmonary trunk with retrograde filling of the pulmonary artery.

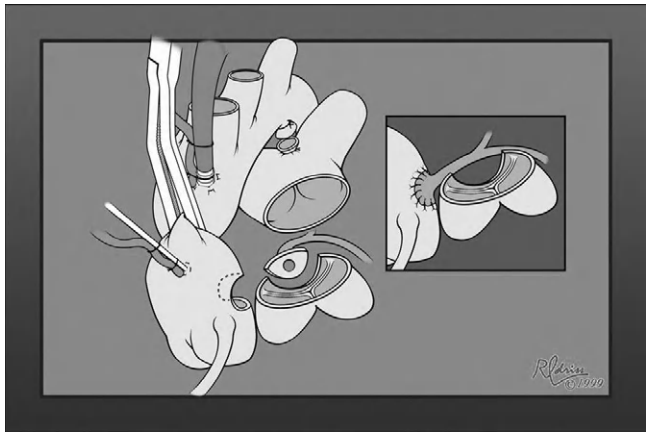

Figure 38.5 After the second dose of cardioplegia, an opening is created in the left posterolateral wall of the ascending aorta for implantation of the anomalous left coronary button. Care is taken not to injure the aortic valve. This opening is typically approximately one-third smaller in size than the button that was created. The large button of coronary artery can then act as a "conduit" for elongation of the left coronary artery. With proper mobilization of the left coronary artery, it is usually quite easy to perform this anastomosis. Once the anastomosis is created (inset), the aortic cross-clamp is removed, and now both right and left coronary arteries are directly perfused. (Reproduced with permission from Backer *et al.* [13].)

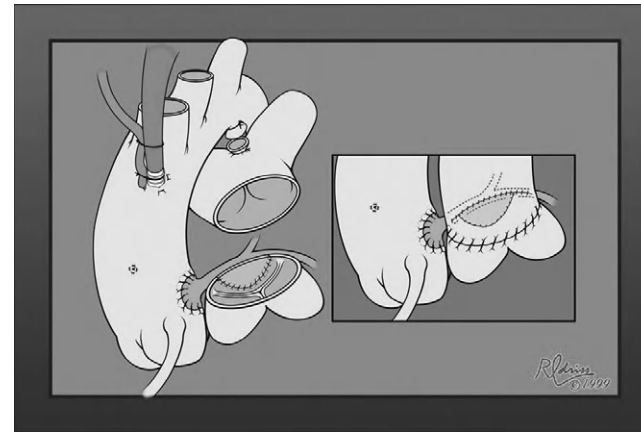

Figure 38.6 The aortic cross-clamp is off. The posterior sinus of the pulmonary artery where the button was harvested is reconstructed with a patch of fresh autologous pericardium. The pulmonary artery is reanastomosed at the site of the transection (inset). This reconstruction of the pulmonary artery with the cross-clamp off helps to minimize the aortic cross-clamp time. In almost all instances, it is possible to perform the entire procedure with two doses of cardioplegia given in the sequence described. (Reproduced with permission from Backer *et al.* [13].)

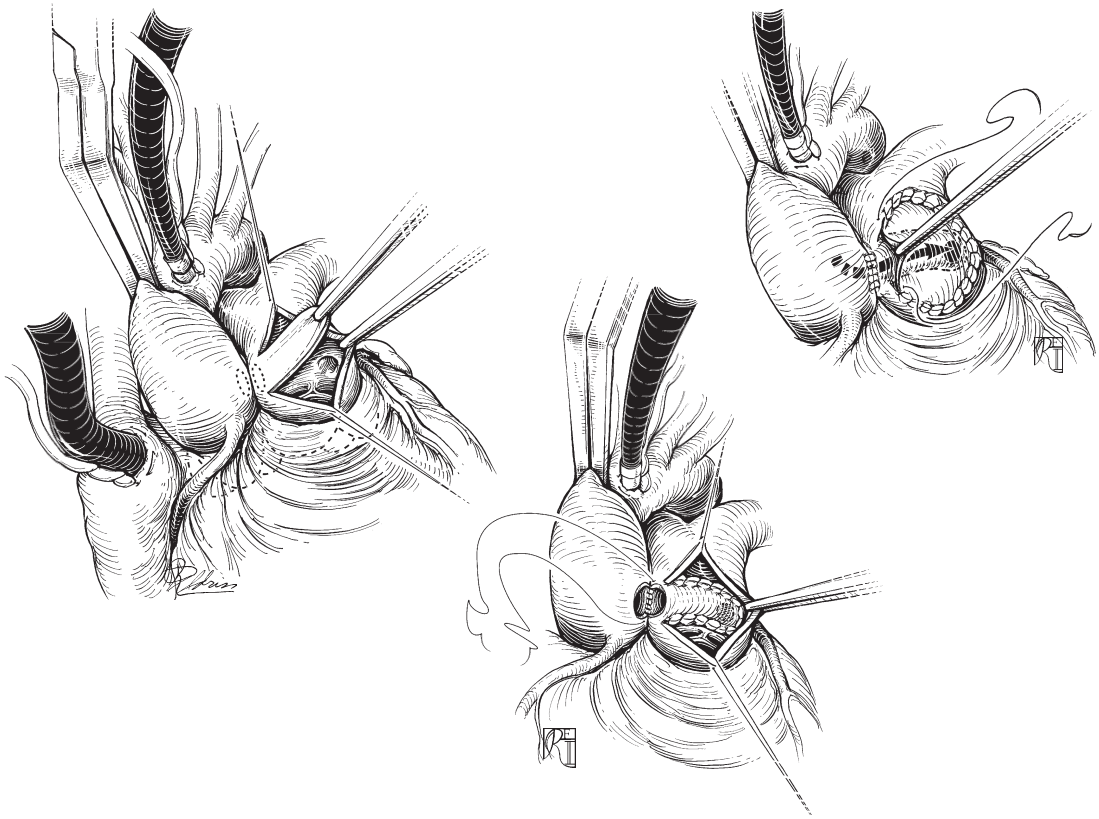

Figure 38.7 Takeuchi procedure through median sternotomy with extracorporeal circulation and cross-clamped aorta. The tunnel for coronary flow (arrow) has been made between the aorta and the anomalous left coronary artery by means of a flap of pulmonary artery wall. The pulmonary artery is then reconstructed with pericardium.

feasible, owing to unfavorable coronary artery anatomy or lack of length (Figures 38.7, 38.8) [6,12]. In the procedure bearing his name, a baffle of PA tissue is used to reroute the ALCAPA into the aorta after an intrapulmonary course. Arciniegas *et al.* [23] described interposing a segment of free subclavian artery to compensate for lack of length and reported an 80% patency rate at a maximum follow-up time of 11 months. Even in the presence of a nonfacing sinus origin of the ALCAPA or other anatomical variations, extending a cuff of pulmonary trunk tissue to elongate the coronary artery [24] or other creative surgical techniques gained through the experience from coronary transfer for arterial switch operations allows for reimplantation into the aorta [11,13–15].

Left internal thoracic arterial bypass grafting in children was described by Fortune and associates [25] in 1987. In 1988, Mavroudis *et al*. [26] proposed and performed cardiac transplantation as a last-resort solution for patients with end-stage left ventricular failure from myocardial infarction. This strategy is used only for patients with global myocardial necrosis as documented by viability studies, whereby no improvement can be expected after coronary revascularization. In adults, direct reimplantation of the ALCAPA may be technically more difficult because of increased coronary artery friability, diminished elasticity for mobilization, the potential for tearing and catastrophic bleeding, or stenosis resulting from anastomotic tension [6,27,28]. In these patients, coronary artery bypass grafting may be more judicious, using the internal thoracic artery [29,30].

Administration of cardioplegia is a crucial point with regard to myocardial protection, common to all surgical techniques. In a review of 16 children undergoing aortic reimplantation for ALCAPA, Backer and associates [13] described a cardioplegia strategy that allows maximal myocardial protection, regardless of the degree of RCA collateralization. After ligation of the ductus and snaring of the PAs, an initial dose of antegrade blood cardioplegia into the ascending aorta is given. The PA is carefully transected and mobilized for maximum visibility, and the ALCAPA button is excised. A second dose of antegrade cardioplegia is given while the orifice of the ALCAPA is occluded with a vascular clamp, after which the coronary transfer is performed into the aorta. They report no

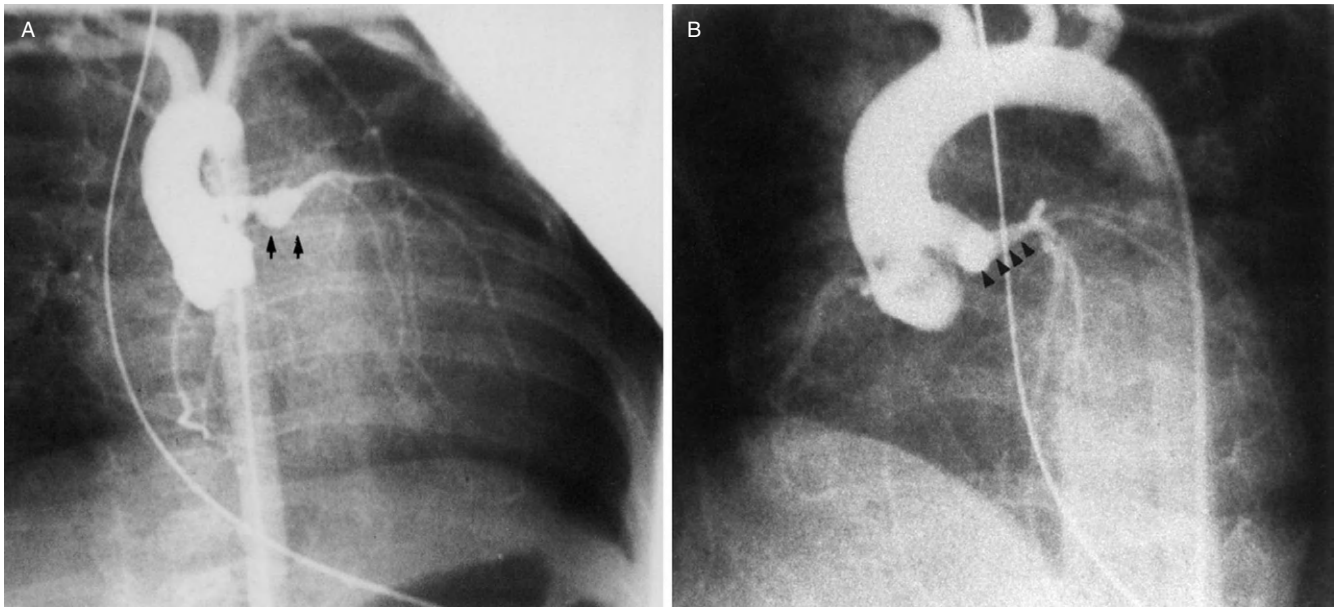

Figure 38.8 Anomalous left coronary artery. **A, B,** Postoperative aortogram (left and right anterior oblique views) after Takeuchi procedure for anomalous origin of the left coronary artery. Prompt opacification of the left coronary artery through the intrapulmonary artery tunnel is evident (arrows).

operative mortality, and no postoperative need for a left ventricular assist device or extracorporeal membrane oxygenation (ECMO) [13].

Surgical correction of ALCAPA addresses the two other structural abnormalities of the left heart that result from ischemic insult, namely global left ventricular function with or without free wall aneurysm, and the mitral valve. It is currently believed that ischemic yet viable myocardium, as assessed with stress thallium-201 or dipyridamole stress echocardiography, will recover postoperatively after reperfusion by any procedure that results in a two-coronary artery system [6,9,14,15,24,31–39]. However, scarred myocardium or its extreme aneurysmal form will not recover, and most surgeons concur in not directly addressing left ventricular aneurysms at the initial operation. Accordingly, resection of left ventricular muscle is hardly ever justified [6,15,40]. Some controversy still surrounds the issue of the mitral valve. Mitral regurgitation is related to both ischemic left ventricular dilatation and ischemic dysfunction of the papillary muscles [6,39]. Even severe mitral insufficiency fully regresses after reperfusion [6,13,15,23,24,32–34,41,42]. Although some authors advocate mitral valve annuloplasty or mitral valve replacement in cases of severe mitral regurgitation [9,31,43], most agree [6,13,15,23,24,32–34,41,42] that mitral regurgitation need not be addressed during initial surgery for reimplantation of ALCAPA. After improvement of left ventricular function, persistent significant mitral insufficiency can be repaired at a later operation. After initial ALCAPA reimplantation, Huddleston *et al*. [41] stress the importance of following mitral valve function as an indirect sign of coronary patency. Indeed, persisting, recurring or worsening mitral valve insufficiency and left ventricular function may be a sign of coronary stenosis, warranting cardiac catheterization to document coronary patency, before reoperation for a mitral valve procedure [6,41].

Results

The combined operative mortality of all commonly used surgical techniques ranges from 0% to 23% [6,11,13–15,23,24,27–32,34,41–43]. Late death is unusual. It is now accepted that reperfusion through a two-coronary artery system with documented long-term patency should eliminate the risk of sudden death. Potential surgical complications include acute intraoperative coronary insufficiency resulting from technical error, as well as bleeding. Complications specific to the Takeuchi procedure include supravalvar pulmonary stenosis (76%), baffle leaks leading to coronary-PA fistula (52%), and aortic insufficiency [32]. Reoperations or catheter interventions are frequently necessary to correct these complications. The incidence of reoperation or reintervention is reported to be as high as 30% [9,32,43].

After successful reimplantation of ALCAPA, poor preoperative left ventricular function; stunned myocardium; or intractable ventricular arrhythmias may prohibit weaning from cardiopulmonary bypass [6]. Encouraging

results have been achieved with the use of mechanical support as a bridge to recovery. Possibilities include left ventricular assist devices [44–46] and ECMO, especially when ventricular arrhythmias preclude the use of an assist device [27,41,44]. Although optimization of intraoperative cardioplegia strategies—using both antegrade and retrograde cardioplegia—combined with appropriate postoperative inotropic support should obviate the need for mechanical circulatory support [13], assist devices and ECMO play an integral part in the modern surgical treatment of patients with ALCAPA [6].

Various operative risk factors that affect survival have been identified in the management of ALCAPA. These include decreased preoperative left ventricular function [11,15,31] and young age at operation [11,32,45]. Although younger patients present with more severe left ventricular failure, early surgery results in more rapid and complete recovery of myocardial function, as assessed by echocardiography [45]. Severe mitral regurgitation has been cited as a risk factor for poor outcome after surgery [32], although not all institutions agree [11,15,31]. Sauer and associates found extreme RCA dominance (perfusion of the posterolateral left ventricle wall beyond the crux cordis) to correlate positively with operative survival ($p < 0.01$) [11]. As a corollary, left dominant or a balanced coronary circulation adversely influences operative survival ($p < 0.01$). Finally, stent thrombosis (ST) elevations on ECG in more than two chest leads or more than one standard lead indicate acute myocardial infarction and correlate with poor operative survival ($p < 0.03$) [11].

Discussion

From a nomenclature standpoint, ALCAPA is an APOCA (the most common). Keeping the sinus configuration described by Smith and colleagues [10], all variations of ALCAPA are classified according to the inclusive nomenclature system presented by the STS Congenital Heart Surgery Nomenclature and Database Project (Figure 38.1) [2].

Patients with ALCAPA may present with two types of coronary physiology that influence the onset and severity of the clinical signs and symptoms. Infantile coronary circulation is seen in most patients and is characterized by a mildly dominant RCA, fewer intercoronary collateral arteries, and no ostial stenosis of the anomalous left coronary artery. A higher "steal" phenomenon results in a more ischemic and dilated left ventricle, with earlier and more severe left ventricular failure. Early surgery is mandatory for survival of these patients. More rarely, the adult-type circulation relies on a large dominant RCA, extensive collateralization, and increased intracoronary pressure from ostial stenosis of the ALCAPA or mild pulmonary hypertension, which results in mild to moderate left ventricular dysfunction. These patients are also at risk for malignant ventricular arrhythmia and sudden death [47], justifying surgical correction as soon as the diagnosis is made [6].

Medical treatment alone carries an unacceptably high mortality rate [9] and has no place in the current era of surgical management for ALCAPA. No difference in operative survival, late survival, or graft patency has been demonstrated for the different surgical procedures, excluding ligation of the ALCAPA, which is no longer an accepted surgical option. The current surgical goal is to achieve reperfusion through a two-coronary system, most commonly by reimplantation of the ALCAPA into the aorta, which is feasible in almost all instances despite anatomic variability [6,13,15,23,24,27–29,41–45,48].

Regardless of degree of preoperative left ventricular impairment, an aggressive early surgical approach is warranted, as it is the only possible way to salvage hibernating but viable myocardium [6,13,15,45]. Mild to moderate mitral insufficiency regresses after reperfusion and does not have to be addressed at the first operation [6,11,15,27, 32,34]. Accordingly, preoperative mitral regurgitation has not been shown to increase operative mortality [6,11,15, 31,34], except in one report [32] in which it was described as adversely influencing operative survival. Persistent, recurring, or worsening postoperative mitral insufficiency should warrant a cardiac catheterization to demonstrate coronary patency before reoperation on the mitral valve [41]. Left ventricular function improves substantially after restoration of a two-coronary-artery circulation, although some degree of chronic impairment from preoperative structural abnormalities may persist. Left ventricular muscle or aneurysm resection is generally unnecessary [15,39]. Documented massive infarction may be the only justification for cardiac transplantation, although this situation is generally becoming obsolete, with a higher awareness of the probable diagnosis of ALCAPA, an increased index of suspicion and immediate referral [6]. Left ventricular assist devices and ECMO improve survival in the surgical management of ALCAPA [31,41,43–46]. Although successful, cardiopulmonary bypass and cardioplegia strategies should reduce the need for postoperative mechanical circulatory support [13].

The best follow-up method for patients with ALCAPA is unknown. Electrocardiography, Holter monitoring, stress-thallium scanning, and cardiac catheterization have shown equivocal results and most often underscore any remaining left ventricular dysfunction that may be apparent only under severe stress testing. Close long-term follow-up evaluation of these patients is necessary to better understand the corrected natural history that currently constitutes the expected goal after surgical correction of ALCAPA.

Anomalous Aortic Origins of Coronary Arteries

Anomalous aortic origins of the coronary arteries (AAOCA) represent one-third of all coronary artery anomalies [49,50]. All three coronary arteries may be involved, and virtually every single combination has been reported as a case report. Most anomalous aortic origins are considered benign, except aberrant origin of the LMCA from the right aortic sinus of Valsalva (RASV) and aberrant origin of the RCA from the left aortic sinus of Valsalva (LASV), which are associated with cardiac symptoms and sudden death [3, 49–62]. The fatal potential of a minor coronary anomaly was first described by Jokl *et al*. in 1962 [58]. In 1992 Taylor *et al*. [49] proposed a classification of anomalous aortic origins (Table 38.3) [49,63–65].The inclusive nomenclature system including all possible variations of AAOCA as described in the STS Congenital Heart Surgery Nomenclature and Database Project is henceforth proposed for all further classification of AAOCA [2].

Although a chest radiograph and ECG remain a part of the standard work-up for all suspicion of AAOCA, they are most always negative. Findings at stress ECG may suggest the diagnosis of ischemia, but even standard transthoracic or transesophageal echocardiography and stress thallium are fairly unreliable [61,66]. Cardiac catheterization is in many centers still the ultimate diagnostic tool [49,50,59, 61,64,66,67] and is indicated in evaluations of young patients with unexplained exertional syncope, dizziness, or angina. Transthoracic echocardiography using contrast-enhanced, color-guided, pulse-wave Doppler-flow interrogation is a promising noninvasive imaging modality, although it is neither universally available nor easily reproducible [51].

However, for screening purposes, preferred imaging should be less invasive and avoid contrast medium or ionized radiation. Newer imaging modalities are increasingly gaining popularity and used for screening purposes, namely coronary magnetic resonance angiography, which allows three-dimensional reconstructions and multidetector CT angiography (Figures 38.9–38.12) [51].

Table 38.3 Classification of anomalous aortic origins of coronary arteries. (CX, circumflex coronary artery; LASV, left aortic sinus of Valsalva; LMCA, left main coronary artery; RASV, right aortic sinus of Valsalva; RCA, right coronary artery.) (Reproduced with permission from Taylor *et al*. [49].)

Type	Incidence
LMCA from RASV	21% [49] of AAOC: four different courses possible in relation to great vessels
RCA from LASV	6–27% [49,64] of AAOC: can cross the aortic root anteriorly, or between the aorta and pulmonary artery
CX from RASV or RCA	10–60% [63] of AAOC (most common): courses either anterior or posterior to the great vessels, not between [63], always retroaortic [65]
Inverted coronary arteries	Rare

Left Main Coronary Artery from Right Aortic Sinus of Valsalva

Left main coronary artery arising from the right aortic sinus of Valsalva (LMCA from RASV) represents the most

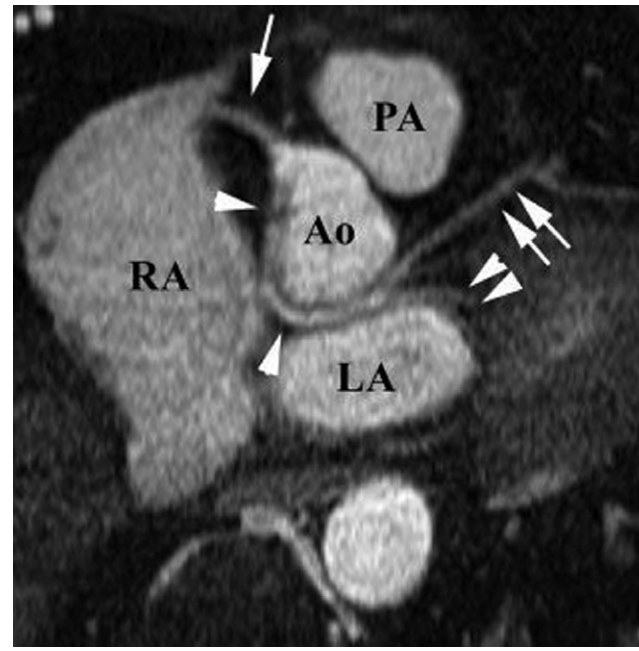

Figure 38.9 Coronary magnetic resonance angiographic images, using the "soap-bubble" reconstruction software tool, showing a common or juxtaposed origin of the left and right coronary arteries from the right sinus of Valsalva with a retroaortic course of the left main coronary artery (path no. 2). The right coronary artery has a normal course (single arrow). The left main coronary artery (single arrowhead) has a "benign" course, running posterior to the aortic root, then dividing normally into the left anterior descending (double arrows) and left circumflex (double arrowheads) coronary arteries. This view approximates a shallow left anterior oblique projection rotated 45 degrees clockwise. (Ao, aorta; LA, left atrium; PA, pulmonary artery; RA, right atrium.) (Reproduced with permission from Angelini *et al.* [51].)

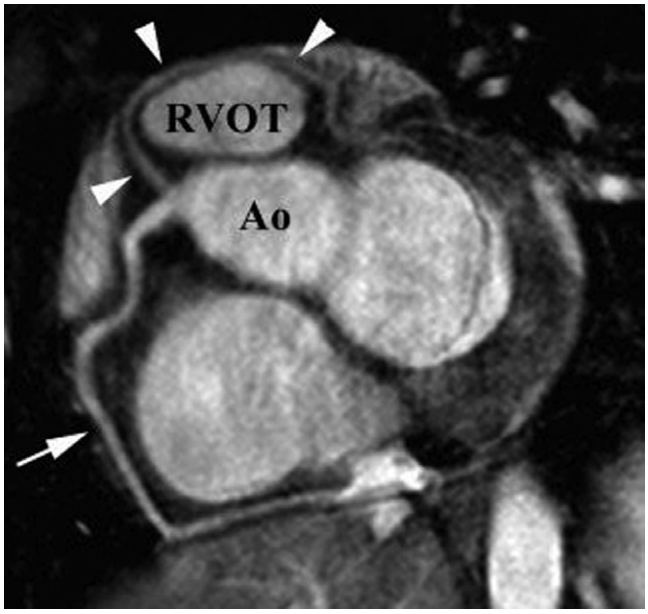

Figure 38.10 Soap-bubble reconstruction of a coronary magnetic resonance angiographic image (approximating a shallow left anterior oblique projection) revealing a common origin of both the left and right coronary arteries from the right sinus of Valsalva. The right coronary artery (RCA) has a normal course (arrow) and is visible to the crux; the left main coronary artery (arrowheads) has a "benign" course running anterior to the right ventricular outflow tract (RVOT, path no. 5), then dividing normally into the left anterior descending artery (not included in this image) and the left circumflex artery. (Ao, aorta.) (Reproduced with permission from Angelini *et al.* [51].)

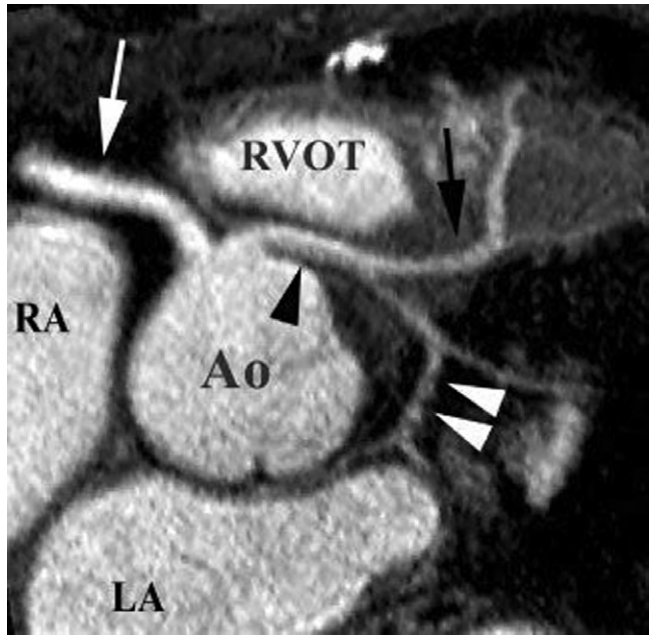

Figure 38.11 Coronary magnetic resonance angiographic image with soap-bubble reconstruction (approximating a shallow left anterior oblique projection rotated 45 degrees clockwise). The left main coronary artery (black arrowhead) originates from the right sinus of Valsalva and courses within the upper ventricular septal myocardium, between the aortic root and the right ventricular outflow tract (RVOT, path no. 4). Note that the epicardial fat is suppressed (it turns black) as a result of a fat suppression pulse used in the imaging sequence; the myocardium is gray. Both the left anterior descending (black arrow) and the left circumflex artery (double white arrowheads) also have intramyocardial courses for their proximal portions. The right coronary artery (white arrow) has a normal course within the right atrioventricular groove. (Ao, aorta; LA, left atrium, RA, right atrium.) (Reproduced with permission from Angelini *et al.* [51].)

serious anomaly of coronary origin and is associated with the highest incidence of symptoms and sudden death [3,49–62,66,67]. The incidence of sudden death in untreated patients reaches 57%, and up to two-thirds of these sudden deaths are related to exercise [49,61,66]. The risk of sudden death is reported as high as 82% if the LMCA courses between the great vessels [49,66,67]. Four courses of the LMCA are possible in relation to the great vessels: 1) anterior to the PA; 2) posterior to the aorta; 3) between the great vessels; and 4) septal course through the conal septum (beneath the right ventricular infundibulum) [66]. If the LMCA courses between the great vessels, the LMCA provides one or two branches to the proximal ventricular septum. Conversely, when the aberrant LMCA is posterior to the aorta, there are no septal branches from the left coronary system but branches arise from the RCA [64]. Perhaps the most important pathoanatomic element of the anomalous LMCA is the often-associated intramural (within the wall of the aorta) course that is almost always stenotic, both at its orifice and over the intramural course. The intramural course can be above the commissure between the left and right coronary cusps or below the commissure (upstream).

The presumed pathogenesis of ischemia and sudden death include an acute origin (angle) of the anomalous vessel causing a slit-like orifice [49,50,61,64,66,67], compression of the coronary artery by aortic root distension at the onset of diastole [49,66], exercise-induced expansion of both the aortic root and the pulmonary trunk causing compression of the LMCA [49], effort-related stretching of the intramural LMCA segment adherent to the aorta along its first 1.5 cm of length [61,66], and compression of the LMCA by the intercoronary commissure particularly during diastole when the aortic valve is closed [61], with resultant spasm, torsion, or kinking [49,64]. The incidence of atherosclerosis is higher among older patients with aberrant

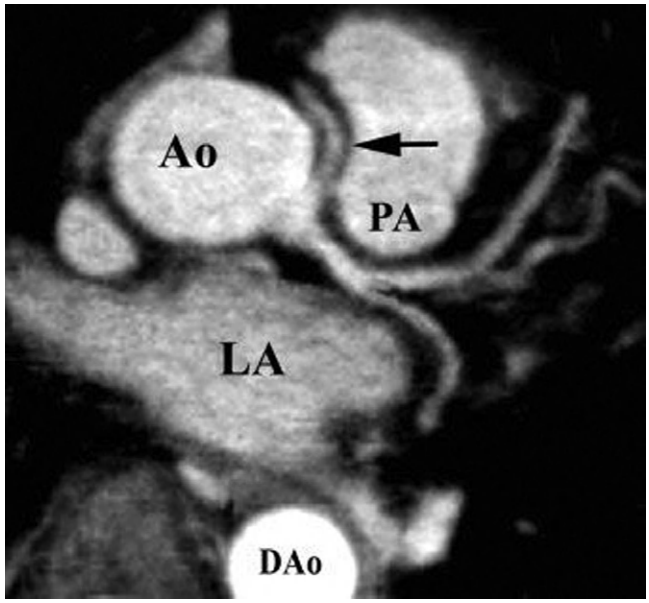

Figure 38.12 Anomalous left coronary artery originating from the opposite sinus, with an "interarterial course (path no. 3)," as seen by soap-bubble reconstruction of a coronary magnetic resonance angiographic image. This view approximates a shallow left anterior oblique projection rotated 45 degrees clockwise. The right coronary artery (black arrow) arises from the left sinus of Valsalva and courses between the aortic root and the pulmonary artery (PA). (Ao, aorta; DAo, descending aorta; LA, left atrium.) (Reproduced with permission from Angelini *et al.* [51].)

LMCA than among age-matched controls. The left system is congenitally small, and therefore most patients have a right dominant circulation [59,64].

Symptoms are frequent, encountered in as many as 38% of patients [49,54]. These include angina (20%), congestive heart failure (14%), syncope (14%), and myocardial infarction (6%), and their presence should alert to the increased risk of sudden death. Angina and syncope predominate among younger patients, while those older than 30 years experience angina and myocardial infarction [50]. Younger patients are more prone to sudden death, which may be their presenting symptom [49,50]. In a retrospective study of 6.3 million US military recruits (ages 17–35 years) undergoing basic military training between 1977 and 2001, 64 sudden cardiac deaths were identified [54]. Of these, the majority (61%) were owing to coronary artery pathology, among which more than half (54%) were from anomalous aortic coronary origins. Sudden cardiac deaths were more likely associated with premortem exertional chest discomfort and/or syncope, compared with deaths resulting from coronary artery disease in this same cohort.

Right Coronary Artery from Left Aortic Sinus of Valsalva

Anomalous RCA arising from the left aortic sinus of Valsalva (RCA from LASV) is reported in 0.26–0.6% of postmortem studies [68], and 0.2% of all angiographic studies [68]. This represents 6–27% of all coronary anomalies [69]. Anomalous RCA from LASV was previously considered benign but more recently is recognized to be associated with considerable potential morbidity [49,62,68–70], with a potential risk for sudden death of up to 25%, being exercise-related in 46% of cases [49,51–57,59,61,62]. Symptoms of angina, myocardial infarction, syncope, and high-grade atrioventricular block [49,62,68–70] are believed to be related to closure of the anomalous ostium within the aortic wall during exercise or hypertensive states [52–57,69]. Proposed mechanisms of coronary ischemia and resultant left ventricular dysfunction during exertion include enlargement of the aortic root and PA, which in turn can obstruct coronary flow during diastole [62,69]. As in the case of left main coronary arising from the right coronary sinus, an RCA arising from the left coronary sinus displays the same characteristics of intramural courses, namely that the course is almost always stenotic at the orifice and along the intramural course. The anatomic configuration can be above the commissure between the right and left coronary cusps or below the commissure (upstream). No relationship is thought to exist between this coronary anomaly and atherosclerosis [62,69].

Recently there has been an increased awareness of this disease entity resulting in several retrospective studies [71–73], which have called for a prospective study to document its natural history. Kaushal *et al*. have noted that symptoms related to the length of the intramural course are measured by CT scans and intraoperative assessment [72]. An ongoing multi-institutional study has been organized [74] to delineate the medical and surgical outcomes of these patients over the long term.

Anomalous Circumflex Coronary Artery from Right Aortic Sinus of Valsalva or Right Coronary Artery

The reported incidence of this anomaly is 0.2–0.71% [65], which represents the most common coronary variation as reported in the Coronary Artery Surgery Study [63]. The anomalous circumflex coronary artery originates most often from the RASV (69%) [65] and commonly as a direct branch of the RCA. Symptoms and sudden death are rare, and diagnosis is incidental. The incidence of atherosclerotic coronary artery disease (ACAD) is similar to that in the control population (40%) [65], although some report a greater degree of stenosis than in controls.

Surgical Management

In the presence of symptoms, there is no debate with regard to the need for surgical correction; a coronary imaging study is performed, and surgery is planned according to standard surgical criteria for ACAD. Patients with an anomalous left coronary present more often with symptoms than those with an aberrant RCA [52]. With anomalous left coronary origin from the RASV, young patients (less than 30 years of age), regardless of symptoms or associated atherosclerosis, are recommended to undergo prophylactic corrective surgery (surgical unroofing of the intramural segment) to avoid a high risk of sudden death [49,52,55,57,60,61]. The surgical indication becomes a semiemergency if the patient has exertional syncope, chest pain, or ventricular tachycardia [59,67]. In the asymptomatic patient with LMCA from RASV, some authors recommend delaying surgery only until 10 years of age, based on the fact that sudden death is rare in children, but would not wait longer [57,60]. If surgical repair is refused, avoidance of strenuous physical activity and competitive athletics is warranted [57,60]. In the asymptomatic young patient with an aberrant RCA from the LASV, treatment is controversial [52]. In the subgroup of asymptomatic older patients with negative results of a thallium study or absence of atherosclerotic coronary lesions, no sudden death is described [50,52,59]. Until recently, most centers have not performed prophylactic surgery on this cohort of asymptomatic patients [59]; however, this trend appears to be reversing in some centers [57].

The aim of surgery is to restore a normal anatomic position of the left coronary ostium [61] or to bypass a problematic proximal juxtacommisural or intramural course that may or may not have atherosclerotic lesions. The first attempts at surgical correction were performed using saphenous vein grafts to bypass the aberrant coronary arteries, followed shortly by internal thoracic artery bypass grafting. Although these techniques are still widely practiced [52,56,57,60] and remain unavoidable in certain circumstances, they expose the patient to the usual problems of grafted coronary artery disease and potential reintervention [57]. Furthermore, as the flow through the anomalous coronary is most often normal at rest, any type of bypass graft may have decreased postoperative patency owing to competitive flow [55,57], raising the question of whether the proximal aberrant coronary should be ligated [56]. We do not recommend this however.

In 1982, Mustafa and Yacoub and colleagues [61] were the first to propose and perform an anatomic ostial correction consisting of opening the aortic root, incising the ostium of the LMCA, and unroofing the stenotic intramural segment along its course to the midpoint of the LMCA sinus, with detachment of the intercoronary commissure. The intima of the LMCA is fixed to that of the aortic root, and the commissure is reattached to the aortic wall, bringing the left main coronary ostium back into its natural position in the LASV (Figures 38.13–38.15) [61,75].

It is reassuring that surgical therapy is available for the specific forms of AAOCA that are potentially lethal, namely an LMCA from the RASV and an RCA from the LASV. Although the short-term follow-up of surgical repair for AAOCA seems encouraging [52,55,57] as documented by absence of ischemia on stress testing, stress echocardiography, and even exercise-perfusion scanning, the durability of the repair is still unknown [57]; subclinical changes suggestive of ischemia despite patent neocoronary ostia have been documented [52]. The long-term results of rerouting aberrant coronaries, unroofing coronary ostia, detachment of aortic valve commissures, and bypass to nondiseased vessels in the setting of AAOCA raise the respective questions of future potential ostial stenosis, aortic valve competence, and competitive graft flow. These surgical techniques are still under evaluation, and the optimal follow-up modalities and frequency of follow-up in these rare patients are still debated and await clearer guidelines.

Anomalous Pulmonary Origins of Coronary Arteries

The various APOCA are described in Table 38.2 [2], including the most common type 1, ALCAPA, already described at the beginning of this chapter. Type 2, or anomalous right coronary artery from the pulmonary artery (ARCAPA), is a very rare congenital anomaly, first described by Brooks [5], affecting 0.002% of the population [76]. Williams *et al*. [76] summarized the 70 cases ever published in the literature, including 7 of their own: 40 were children less than 18 years, and 11 were infants. Most patients were asymptomatic and presented with a murmur, but angina, congestive heart failure, cyanosis, palpitations, and even myocardial infarction with sudden death have been described [76]. Electrocardiogram findings are nonspecific, and currently, echocardiography is the most common method of diagnosis [76]. Although considered a benign lesion, the potential for sudden death as an initial and terminal presentation exists. Given the satisfactory advances achieved with standardized surgical technique and postoperative care, coronary reimplantation is indicated on diagnosis of the anomaly with expected good outcomes [76].

Single Coronary Artery

Single coronary artery is a rare anomaly frequently associated with complex congenital heart disease [77], with a reported incidence of 0.0024–0.066% [78–81]. Single coronary artery was first described by Thebesius in 1716 [82]. In 1950, Smith [83] proposed the first classification:

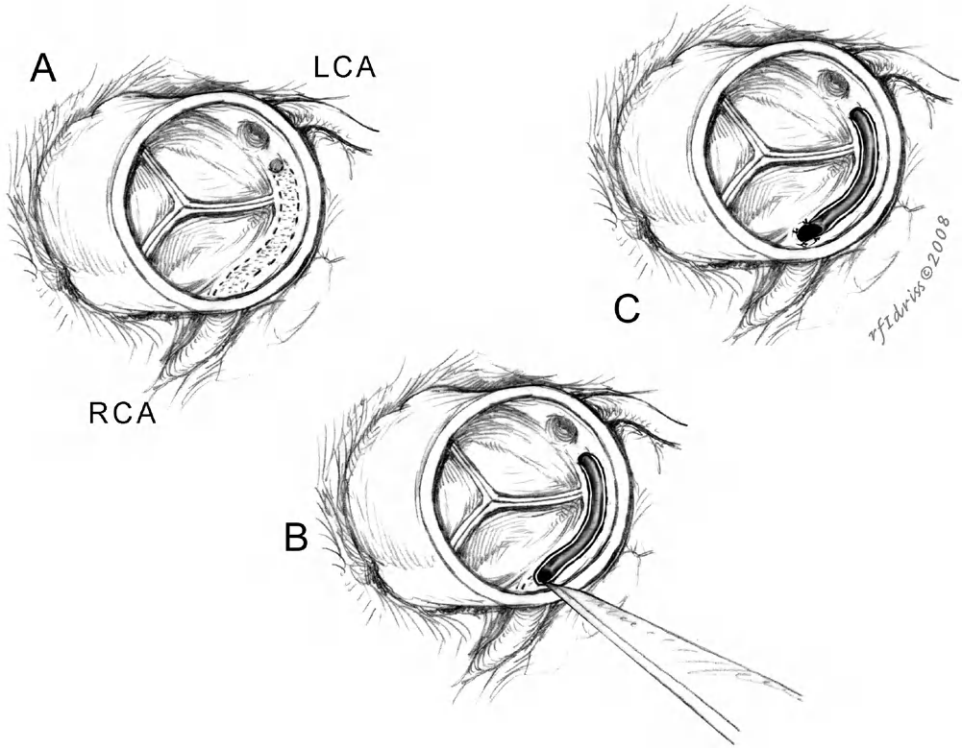

Figure 38.13 A, A transected aortic root demonstrates a normal left main coronary artery (LCA) and an abnormal intramural course of the right coronary artery (RCA), which takes its origin from the left coronary cusp, traverses intramurally (within the wall of the aorta) toward the right coronary cusp, and emerges there to perfuse the heart. **B,** The unroofing procedure is performed along the length of the intramural course. **C,** The tacking sutures are placed at the neoorifice and serve to reattach the intimal layers, thereby preventing dissection and thrombosis. We employ interrupted 8-0 Prolene. (Reproduced with permission from Mavroudis *et al*. [75].)

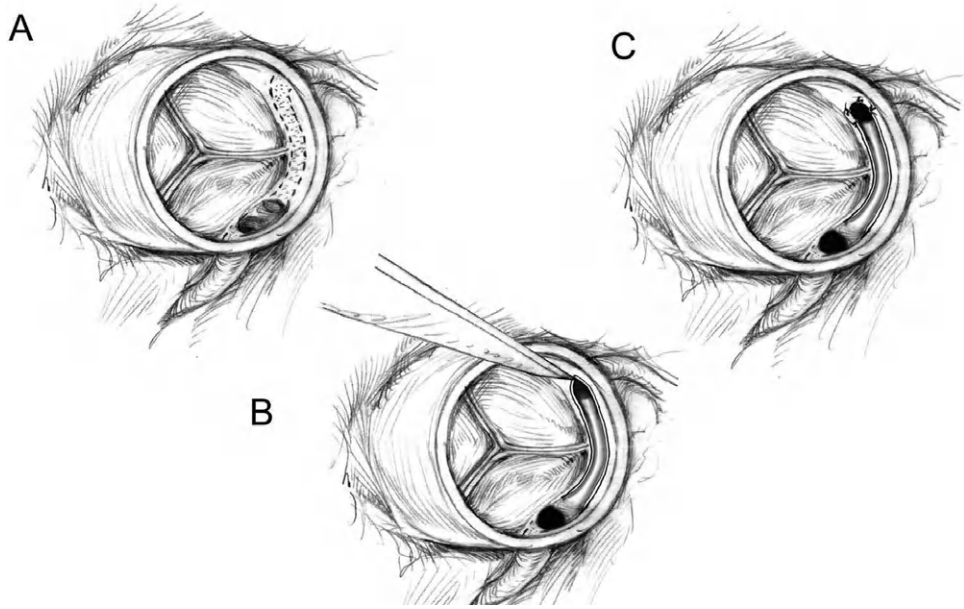

Figure 38.14 A, A transected aortic root demonstrates a normal right coronary artery and an abnormal intramural course of the left main coronary artery, which takes its origin from the right coronary cusp, traverses intramurally. **B,** The unroofing procedure is performed along the length of the intramural course. The dissection ends where the artery emerges from the aorta to supply the heart. **C,** The tacking sutures (8-0 Prolene) are placed at the neoorifice and serve to reattach the intimal layers, thereby preventing dissection and thrombosis. (LCA, left coronary artery; RCA, right coronary artery.) (Reproduced with permission from Mavroudis *et al*. [75].)

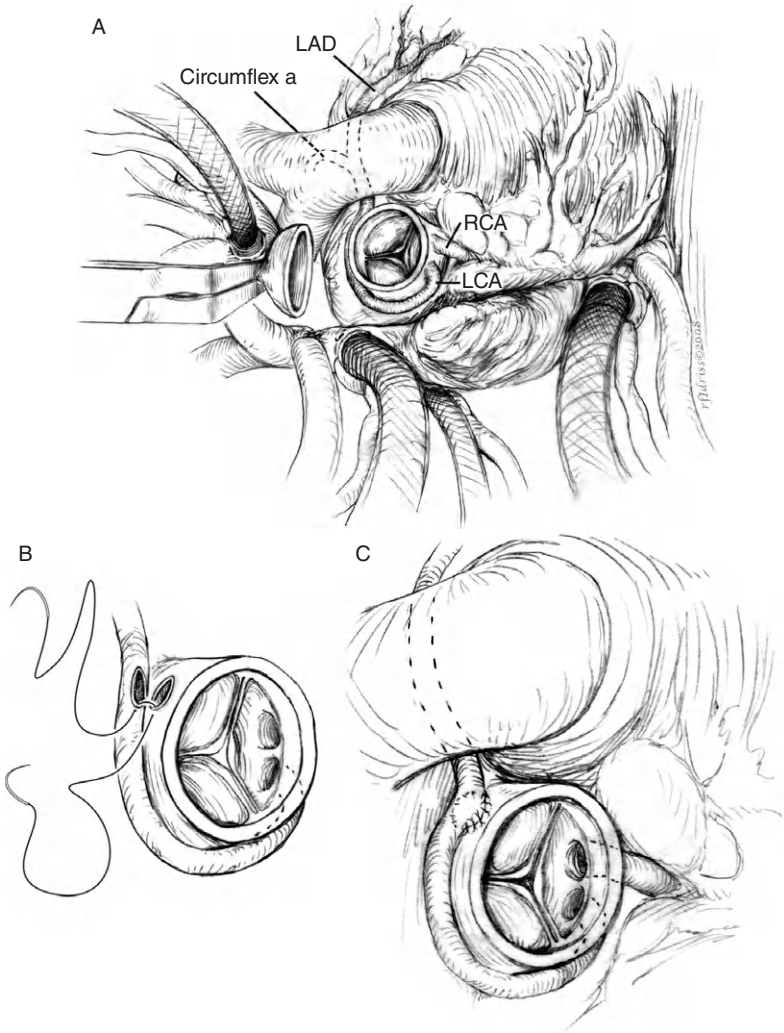

Figure 38.15 A, The anomalous origin and pathway of the left main coronary artery is depicted. The origin is within the right coronary cusp adjacent to the takeoff of the right coronary artery. The artery is elongated and courses to the right and posterior of the aorta to emerge at the usual location and origin of the left main coronary artery near the left coronary cusp. Note that the course of the coronary artery is not intramural and the usual unroofing approach as described in the previous figures is not indicated. **B,** Instead, we have chosen to perform side-to-side anastomoses for these abnormal coronary artery courses. **C,** This procedure succeeds in a neoorifice formation more closely related to the normal coronary artery anatomy. (LAD, left anterior descending coronary artery; LCA, left coronary artery; RCA, right coronary artery.) (Reproduced with permission from Mavroudis *et al.* [75].)

• type 1: one artery supplies the entire heart, the other being truly absent; left or right in equal distribution;
• type 2: a single artery subdivides into two branches with distribution patterns corresponding to "normal" right and left coronary arteries (most common pattern) [77];
• type 3: other.

An additional subdivision of type 2 was proposed by Sharbaugh and White in 1974 [77], later modified by Lipton *et al*. in 1979 [80], and then by Yamanaka and Hobbs in 1990 [81] (Figure 38.16) [12,77]:
• type 2a: the branch that is the missing artery of origin passes anteriorly to the great vessels;
• type 2b: the branch that is the missing artery passes between the great vessels;
• type 2c: the branch that is the missing artery passes posteriorly to the great vessels.

The artery that originates from the aorta and from which the missing branch derives, is designated *L* or *R* for left or RCA, respectively. This classification (L or R and types 1, 2a, 2b, 2c, and 3) is a thorough one and has been adopted by the STS Congenital Heart Surgery Nomenclature and Database Project [2]. As mentioned previously, there exists a high incidence of associated congenital heart disease (17–40%) [78–81]. These anomalies include transposition of the great arteries, tetralogy of Fallot, truncus arteriosus, coronary arteriovenous fistula (CAVF), endocardial fibroelastosis, and bicuspid aortic valve. Type 2 is the most common form, and type 2a is more frequently associated with transposition of the great arteries and tetralogy of Fallot.

The overall survival rate is comparable with that of the general population. However, sudden death is possible (23%) [77,84] in type 2b cases in which the anomalous missing coronary artery of origin may be compressed between the great vessels. No particular ECG pattern is diagnostic, and coronary angiogram is the gold standard diagnostic tool. It remains unclear if atheromatous coronary disease is more prevalent in patients with single coronary artery [78,79]. As a corollary, the prognosis seems to be dependent on associated congenital heart defects.

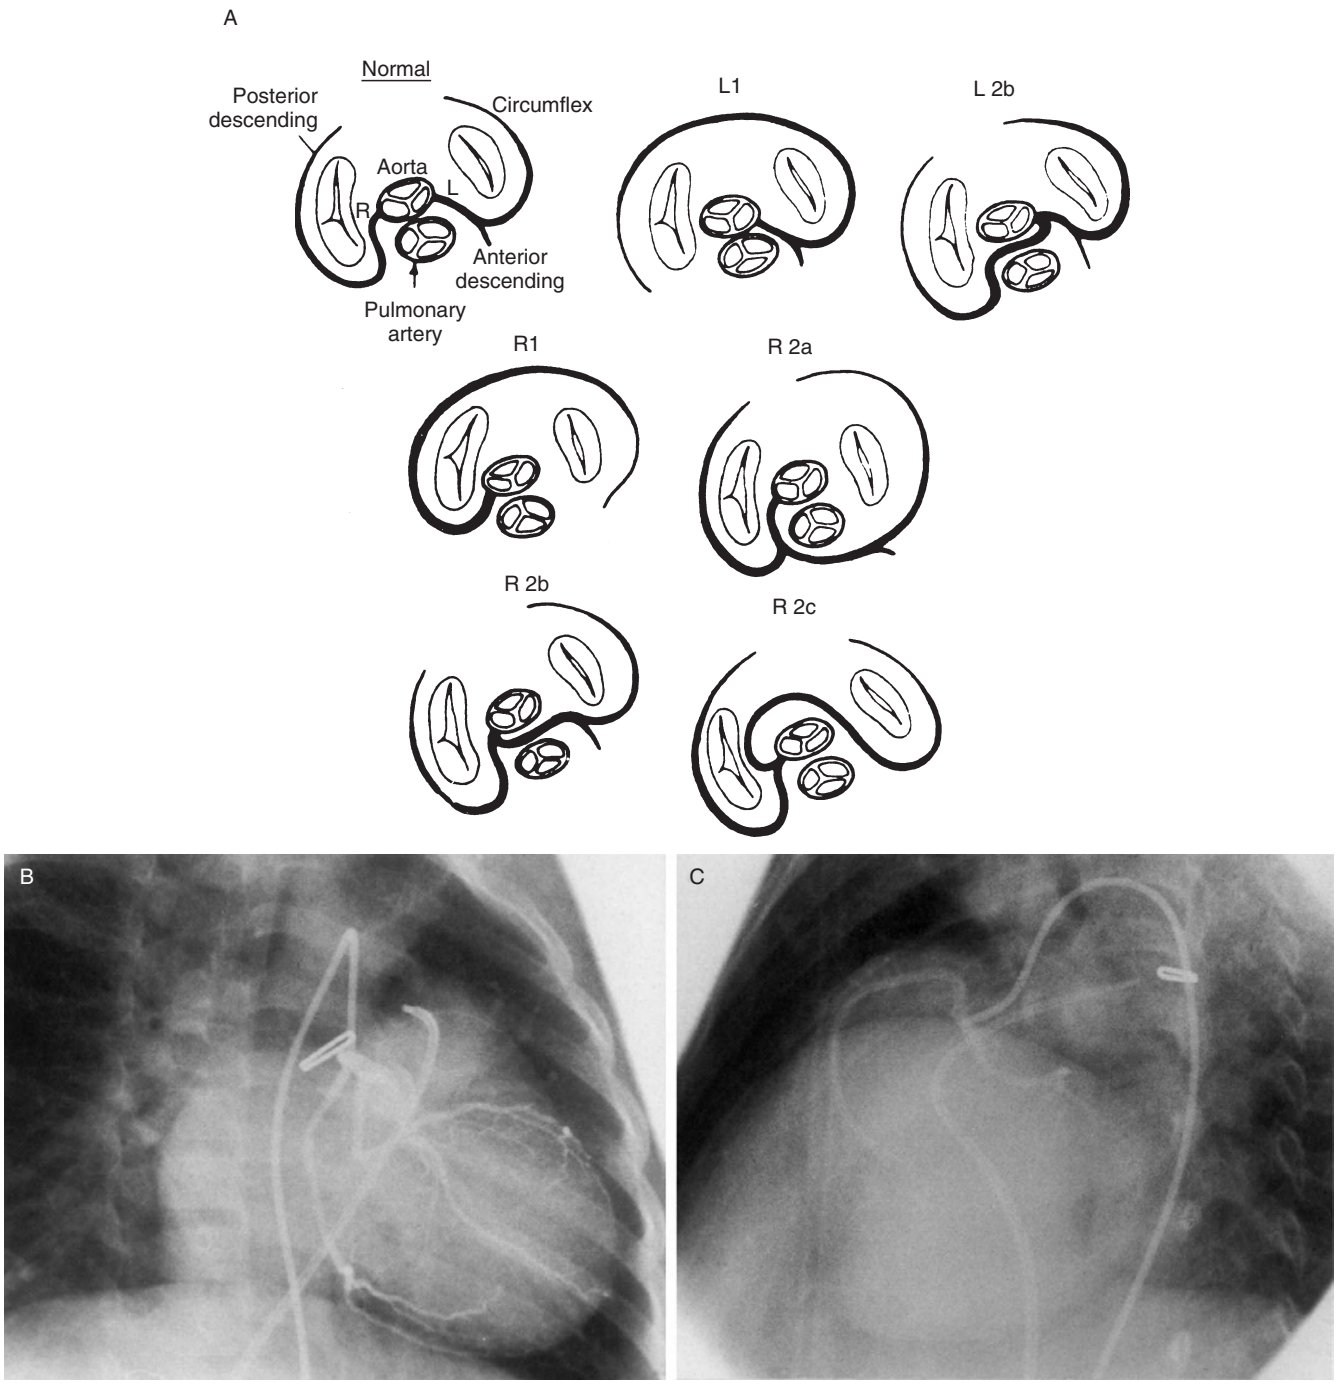

Figure 38.16 A, Single coronary artery with main patterns of distribution. Myocardial ischemia with sudden death may occur in R2b, in which the coronary artery courses between the aorta and the pulmonary artery. L, single left coronary artery; R, single right coronary artery. Frontal (**B**) and lateral (**C**) selective single right coronary arteriograms with left main coronary artery branch coursing between the great vessels. (A, Reproduced with permission from Sharbaugh *et al.* [77].)

Expectant medical management, coronary artery bypass grafting, and percutaneous coronary angioplasty have all been performed with success [78,79], although it remains unclear how these protocols potentially influenced the otherwise "natural history" of the anomaly. Currently, the extant data is insufficient to recommend optimal surgical/interventional or follow-up strategies [78,79], although some find medical treatment adequate for middle-aged or elderly patients in the absence of an ischemic coronary syndrome [78].

Congenital Atresia/Stenosis of the Left Main Coronary Artery

Congenital atresia/stenosis of the left main coronary artery (CALM) is an extremely rare minor anomaly, with approximately 60 cases described in the literature. Until the mid 1970s it was considered a single coronary artery until Lurie [85] defined it as a distinct entity with a flow pattern and physiology of its own. ALCAPA and single coronary artery are the most important differential diagnoses. In single coronary artery, a single left or RCA gives flow to the entire heart in a centrifugal anterograde pattern from the aorta to the periphery with a decreasing diameter of the vessel as it progresses distally toward the capillaries. In CALM, however, a single RCA vascularizes the entire heart, but flow in the left anterior descending (LAD) coronary artery as well as into the circumflex coronary artery is centripetal, and therefore retrograde, depending on collateral vessels from the RCA [86]. Collateral channels are through the circle of Vieussens, which includes the conal artery, intraseptals, and apical-anterior and posterior ventricular anastomoses [86,87]. There are also collaterals between the anterior interventricular branches of the right and LAD coronary arteries and between the final ramifications of the posterior descending branch of the RCA and LAD [86]. There is no left coronary ostium because the proximal left main trunk ends blindly. Most important, the LAD and circumflex coronary artery are located in their normal anatomic positions and connect in the usual way [87–90].

When excluding ALCAPA in the differential diagnosis of CALM both with regard to the clinical picture and diagnostic work-up, the ECG is unspecific and may also show evidence of ischemia or myocardial infarction in the anteroapical leads, and the chest radiograph unspecifically reveals cardiomegaly and pulmonary venous congestion. Therefore, diagnosis should be made by two-dimensional echocardiography [89], but the definitive anatomy and hence operative strategy need to be defined with coronary angiography [86–93]. The angiographic criteria common to both CALM and ALCAPA are a solitary RCA originating from the aorta with inability to inject into an obstructed left ostium and a left coronary artery filling retrograde through collateral vessels from the RCA. However, in CALM, the LAD and circumflex coronary artery are situated normally, and there is no "blush" into the PA from the proximal LMCA. Differentiating ALCAPA and CALM is not always angiographically possible, especially if the former has poor collateralization from the RCA and therefore not enough pressure to induce the characteristic "blush" in the PA [88]. Furthermore, in CALM, there is no oxygen step-up from a left-to-right shunt in the PA [88]. Evaluation for potential ischemia can be done with a stress-thallium study that typically demonstrates perfusion defects of the anteroapical segments [89,91].

The clinical manifestations strikingly resemble those of ALCAPA, and symptoms may begin in early infancy with syncope, tachyarrhythmia, dyspnea, failure to thrive, and sudden death. Survival into adulthood is rare but is possible and depends on the degree of collateralization from the RCA [86]. All patients ultimately develop ischemia on exertion, if not at rest, after the fifth decade. This condition results from left ventricular hypertrophy, increased oxygen demand, and superimposed atherosclerosis, which is estimated to be present in 15% of cases [87], similar to the frequency in a control population. Symptoms are believed to result from the delay of blood delivery to the left coronary system, as blood reaches the LAD and circumflex coronary artery in systole rather than in diastole [87]. The natural history of this disorder is poor, as patients with this anomaly have died suddenly, with or without medical treatment or while awaiting surgical correction [87,89]. An association is found with supravalvar aortic stenosis, especially in Williams-Beuren syndrome.

Surgical Management

Currently, surgery on diagnosis is the recommended therapy, consisting of bypass grafting of the LAD with saphenous vein or internal mammary artery [25]. Gay and associates [92] have performed a baffle technique using the ascending aorta to reconstruct the proximal CALM without the use of bypass grafting.

Good surgical results have been obtained with low mortality. Intermediate angiographic and clinical follow-up evaluation have demonstrated graft patency [89,91,92]. It is expected that long-term internal mammary artery graft patency will be superior to that of venous grafts.

In conclusion, CALM is an extremely rare congenital coronary anomaly that carries a serious prognosis if the patient is not treated. Ischemia, myocardial infarction, and sudden death are potential outcomes and may be prevented by surgical bypass grafting to the LAD, preferably with an internal mammary artery graft or proximal coronary arterioplasty. The clinical manifestations resemble those of ALCAPA, which is the most important differential diagnosis. The anatomic course can be confused with single coronary artery, from which CALM is clearly classified as a distinct entity. Long-term results are lacking in this very rare anomaly.

Coronary Arteriovenous Fistulas

Coronary arteriovenous fistulas represent an anomaly of termination. Coronary arteriovenous fistula was first described by Krause in 1865 [94] and is present in 1–2% of the general population [95–97]. Angiographic series report an incidence of 0.2–0.85% [98]. These fistulas represent nearly one half of all congenital coronary artery anomalies [99] and are the most common hemodynamically signifi-

cant coronary anomaly [95–97,100–102]. Approximately two-thirds of fistulas are congenital, but acquired lesions are steadily increasing in number. The etiology of congenital CAVF appears to represent persistence of the embryonic intramyocardial trabecular sinusoids, with anomalous development of the intratrabecular spaces, through which blood is supplied to the myocardium during intrauterine life [98]. Acquired lesions may appear after trauma, Takayasu arteritis, cardiac surgery, in patients with indwelling transvenous pacemaker leads, postangioplasty, postendomyocardial biopsy in transplant recipients, or following interventional device closure of intracardiac defects [98,103].

Coronary arteriovenous fistulas can be isolated (55–80% of cases) [95-97,102,104] or associated with other congenital heart disease (20–45% of cases). Associated anomalies include tetralogy of Fallot, atrial septal defect, patent ductus arteriosus, ventricular septal defect, and superimposed coronary artery disease (35%) [95]. Single fistulas are most common, the frequency ranging from 74–90% [95–97,100,102,104]. Multiple fistulas are present in 10.7–16% [95,96,104] of cases, and fistulas originating from both coronaries in 4–18% [95–97,104]. Although most fistulas originate from the RCA, a recent review of large surgical series reveals both the RCA and the LAD as the most common sites of origin; coronary fistulas rarely arise from the circumflex artery [103]. The most common sites of termination are the PA and right ventricle [103]. Drainage into the right side of the heart is more prevalent (92%) owing to the lower pressures, and drainage into the left side of the heart occurs in only 8% of cases [96,100,101,103,104]. Coronary dilatation is usual, although the degree is not related to the amount of shunting [98]. Nomenclature is descriptive and includes the vessel of origin and the chamber of termination. There exists one angiographic classification by Sakakibara and associates (1966) (Table 38.4) [105].

Patients are usually asymptomatic in the first two decades of life [106]. Afterward, or in younger patients with larger fistulae, symptoms are present in 55–73% of patients and include angina (3–60%), dyspnea (34–60%), congestive heart failure (15–19%), arrhythmias (22–24%), and more rarely, dizziness, palpitations, and fatigue [95–97,100–103].

Diagnosis often can be made clinically with the finding of a continuous machinery murmur (differential diagnosis: patent ductus arteriosus, ventricular septal defect and prolapse of the aortic valve cusp, or aortopulmonary window) at the second and third right or left parasternal border. Electrocardiographic changes are present in two-thirds of patients and include ischemia, chamber overload, infarction, and arrhythmias (premature ventricular contractions [11%], atrial tachycardia [5.6%], and conduction defects [5.6%]) [95]. Cardiomegaly is present on chest radiograph in two-thirds of cases, and a left-to-right shunt may reveal itself on radiograph with increased pulmonary vascular markings in 16.5% of cases [95]. Color-flow Doppler echocardiography can define the exact anatomy in CAVF, but most surgeons agree that cardiac catheterization is needed before surgery to define multiple fistulas, hemodynamics, the eventual degree of left-to-right shunting [95], and the eventual feasibility of transcatheter device closure of solitary distal fistulous lesions [98,99,103,106]. More recently, MRI angiography and 64-slice CT allow for precise anatomical delineation of coronary fistula origins and sites of termination, thereby helping to define treatment strategy [98,106,107].

Rarely, coronary fistulas may close spontaneously [98,106]. More often, without surgery or intervention, patients with CAVF do not have a normal life expectancy [100]. The onset of symptoms and complications in untreated patients typically begins by the second or third decade of life [95,100–102,104]. These complications include myocardial infarction (3–11%), subacute bacterial endocarditis (5–20%), aneurysm formation (19–26%), and death (7–14%). Angina is caused by coronary steal, ischemia, superimposed atherosclerosis, thrombosis from turbulence and high flow, and critical coronary flow distal to the fistula. Congestive heart failure results from chronic volume overload. Aneurysmal dilatation of the coronary artery may predispose to rupture and tamponade [108]. In rare instances, sudden death may be the first manifestation of CAVF [104]. Subacute bacterial endocarditis and pulmonary hypertension are the eventual

Table 38.4 Angiographic classification. (Reproduced with permission from Sakakibara *et al.* [105].)

	Type A	Type B
Description	Proximal segment dilated to origin of fistula Distal end normal	Distal form, coronary artery dilated over entire length, terminating as a fistula in right side of the heart (end-artery type) Proximal to fistula, regular branching of coronary
Implications for surgery	Ligation of epicardial course distal to origin maintains normal branch flow No cardiopulmonary bypass required	Ligation of precapillary end by intracameral pursestring sutures at site of termination Requires cardiopulmonary bypass

results of long-standing left-to-right shunts. Pulmonary hypertension and coronary thrombosis with resultant embolization are more common in those patients older than 30 years. The risk of subacute bacterial endocarditis in unmanaged CAVF is approximately 0.002 per patient-year [104,109].

Björck and Crafoord [110] performed the first surgical correction of CAVF in 1947, while closing a patent ductus arteriosus. After a fortuitous discovery, they ligated the fistula proximally and distally [110]. Cooley and Ellis [111] performed the first tangential arteriorrhaphy in 1962, and the first successful transcatheter embolization was reported by Reidy in 1983 [112]. The goal of surgery or transcatheter device closure is to close the fistulous tract without compromising normal coronary flow. Consensus exists for surgical patients with symptoms, regardless of age [95–102,104]. In patients without symptoms however, the timing of and indications for surgery or intervention are controversial, although surgical series advocate early prophylactic closure, owing to near zero morbidity and mortality in cases of isolated fistulas [97,99,101,103,106,113]. Operative mortality ranges between 2% and 7% in cases with associated congenital heart defects, which determine the operative risk [95–102,104,105]. The various techniques described include internal cameral closure on cardiopulmonary bypass, tangential arteriorrhaphy with or without bypass, distal ligation, and proximal and distal ligation (currently abandoned) (Figures 38.17, 38.18) [12]. Other procedures include ligation and saphenous vein graft or left internal mammary artery bypass if there is compromised flow distal to the fistula and planned site of closure, closure from within the aneurysm, and finally transcatheter coil embolization [98,99,106,113]. In general, cardiopulmonary bypass is not necessary if epicardial ligation or tangential arterior-

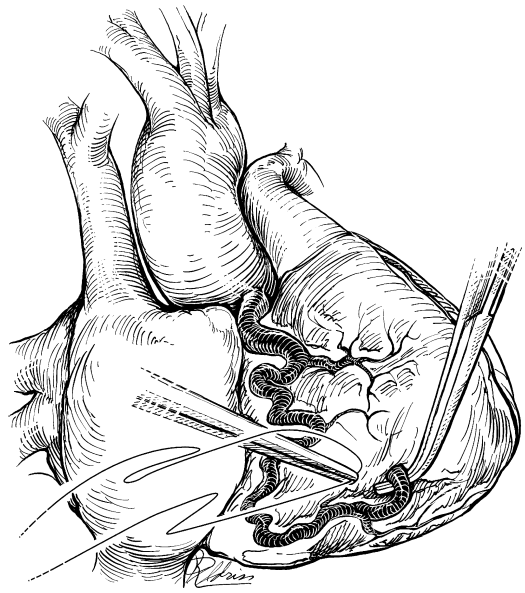

Figure 38.17 Epicardial coronary artery fistula has been dissected and is being ligated without cardiopulmonary bypass.

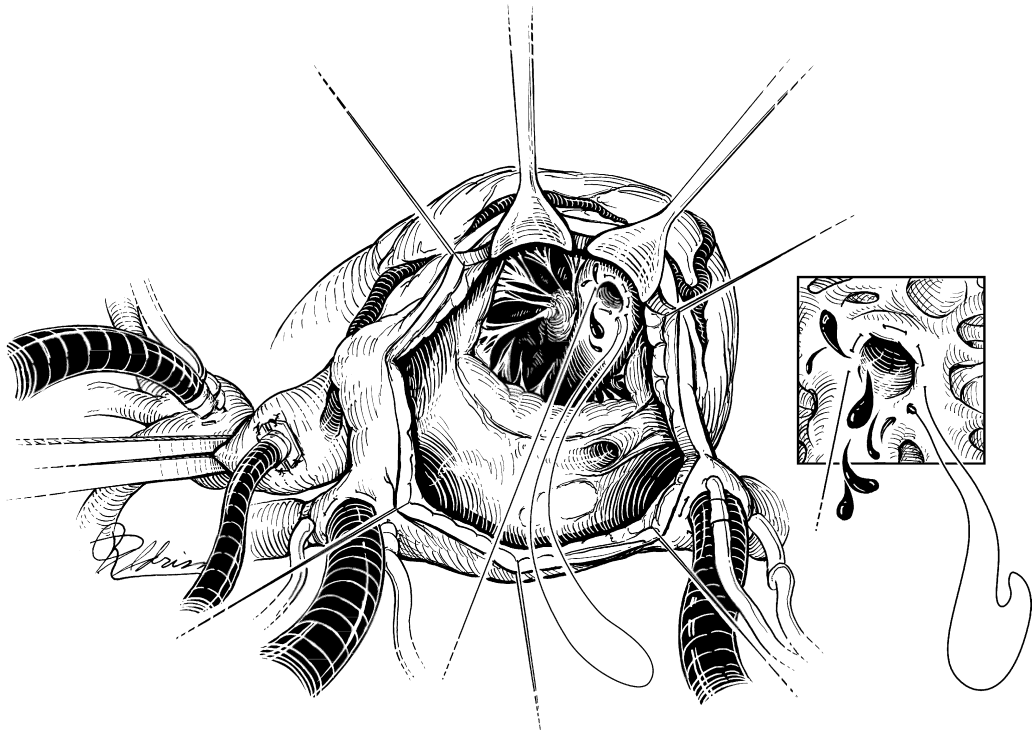

Figure 38.18 Right ventricle-to-coronary artery fistula through right atriotomy and tricuspid valve. Antegrade cardioplegia can be used to mark the effluent stream, and a purse-string suture can be used to ligate the fistula.

rhaphy [95,96,102,104,111] is performed, although it is recommended that cardiopulmonary bypass be on standby. Conversely, cardiopulmonary bypass is routinely required if there are associated congenital heart defects and ligation or purse-string closure at the intracardiac end is anticipated. Internal closure in the right heart chambers can be performed with cardiopulmonary bypass without cross-clamping or cardioplegia but on a beating or fibrillating heart [102]. Surgical techniques must be adapted to individual anatomy, and no data exist as to the superiority of one technique over another. More recently, transcatheter device or coil closure of coronary fistula has established itself as a safe alternative to surgery, when the anatomy is judged favorable. Mortality approaches zero and complications are rare [98,106]. However, no randomized studies have compared surgery with interventional techniques. No guidelines exist for a treatment algorithm depending on shunt size or anatomy, and therapeutic strategies are currently institution-dependent.

In conclusion, the nomenclature for CAVF is purely descriptive and is based on the origin and termination of the fistula. One angiographic classification (Sakakibara *et al.* [105]) has surgical implications according to type A or B. Younger patients tend to have no symptoms, but after the age of 20, symptoms develop with increased risk of complications, namely angina, myocardial infarction, congestive heart failure, fatigue, arrhythmia, aneurysm rupture and tamponade [108], subacute bacterial endocarditis, and sudden death. Surgery is recommended in all symptomatic patients at diagnosis. Operative or interventional mortality for isolated CAVF closure should be low. Consensus needs to be reached about surgical or interventional indications and timing of surgical procedure in the care of patients without symptoms. Because the natural history is not equivalent to that in the general population, many surgeons argue in favor of surgery or intervention before the onset of symptoms. This policy is advocated to avoid the increase in operative complications and death, which are more common among patients older than 20–30 years of age [97,100,101, 104,114,115]. At late follow-up, all surgically closed CAVFs remained closed, and late death was rare [103]. Improvement of functional class is the expected postoperative outcome [104]. No anatomic, clinical, or angiographic risk factors that effect operative or late survival have been defined, because most series are small. Transcatheter embolization is a relatively new technique whose long-term results remain to be evaluated [98,99,102,106,112,113].

Intramyocardial Course of Coronary Arteries (Bridging)

Intramural (intramyocardial) segments of epicardial coronary arteries, also known as *bridging*, were first described by Crainicianu in 1622 [116]. There is great discrepancy between autopsy and angiographic reports, with a wide swing of incidence between 0.5% and 85% [116–123], as is the reported incidence in the general population, estimated between 5.4% and 85.7% [117–119,123]. Bridging is most commonly seen in the mid-segment of the LAD, although it has been described in diagonal branches, the posterior descending artery of the RCA, and in the marginal arteries of the circumflex coronary [118]. Symptoms often occur after the third or fourth decade of life [123]. There exists an association with hypertrophic cardiomyopathy, ischemic cardiomyopathy, idiopathic cardiomyopathy, mitral valve prolapse, and muscular subaortic stenosis [117,121,122]. Initial clinical reports include those by Reyman (1737) [124] and Black (1805) [125]. In 1951, Geiringer [126] reported a 23% incidence at autopsy and proposed a first classification:

- type 1: LAD coronary artery deep in the interventricular groove with a circumferential muscle bridge;
- type 2: (more common) muscle bridge from trigonum fibrosum "investing the LAD" as it passes toward the apex.

Fibrous thickening of the intima was described in both types. The first angiographic description was given in 1960 by Porstmann and Iwig [127], who coined the *milking-compression effect* of the vessel during systole. Noble *et al*. in 1976 [121] proposed the first angiographic classification according to systolic narrowing of the LAD during a stress test, as simulated by atrial pacing: group 1, less than 50% narrowing; group 2, 50–75%; and group 3, more than 75% narrowing. According to Noble *et al*. [121], only group 3 patients with severe narrowing of the LAD were at risk of myocardial ischemia at effort, which still holds true in the management algorithm in many cardiology and surgical centers. They recommended that patients avoid strenuous exercise. Furthermore, they proposed propranolol treatment to attenuate heart rate and contractility and were the first to suggest a theoretic indication for surgical relief. Kramer *et al*. in 1982 [128] proposed a variation of the Noble *et al*. classification [121] and retrospectively attempted a correlation between electrocardiographic findings and stress-thallium viability.

In 1991, Ferreira and associates [129] proposed a more detailed version of the Geiringer classification based on 50 heart specimens, taking into account the morphology of the bridge in relation to the LAD.

The mechanisms of ischemia in coronary bridging are still subject to debate. Because not all patients with ischemia have systolic bridge narrowing or fixed coronary artery disease, the ischemia-to-bridge relationship is difficult to prove [117]. Some investigators argue that muscular exercise and cardiac pacing have not consistently provoked ischemia and thereby cast further doubt on the role of myocardial bridging in ischemic heart disease. The indication for surgery is also controversial [117]. Angelini and colleagues [117] believe in the protective effect of bridges on atherosclerosis. They compare LAD bridges with peripheral intramuscular arteries of skeletal muscles that are relatively resistant to atherosclerosis.

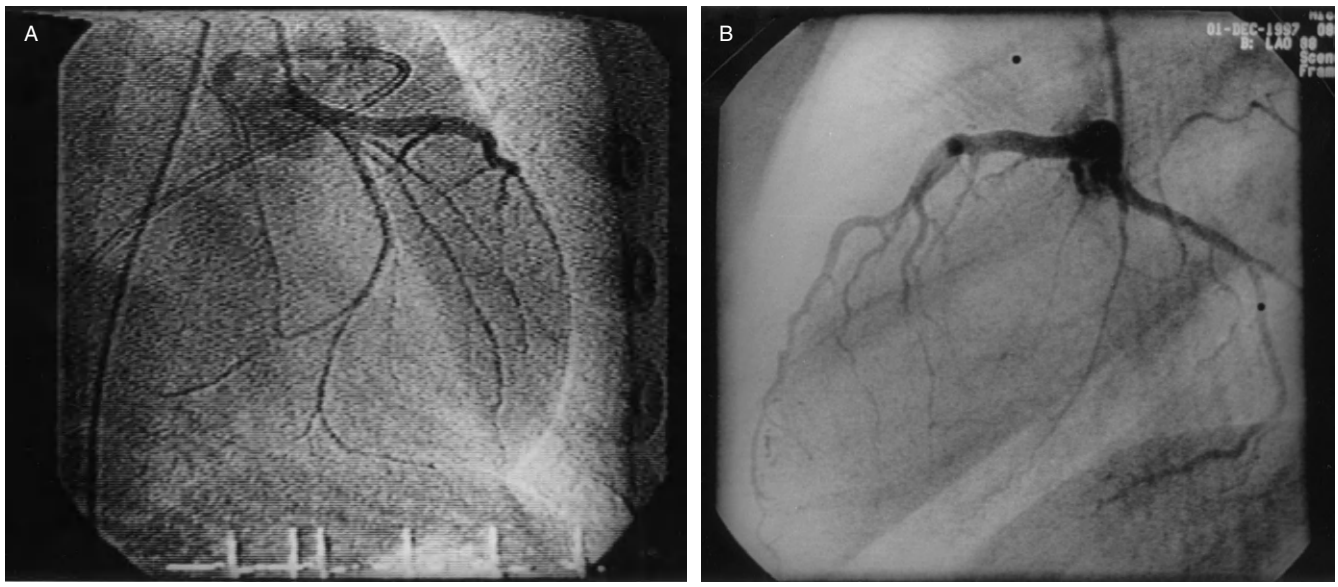

Figure 38.19 A, Coronary angiogram during systole shows constriction of the midportion of the left anterior descending coronary artery. **B,** Coronary angiogram during systole in the same patient after supra-arterial myotomy. The constrictive pattern caused by the intramural course has been alleviated.

There exists, nonetheless, angiographic evidence that systolic narrowing of coronary arteries invested by bridges does occur (Figure 38.19) [12,118,120–122,126,129–134]. Systolic coronary flow represents 5–30% of total coronary flow. There is a considerable time lag during diastole before flow in the septal coronary artery branches returns to normal. In bridging, it is estimated that one half of the flow in septal vessels is impaired during diastole [135]. Some authors postulated that turbulent flow through the bridge enhances intimal trauma and possible platelet aggregation [118,123,134]. Critical shortening of the diastolic filling time compromises local oxygen delivery, leading to ischemia, conduction abnormalities, tachyarrhythmias or syncope [118,119,123,129,131].

Currently, angiography and intravascular ultrasound (IVUS) are the gold standards for diagnosing and quantifying bridging [118]. As a rule, significant *milking* effect is present when diameter of the coronary is reduced by <70% in systole and >35% during mid-to-late diastole [118]. With IVUS, the *half moon* and early diastolic *finger tip* phenomena are highly specific for a significant bridge, depicting diameter narrowing in relation to delayed vessel relaxation, reduced antegrade systolic flow, and abrupt early diastolic flow acceleration [118]. Increased heart rate, decreased systolic blood pressure, and coronary vasospasm aggravate these phenomena [118,121–123].

Therapeutic Considerations

Initial treatment for symptomatic or asymptomatic bridging is medical [118,136]. Through their negative chronotropic and inotropic effects, beta-blockers reduce tachycardia and prolong diastole, which reduces external muscle compression [118,123,130,134], and calcium channel blockers have also been used with success [118]. Nitroglycerine has been used in the symptomatic management of angina in bridging, although ischemic symptoms worsen in some patients [123]. Pacemakers are implanted if syncope and conduction disturbances exist [119]. When symptoms are refractory to medical treatment, most surgeons agree to relieve documented angiographic systolic narrowing. In 1975, Binet *et al*. were the first to perform and report surgical myotomy, thereby unroofing the supracoronary bridge over the involved vessel [137]. Later, bypass grafting distal to the bridging, using either vein or the internal thoracic artery were also performed. Both surgical myotomy and bypass grafting, with or without cardiopulmonary bypass, have met with documented good results at follow-up evaluation. This outcome is attested by disappearance of symptoms and normalization of ECG and angiographic findings [122,123,129,130,132,136,137]. Interventional percutaneous stenting of bridged vessels has been attempted, although the rate of in-stent stenosis has been relatively high, and the midterm results are still unknown [138].

In conclusion, no consensus exists for treatment of patients who have symptoms versus those who do not. There is no randomized evidence for comparing patient outcome with surgery, stenting, or medical therapy. Most reports are isolated, and there are few long-term series.

The Geiringer and Ferreira classifications are based on autopsy studies, are purely morphologic, and have no proven different clinical correlations between superficial

and deep bridges. The Noble and Kramer classifications are based on angiographic studies and their relation to ischemia on ECG and stress-thallium studies. Noble's classification is chronologically the first, was developed in a controlled-study setting, and was adopted by the STS Congenital Heart Surgery Nomenclature and Database Project [2].

Coronary Aneurysms

First described by Morgagni [139] in 1761 in a patient with syphilis, and later by Bougon in 1812 [140], *coronary aneurysm* is synonymous with *ectasia* or *dilating atherosclerosis*. The first angiographic and radiologic description was documented by Munkner *et al*. in 1958 [141]. The incidence in the general population is 0.3–4.9% [142–145]. The aneurysm is more common in males (88.2%).

Aneurysm is defined as dilatations of a coronary vessel 1.5 times the adjacent normal coronary vessels. There exist two forms, fusiform and saccular, fusiforme being the more common. Fusiform aneurysms are typically poststenotic dilatations, and most occur in the setting of atherosclerosis [142]. Saccular aneurysms are more prone to rupture, thrombosis, or fistulization. Both saccular and fusiform aneurysms occur singly or in multiple patterns. They are most commonly located in the proximal and middle RCA (40–87%), followed by the LAD (25–50%), the circumflex coronary artery (24–50%), and the LMCA (7%) [142–148]. Aneurysms are caused by destruction of musculoelastic elements of the vessel wall leading to increased wall stress and dilatation [142–145,148–150]. Disease starts in the media, not in the intima, as attested by aneurysm development in the absence of atherosclerosis [141,146–149,151]. Inflammatory reactions, focal calcium, subintimal fibrosis, and lipoid material may coexist in the vessel media (Figure 38.20) [142,152].

Markis and colleagues in 1976 were the first to propose an angiographic classification [149]. Type I has diffuse ectasia of two to three vessels. Type II has diffuse ectasia of one vessel and localized ectasia in one other. Type III has diffuse ectasia in one vessel only, and type IV has localized ectasia in one vessel.

The Coronary Artery Surgery Study [148] proposed another classification of aneurysms in patients with ACAD. Group A patients have an aneurysm but no ACAD. In group B an aneurysm is present in association with atherosclerosis with less than 70% stenosis. In group C an aneurysm is present as is ACAD with more than 70% stenosis.

Most aneurysms are secondary to atherosclerosis (50%) or other conditions, including Kawasaki disease, trauma, polyarteritis nodosa, Takayasu's disease, syphilis, bacterial infection, septic embolism, dissection, scleroderma, metastatic tumor, and iatrogenic insults after angioplasty or stent placement [146,147,149–151]. Congenital aneurysms account for 20–30% of coronary aneurysms [151], associated with Ehlers-Danlos syndrome, Marfan disease, cyanotic congenital heart disease, and supravalvar aortic stenosis [141,144].

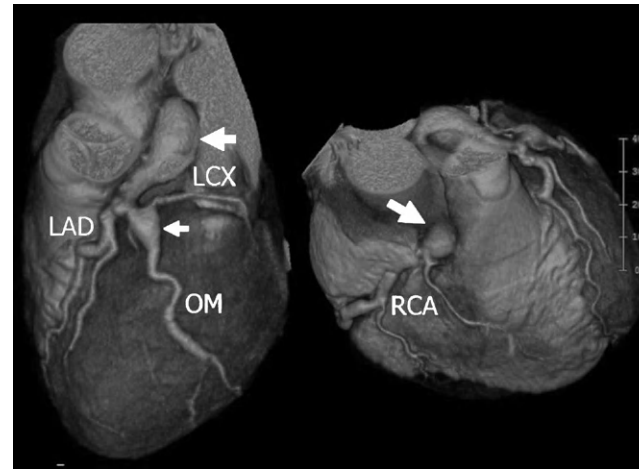

Figure 38.20 Volume rendering image from the cranial left anterior oblique view (left) showing the enormously dilated left main coronary artery (large arrow) and an aneurysm of the left circumflex artery (small arrow). Volume rendering image from the cranial right anterior oblique view (right) showing an aneurysm of the right coronary artery (arrow). (LAD, left anterior descending artery; LCX, left circumflex artery; OM, obtuse marginal artery; RCA, right coronary artery.) (Reproduced with permission from Ayusawa *et al*. [152].)

Aneurysms represent the most common manifestation of Kawasaki disease (15–20%) [146,147], and Kawasaki disease has been reported as the most frequent etiology causing aneurysms [150,153]. Some authors consider aneurysms a subset of atherosclerosis, having a prognosis no worse than that of coronary artery disease without aneurysms [141,144,147,153]. An association with abdominal aortic aneurysms and hyperlipidemia is suspected, but the true incidence is unknown [141,144,146,148,151].

Symptoms are frequent, most being indistinguishable from those of ACAD symptoms, namely angina, congestive heart failure, and myocardial infarction. The risk factors are the same as in ACAD [142,148,151]. Hypertension, abnormal ischemic ECG, and a family history of the disease [148] are more frequently encountered in patients with aneurysms [141,144,147,149] than in patients with coronary artery disease without aneurysms. The physical finding of a systolic murmur is inconsistent. Diagnosis can be made by an ECG or by echocardiography [146,147,150,151,153]. Angiography is still the standard diagnostic tool, although newer imagery with MRI and CT scanning is rapidly gaining popularity, allowing for very precise anatomic definition (Figure 38.20) [152].

The pathogenesis of ischemia and myocardial infarction is unclear if there is no associated atherosclerosis. It is postulated that local changes in flow and thrombosis in an aneurysm and subsequent embolization to the distal coronary artery could cause ischemia and left ventricular dysfunction [141,144,151]. Aneurysms are more frequently associated with three-vessel coronary artery disease (42.3%). Given the same left ventricular ejection fraction, there is a higher observed rate of myocardial infarction in those patients with aneurysms, but this finding may simply reflect a higher prevalence of three-vessel coronary artery disease.

Medical treatment has not improved the functional class of patients with aneurysms [141,144,151]. There is no difference in 5-year survival rate between medical management of aneurysms alone and that of aneurysm associated with atherosclerosis [146,148]. The short-term prognosis (24 months) after medical management of aneurysmal disease is the same as that of medically managed three-vessel coronary artery disease [149]. In patients with symptoms, prognosis is poorer and death of myocardial infarction is more probable if no surgery is performed [149].

Surgery is warranted for coronary aneurysms associated with atherosclerosis as it is for ischemic coronary artery disease without aneurysm [141,142,144–146,148,149]. In the absence of associated atherosclerosis with isolated aneurysmal disease, it is unclear if prophylactic surgery is warranted. With symptoms, bypass surgery with saphenous vein graft or left internal mammary artery (Figure 38.21) [12] carries the same low mortality and incidence of postoperative myocardial infarction at follow-up evaluation, as regular coronary artery disease surgery [148]. Accordingly, mortality 5 years after repair of aneurysms alone is similar to that for simple coronary artery disease [146,148]. Techniques for repair of saccular aneurysms include lateral aneurysmorrhaphy, thrombectomy, and endarterectomy.

In conclusion, coronary aneurysms are a surgical disease with the same operative indications and risk factors as ACAD. The approach to complicated aneurysms, that is, thrombosed, occluded, or ruptured aneurysms, is tailored according to individual findings. No current surgical consensus exists as to the superiority of thrombectomy, endarterectomy, ligation, or aneurysmorrhaphy in addition to bypass of a stenotic aneurysm.

Markis' angiographic classification (I–IV) addresses the morphology, number of lesions, and extent of aneurysmal disease. This classification appears complete and has been adopted by the STS Congenital Heart Surgery Nomenclature and Database Project [2].

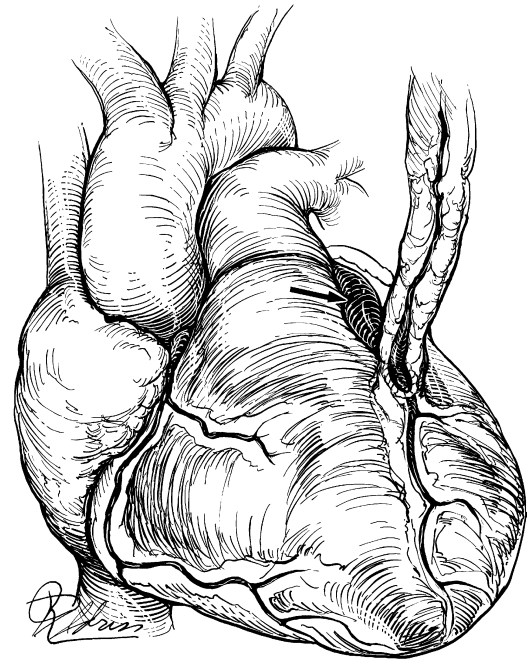

Figure 38.21 Internal thoracic artery bypass to midanterior left anterior descending coronary artery distal to saccular aneurysm.

Coronary Aneurysms in Kawasaki Disease

Coronary artery involvement in Kawasaki disease was first described by Kato *et al*. in 1975 [154]. Aneurysms and ectasia are present in 12.8–25% of patients with unmanaged Kawasaki disease and thus represents the most common cause of acquired coronary artery disease in children [154–169]. This consists of a vasculitis involving the arterioles, capillaries, and venules; the coronary wall undergoes focal and segmental destruction leading to aneurysm formation [154,156]. The inflammatory insult to the endothelium and coronary wall may be followed by remodeling and/or revascularization, with intimal proliferation and angiogenesis, leading to accelerated atherosclerosis [157] and stenosis [166]. Virtually all other cardiac structures may be involved, including the pericardium, myocardium, endocardium, and valves [166].

Diagnosis of cardiac lesions may be made with echocardiography and coronary angiography. Although aneurysms rarely develop before 10 days after the onset of illness, echocardiography may show perivascular brightness, ectasia, and lack of coronary tapering representing coronary arteritis in the acute stage [166]. Also, left ventricular function, mitral valve insufficiency, and pericardial effusion may be evaluated [166]. The American Heart Association (AHA) classifies aneurysms as small (<5 mm internal diameter), medium (5–8 mm), or giant (>8 mm internal diameter). The most common sites include the proximal LAD, the proximal RCA, followed by the LMCA [166]. Aneurysms of the LMCA usually do not involve the orifice unless the rare association of both LAD and circumflex artery aneurysms occurs [166]. Systemic aneurysms may occur with coronary aneurysms [162,166,168], and are associated in 0.6–11.5% of cases. These aneurysms are most

commonly found in the subclavian artery, the internal mammary artery, the iliofemoral arteries, the abdominal aorta, and the renal arteries [167].

In 1982, Kato and associates [164] proposed an angiographic classification, based on anatomic and clinical findings at follow-up evaluation 4 years after acute disease. This classification divides patients into four groups. Group I represents 50% of Kawasaki patients, who have regression of aneurysm, no symptoms, no electrocardiographic changes, and a negative thallium test result. Group II Kawasaki patients (24%) have an unobstructed aneurysm. Group III patients (17%) have an obstructed aneurysm. Group IV patients (9%) have a nonstenotic irregular arterial wall.

Several scoring systems exist to predict the risk of aneurysm development in Kawasaki disease. Risk factors include male sex, age younger than 1 year, persistent fever longer than 14 days or recurrent fever, hemoglobin concentration less than 10 g/dL, white blood cell count greater than 30 000/μL, thrombocytopenia [166], erythrocyte sedimentation rate greater than 101 mm/hour, increased C-reactive protein level for more than 30 days, ischemia or myocardial infarction [170], and age older than 5 years [156]. Anemia is a strong predictor of aneurysm development and is of the normochromic normocytic type [154]. Follow-up for established aneurysms consists of a baseline echocardiographic study 6–8 weeks after acute onset, followed by echocardiographic assessment 6 and 12 months later. Coronary angiography is rarely recommended before the initial 6–12 months after onset of illness, unless clinical symptoms develop. At follow-up evaluation, the decision to perform angiography may be guided by echocardiographic findings or other noninvasive diagnostic methods suggesting ischemia [166]. Even healed vessels, as documented by angiography or echocardiography, may present with atherosclerosis, calcification, and a decreased response to vasodilators owing to depressed endothelial function [166].

Coronary aneurysms may either progress toward thrombosis of the lumen and stenosis or more rarely expand and rupture [166]. Occlusion of the coronary arteries exists in 66.1% [157,167] of cases, involving most commonly the RCA (61.5%), the LAD (53.8%), and the circumflex coronary artery (12.8%). Collateralization exists in 44.1% of cases. Giant aneurysms may evolve into life-threatening coronary lesions in 1% of patients [156,166,167] and typically do not regress [155,160,161,167]. These aneurysms progress to occlusion, myocardial infarction, and sudden death [155,160,162]. Conversely, 50% of smaller aneurysms regress within 1 year [154,156,164,165], and most of the others regress up to 2 years after initial presentation [164]. Actuarial persistence of all aneurysms combined is 72% at 1 year and 41% at 5 years [155,161,162].

High-dose intravenous gamma-globulins and aspirin have reduced the prevalence of aneurysm development to 5–10% if treatment is initiated within the first 10 days of illness [154,156,162,166,167]. Newer therapies including abciximab, a platelet glycoprotein receptor inhibitor, plasma exchange, or cyclophosphamide are still awaiting evaluation [166]. Angiographic resolution has occurred in up to two-thirds of lesions by 1 and 2 years after disease onset [166]. Factors positively associated with aneurysm regression include smaller initial size, age at onset of Kawasaki disease less than 1 year, female gender, fusiform rather than saccular, and distal segment aneurysms [155,166].

Myocardial infarction complicates the cases of 1.5% of all patients with Kawasaki disease and 11.3% of those with documented coronary disease. It is specific to patients with giant aneurysms [155], and the highest risk for infarction is within the first year after presentation [168]. Curiously, myocardial infarction is present in 35% of patients with healed coronary lesions and in 25% of those with acute coronary lesions. Mortality from myocardial infarction is high and approximates 25% [161,164].

Surgical Management

Excision or plication of coronary aneurysms have been attempted with poor results, even leading to death, and should be abandoned. Although not firmly established by clinical trials in children, indications for coronary artery bypass grafting include severe proximal stenosis (>75%), left main stenosis, proximal LAD stenosis, ischemia post-percutaneous transluminal coronary angioplasty, and proximal aneurysms [155,160,166,167]. The rationale for coronary artery bypass graft is the unacceptable rate of myocardial infarction or sudden death without surgery [155]. Furthermore, all stenotic lesions develop proximal or distal to aneurysms that are otherwise prone to rupture and/or thrombosis [30]. Saphenous vein bypass is used with good results and low mortality and has a 67% patency at 1-year angiographic follow-up evaluation [169,171]. The internal mammary artery has far better long-term patency and growth potential (86–100% at 1 year) [30,163,171]. Kitamura and associates [172] advocate the use of bilateral internal mammary artery grafts to the LAD and RCA and report no sternal infections or adverse effects on chest wall development in the pediatric population.

Patent and nonstenotic aneurysms present a particular problem, in that localized flow perturbation and stasis may be responsible for acute coronary events. If grafted, patent aneurysms can be subject to postoperative thrombosis with resulting myocardial infarction and possible death. The current recommendation is therefore to graft only stenotic vessels [166,169]. Indications for percutaneous transluminal coronary angioplasty in the management of Kawasaki disease are the same as for ACAD, namely, localized proximal stenosis [173]. A predictor of successful coronary angioplasty is the time elapsed between the onset of acute illness and the procedure, ideally within 6–8 years. Good

results are obtained with a reduction in stenosis from 84% to 33% (p <0.05) [173]. Percutaneous transluminal coronary angioplasty does not seem to be indicated in the treatment of children older than 10 years or in those whose coronary arteries reveal calcification on fluoroscopy.

Transplantation has been performed for end-stage heart disease in patients with Kawasaki disease. Indications for transplantation include left ventricular dysfunction from myocardial infarction, ventricular arrhythmias and cardiac arrest, and multivessel or inoperable coronary artery disease [160]. Rejection rate is 20% with routine triple-therapy immunosuppression. At 1–6 years' follow-up evaluation, no atherosclerotic aneurysm has been documented to suggest recurrence of Kawasaki disease in the transplanted heart [160].

In summary, Kawasaki disease has become the leading cause of acquired heart disease and coronary artery involvement in the United States and Japan [166]. Coronary aneurysm and ectasia develop in 15–25% of untreated children, and high-dose intravenous immunoglobulin has decreased the incidence of late aneurysm development, with angiographic resolution in up to 50% of cases. Coronary aneurysms may develop progressive stenosis or occlusion leading to ischemia and infarction, most commonly in the first year after disease onset. The experience with angioplasty in children is limited. Surgical therapy includes coronary artery bypass grafting with good midterm results. Cardiac transplantation is feasible without documented recurrence in the graft but should become an exception in the current era of appropriate coronary follow-up evaluation.

CHAPTER 39

Cardiac Tumors

Rüdiger Lange and Thomas Günther
German Heart Center, Technische Universität München, Munich, Germany

Historical Background

The first description of a primary cardiac neoplasm is credited to Matteo Realdo Colombo in 1559 [1]. During the autopsy of Cardinal Gambara, Columbo discovered a left ventricular polypus tumor. In 1666 Malpighi, in his dissertation "De polypo cordis" described for the first time a postmortem clot formation in the right and left sides of the heart [2]. The first report of a cardiac tumor in a living patient was not made until 1934, when Barnes *et al*. diagnosed a primary cardiac sarcoma with the aid of electrocardiography and biopsy of a peripheral metastatic lymph node [3]. Claude S. Beck performed the first successful resection of an intrapericardial teratoma in 1936 [4]. The first successful resection of an epicardial lipoma was performed in 1951 by Mauer [5]. In 1951 Goldberg and colleagues first diagnosed a left atrial myxoma in a 3½-year-old child by angiography but attempts at surgical removal were unsuccessful [6]. The first echocardiographic diagnosis of an intracardiac tumor was made in 1959 [7]. In 1952 Bahnson and Newman attempted to remove a large right atrial myxoma in a 54-year-old woman via right anterior thoracotomy using caval inflow occlusion, but the patient expired 24 days later [8]. Subsequently, Crafoord in 1954 employed cardiopulmonary bypass to perform the first successful resection of an atrial myxoma [9]. During the past three decades, the development and refinement of noninvasive imaging modalities as well as the technical advances in heart surgery have profoundly changed the diagnosis and treatment of cardiac tumors.

Nomenclature

Following the definitions proposed by Mehta and Myers [10], cardiac tumors are defined as an "abnormal growth of tissue in or on the heart, demonstrating partial or complete lack of structural organization, and no functional coordination with normal cardiac tissue." Cardiac tumors may be divided into two categories: primary cardiac tumors that arise from tissues of the heart and secondary cardiac tumors that arise from tissues distant from the heart, with subsequent spread to the normal tissues of the heart. Primary cardiac tumors include the following types: myxoma, papillary fibroelastoma, rhabdomyoma, fibroma, lipoma, teratoma; hemangioma; lipomatous hypertrophy of the interatrial septum, mesothelioma of atrioventricular (AV) tissue, pheochromocytoma, sarcoma, cardiac lymphoma, cardiac thrombus, and cardiac vegetation. Secondary cardiac tumors are either metastatic extensions from a remote organ system, which spread to the heart through direct hematogenous or lymphatic routes, or direct extensions of tumors originating from contiguous thoracic or infradiaphragmatic structures. The latter abdominal or pelvic tumors may spread cephalad through the inferior vena cava to the right atrium [10].

Incidence

Primary cardiac tumors are rare in all age groups. The reported incidence in autopsy series varies between 0.0017% and 0.28% [11]. Reynen analyzed the data of 22 large autopsy series to approximate the true incidence and found the frequency of primary cardiac tumors to be approximately 0.02% corresponding to 200 tumors in 1 million autopsies [12].

In the pediatric age group the incidence of primary cardiac tumors is reported to be 0.027% based on the analysis of 11 000 pediatric autopsies reviewed by Nadas and Ellison in 1968 [13]. However, with the improvement in noninvasive imaging techniques, the more intensive routine echocardiographic screening of children, and the increasing application of fetal ultrasonography in recent

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.
© 2013 Blackwell Publishing Ltd. Published 2013 by Blackwell Publishing Ltd.

decades, pediatric cardiac tumors are diagnosed with an increasing frequency [14,15]. In a 1995 multicenter review of 14000 fetal echocardiograms, cardiac tumors were detected in 0.14% [16]. Beghetti and associates analyzed 27640 infants and children assessed for cardiac disease over a 15-year period and noticed an increase in tumor recognition from 0.06% to 0.32%. [15]. About 14% of all cardiac tumors occur in patients who are less than 16 years of age [17].

The majority of primary cardiac tumors are benign ranging between 72% and 94% in selected series [11,18–23]. The myxoma is the most common tumor type in adult patients accounting for approximately 50% of all primary tumors, followed by papillary fibroelastomas, fibromas, and lipomas [11,22,23]. In pediatric patients, more than 90% of primary cardiac tumors are benign [24]. Nearly one-half of the tumors are rhabdomyomas, followed by fibromas, intrapericardial teratomas, myxomas, and hemangiomas [18,25-29]. Rhabdomyomas, fibromas, and intrapericardial teratomas are more common in newborns and infants; myxomas predominate in older children and adolescents. Table 39.1 summarizes the approximate frequency of occurrence based on collective series [13,18,30] of primary cardiac tumors in infants and children. Approximately one-fourth of all tumors diagnosed in adults are malignant [11]. The majority (75–95%) of these tumors are sarcomas [31–33]. Primary malignant cardiac tumors in pediatric patients are exceedingly rare (<10%) [18,24,30,34].

Secondary cardiac tumors are 20–40 times more common than primary cardiac neoplasms [11,35–38]. The incidence of secondary tumor involvement in pediatric patients in autopsy series was 5.7% [30]. In adults the most common tumors causing secondary involvement of the heart are carcinomas (lung, breast, pancreas, kidney, gastrointestinal, ovary, and testes) followed by malignant melanoma, non-Hodgkin's lymphoma, and various soft tissue and bone sarcomas [10,30,39]. In children, the most frequent primary tumors are in descending order of frequency; non-Hodgkin's lymphoma, neuroblastoma, Wilms' tumor, soft tissue and bone sarcomas, and hepatoma [30].

Tumor	Age 0 to 1 year n (%)	Age 1 to 15 years n (%)
Rhabdomyoma	28 (62)	35 (45)
Teratoma	9 (21)	11 (14)
Fibroma	6 (13)	12 (15.5)
Hemangioma	1 (2)	4 (5)
AV node mesothelioma	1 (2)	3 (4)
Myxoma	–	12 (15.5)
Neurofibroma	–	1 (1)
Total	**45 (100)**	**78 (100)**

Clinical Appearance

Although each tumor type has its characteristic features, general comments can be made regarding the spectrum of their clinical appearance. The clinical manifestations of cardiac tumors vary considerably from asymptomatic presentations to life-threatening cardiac events [24,40]. Because various cardiac diseases may be mimicked [40,41], the presence of a cardiac tumor should always be considered in the differential diagnosis.

The symptoms are usually related to the size, location, invasiveness, number, and rate of growth of the tumor rather than the histological tumor type [15,21,42]. Symptoms are caused by tumor-related intracardiac obstruction, compression of the heart or the great vessels, embolization of tumor fragments or adherent thrombi, and tumor infiltration [29,42–45].

Cardiac tumors often remain asymptomatic until they reach an advanced stage and many tumors are discovered incidentally during routine screening. In the series of Beghetti and associates, 30 of 56 patients (54%) exhibited no symptoms and were diagnosed during routine screening for tuberous sclerosis, assessment of a cardiac murmur or even prenatally [15]. If symptoms occur, they are usually nonspecific, such as heart murmur, arrhythmia, dyspnea, and congestive heart failure [15,24,27,29,40,46].

Syncope and signs of systemic embolization (stroke, retinal, coronary mesenteric, or renal artery emboli as well as emboli to the arteries of the extremities) are also common. ElBardissi and associates reported a 25% rate of tumor embolization, most often associated with aortic valve and left atrial tumors [47]. In 30–91% of the cases, cardiac rhabdomyomas were associated with tuberous sclerosis [15,25,26,46]. These patients may present with seizures as the leading symptom. Constitutional unspecific symptoms such as fever, night sweats, arthralgia, weight loss, and fatigue are not uncommon [21,40].

Right atrial tumors may cause symptoms of right heart failure and produce the characteristic murmurs of tricuspid insufficiency or stenosis. Tumors involving the right atrium have been mistaken for congenital cardiac lesions, including Ebstein anomaly and tricuspid stenosis. Because of substantial increase in right atrial pressure, these tumors may produce cyanosis by virtue of right-to-left shunting across a patent foramen ovale [48,49]. Intracavitary tumors of the right ventricle also have been associated with right heart failure as a result of obstruction or valvar dysfunction. Tricuspid insufficiency and right ventricular outflow tract obstruction have been described [49], with the latter

mimicking pulmonary atresia with intact ventricular septum. Right heart failure may also be a consequence of extensive intramural tumor infiltration of the right ventricle. Thrombi or tissue fragments from right-sided cardiac tumors may embolize to the pulmonary circulation and cause pulmonary hypertension [48,50]. Left atrial tumors typically mimic mitral valve disease. Murmurs and hemodynamic findings consistent with mitral stenosis and insufficiency have been described. Left atrial myxomas may produce obstructive symptoms only intermittently, particularly when the patient assumes the upright position [30]. Systemic embolization of left atrial myxomas is a well documented phenomenon. The diagnosis is made by histologic examination of the embolic material or by echocardiography during a search for the embolic source. Tumors encroaching on the left ventricular cavity may produce mitral regurgitation as well as inflow or outflow tract obstruction. The differential diagnosis of such tumors includes aortic stenosis, subaortic stenosis, hypoplastic left heart syndrome [51], and hypertrophic cardiomyopathy. Extensive infiltration of a tumor into the left ventricular myocardium has resulted in cardiac failure, as well as myocardial ischemia from coronary compression [52]. In the fetus, left heart tumors can become apparent as nonimmune hydrops fetalis [53]. Rhythm disturbances are another initial feature of pediatric cardiac tumors. Virtually every type of arrhythmia has been reported [54] in patients with underlying cardiac tumors, with the type of arrhythmia primarily related to the location of the tumor. Involvement of the conduction system may yield preexcitation syndrome, bundle branch block, or various degrees of AV block [53–56]. In addition, both supraventricular and ventricular tachycardia have been described, the latter being particularly associated with fibromas, hamartomas, and rhabdomyomas [15,24,57]. Sudden death also has been reported with a variety of tumors [28]. Any child who exhibits an unexplained arrhythmia should be evaluated with echocardiography to rule out an underlying cardiac neoplasm.

Diagnostic Modalities

Chest Roentgenography

Although over 80% of patients with cardiac tumors may present with abnormalities on their chest X-ray, these abnormalities are nonspecific [58]. Cardiomegaly, mediastinal widening, pleural effusions, congestive heart failure, and pulmonary edema are common findings. Occasionally, primary cardiac tumors, particularly fibromas, may calcify and become evident on plain chest radiographs [48,59]. Any chest X-ray that reveals an irregular cardiac silhouette or suspicious mediastinal calcification should prompt further investigation for a cardiac tumor [48].

Electrocardiography

In the presence of cardiac tumors, electrocardiographic findings are not uncommon, but are also generally nonspecific. In addition to the rhythm disturbances discussed above, electrocardiographic abnormalities include various degrees of AV block, atrial enlargement, ventricular hypertrophy, and ST-T segment changes. Focal ST-T segment abnormalities may herald myocardial ischemia owing to coronary artery compression, while diffuse ST-T segment abnormalities and low voltage have been associated with extensive intramural infiltration by the tumor.

Echocardiography

Echocardiography is the primary imaging technique for the evaluation of cardiac tumors. M-mode and two-dimensional echocardiography provide a safe and effective means for the noninvasive diagnosis in the fetus and in the child [16,25,60–62]. Tumor location, extent, and characteristics (single or multiple, intramuscular or intracavitary, solid or cystic) can be evaluated accurately and rapidly (Plates 39.1–39.4, see plate section opposite p. 594). Associated pericardial effusions are identified, and timely decompression of intrapericardial fluid collections may be performed under ultrasonographic guidance. With the addition of color-flow Doppler echocardiography, the obstructive nature and hemodynamic significance of cardiac tumors can be assessed, although very small and intramurally located tumors may not be detected. In most cases echocardiography provides accurate imaging of cardiac tumors and eliminates the need for invasive imaging techniques. More intensive routine echocardiographic screening and increasing application of fetal ultrasonography leads to early diagnosis of pediatric cardiac tumors, permits prevention of life-threatening complications, and allows for better planning of postnatal care [21].

Magnetic Resonance Imaging

Echocardiography is very sensitive in predicting the etiology of most intracavitary tumors but is less reliable in determining the nature of intramural or extramyocardial neoplasms [21]. Magnetic resonance imaging (MRI) provides complementary information to echocardiography [63,64]. Magnetic resonance imaging helps to elucidate the relationship of the tumor to the normal myocardium and the great vessels [63–66]. It provides information on tumor location, size, and boundaries (Figure 39.1). Another promising attribute of MRI is its ability to characterize certain tissue types, thus enhancing its value as a noninvasive diagnostic tool. For example, a lipoma exhibits a characteristic appearance on MRI [67] (Figure 39.2). This feature is particularly valuable in planning the extent and feasibility

of tumor resection [65,66]. Tumor size, location, and borders can be determined by T1-weighted standard spin echo [68]. Fast gradient cine magnetic resonance angiography sequences provide information on the hemodynamic consequences of the tumor. The addition of spatial modulation of magnetization (tagging) is helpful in the differentiation of normal myocardial motion from that of the noncontracting tumor [65]. A T2-weighted spin echo sequence is useful in distinguishing vascular tumors, such as hemangiomas, from avascular tumors, such as fibromas [68]. Generally, malignant tumors appear to be inhomogeneous, infiltrate the adjacent tissues, and are often associated with pericardial or pleural effusions [69]. The major shortcoming of MRI for imaging cardiac tumors in younger patients is that it requires deep sedation or even general anesthesia to eliminate artifacts caused by respiration and patient movement. Furthermore, uncontrollable tachyarrhythmias may also produce motion artifacts and thus preclude the use of MRI for cardiac imaging [70].

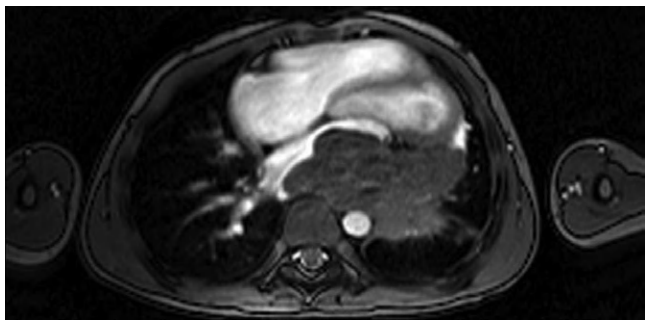

Figure 39.1 Malignant fibrous histiocytoma, magnetic resonance image. Axial T1-weighted magnetic resonance imaging demonstrating a malignant fibrous histiocytoma infiltrating the left atrium and the posterior wall of the left ventricle. (Courtesy of Dr. Albrecht Will, Department of Radiology, German Heart Center, Munich, Germany.)

Angiography

Angiography once was considered the primary imaging modality for the diagnosis of cardiac tumors. Today however, cardiac catheterization is complementary in cases with associated congenital heart disease or in selected cases where hemodynamic evaluation is required. It is of particular importance in patients with suspected coronary artery disease [21]. In addition, electrophysiologic mapping at the time of angiography may identify the exact arrhythmogenic site in children with small or multiple tumors [15,24]. In the rare case in which a nonoperative tissue diagnosis is desired, transcatheter biopsy may be employed, with the inherent risk of tumor hemorrhage and tumor fragment embolization [71,72].

General Principles of Surgical Resection

Although the exact surgical management of a cardiac tumor depends largely on the site and extent of the mass,

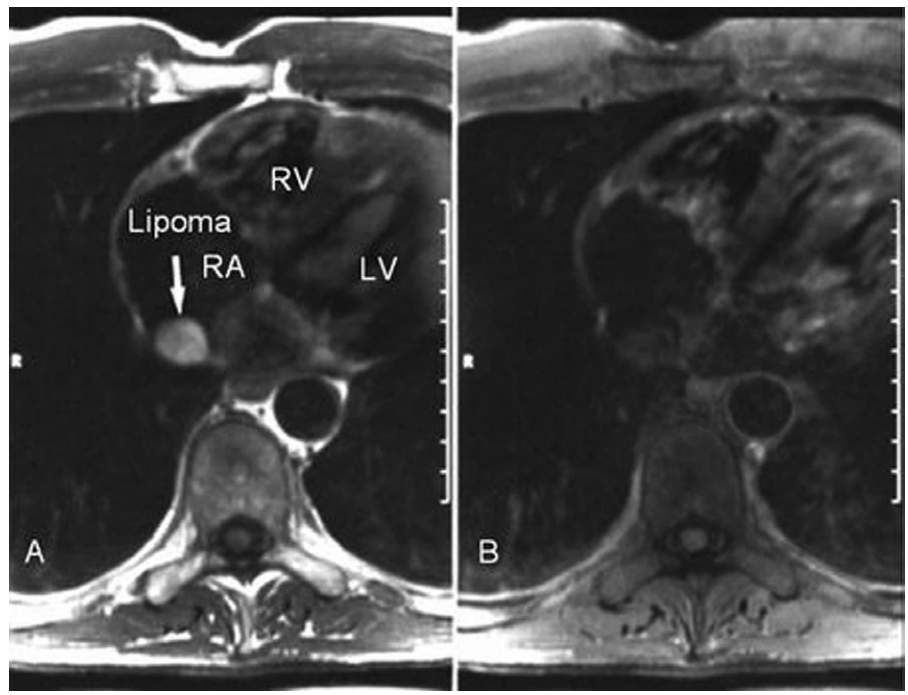

Figure 39.2 Lipoma, magnetic resonance image. Axial T1-weighted image (**A**) and with fat suppression (**B**). (LV, left ventricle; RA, right atrium; RV, right ventricle.) (Courtesy of Dr Albrecht Will, Department of Radiology, German Heart Center, Munich, Germany.)

some general comments regarding surgical resection are appropriate. Excision of virtually all intracardiac tumors requires the use of cardiopulmonary bypass, with tumor location occasionally mandating alternative cannulation sites. In contrast, most intrapericardial tumors may be excised without using cardiopulmonary bypass.

Tumors arising from the atria are approached directly through an atriotomy. A left atrial tumor can be approached through the right atrium and across the interatrial septum at the fossa ovalis.

Right ventricular tumors are usually amenable to resection via a right atriotomy and retraction of the tricuspid valve, thus obviating the need for a right ventriculotomy. Beghetti and associates report the case of a newborn with a huge right ventricular fibroma causing inflow obstruction who underwent partial resection associated with bidirectional cavopulmonary connection [73].

Surgical extirpation of left ventricular tumors, particularly those involving the outflow tract, may prove challenging [74]. In the interest of avoiding a left ventriculotomy, some tumors may be excised via a retrograde technique involving an aortotomy and retraction of the aortic valve leaflets (Plate 39.5, see plate section opposite p. 594). However, the small size of the neonatal aortic annulus may prevent complete resection via the retrograde technique, necessitating a concomitant antegrade approach via a left atriotomy and through the mitral valve. In cases of extensive left ventricular outflow tract and aortic valve involvement, the Ross procedure has proved successful [75]. A tumor mimicking hypoplastic left heart syndrome may require a variant of the Norwood operation [51,76].

General Considerations of Treatment Strategies

The vast majority of primary cardiac tumors in pediatric patients are benign. Tumor growth is slow and generally not invasive. Mechanical compromise and not the neoplastic potential should be considered [77]. Rhabdomyomas are the most common type of tumor and spontaneous regression has been reported in 50–100% of these patients [15,29,78–80]. Therefore, a conservative approach is advocated to allow the tumor to regress, and surgery is indicated only for severely symptomatic patients with hemodynamic compromise or patients with refractory dysrhythmias [15,25,27,29,41,77,79].

When an operative resection is required, the surgeon will usually attempt a complete resection [81]. Some authors even state that it should be the primary goal to remove the tumor as radically as possible in any case and to remove any potential obstruction [24,82]. Extensive myocardial involvement of the tumor or its proximity to critical structures (e.g., great vessels, coronary arteries, valves) may preclude complete excision. In many such circumstances, partial resection is appropriate [83] and can be accomplished with satisfactory results [73,84]. Thus, total resection of the tumor is not the only therapeutic aim, and some authors argue that it is more important to restore the best possible heart function [41,77]. For malignant and unresectable benign tumor cardiac explantation, extracorporeal tumor excision and autotransplantation or orthotopic cardiac transplantation has been proposed to achieve complete resection [85–88]. The ultimate role of cardiac transplantation in treating malignant neoplastic disease in infants and children needs to be established.

The specific treatment for each type of cardiac tumor, as well as the indications for and outcome of each treatment, are discussed in more detail below.

Primary Benign Cardiac Tumors

Rhabdomyomas

The rhabdomyoma is the most common primary intracardiac tumor in the pediatric age group, found in 36–78% of pediatric clinical and autopsy series [13,15,25,29,30,34,40, 89,90]. The cardiac rhabdomyoma is a benign tumor of cardiac myocytes.

Rhabdomyoma tends to be more common in neonates and infants [18,80,91], and the majority are diagnosed within the first year of life [18,80]. In the Armed Forces Institute of Pathology series, 78% of patients with rhabdomyomas were younger than 1 year of age [18]. Males are more often affected than females [46,90].

Grossly, rhabdomyomas are white, grey, or yellow nodules that are well circumscribed and nonencapsulated (Plate 39.5, see plate section opposite p. 594). The tumors vary in size from 1 mm to 10 cm [26]. They are often located in the ventricles with equal predilection for the right and left ventricles but can also be found in the atria, at the cavoatrial junction, within the papillary muscles, within the myocardial wall and the septum, or even on the epicardial surface [18,26,29,74,90,92]. In 90% of cases, rhabdomyomas emerge from multiple sites (Plate 39.1, see plate section opposite p. 594). Although rhabdomyomas tend to reside in an intramural location, they may grow also in an intracavitary fashion and fill an entire cardiac chamber causing outflow or inflow tract obstruction. Small lesions may involve the conduction system causing dysrhythmias [26,92].

Histologically, rhabdomyomas are characterized by large, round, or polygonal cells with clear cytoplasm and abundant glycogen. Classic "spider cells" feature a central cytoplasmic mass containing the nucleus, with thin projections extending toward the cell membrane. Calcification or fibrosis is rare [26]. These tumors occur most frequently in neonates and infants, often regress over time, and are composed of cells without mitotic activity. Rhabdomyomas are believed to represent fetal hamartomas rather than true cardiac neoplasms [90].

In 1862 von Recklinghausen first described the coincidence of cardiac tumors and intracerebral sclerotic areas in a newborn baby [93]. Up to 91% of children with rhabdomyomas will have associated tuberous sclerosis [15,20,26,74,94,95]. Conversely, patients with tuberous sclerosis develop cardiac rhabdomyomas in 43–67% of cases [79,91,92,96]. Tuberous sclerosis is an autosomal dominant inherited disorder with a highly variable phenotype characterized by the development of benign tumors (hamartomas) in multiple organ systems, including skin, brain, heart, lungs, kidney, and liver [91,97]. Although it can affect virtually every organ system, the classic clinical triad of tuberous sclerosis consists of seizures secondary to cerebral cortical tubers, mental retardation, and characteristic skin lesions (adenoma sebaceum). Seizures occur in over 80% of the patients and developmental delay in over 60% [97]. However, because these clinical features may not be detected until later in life, cardiac rhabdomyomas may be the only manifestation in neonates and infants with tuberous sclerosis [98]. All newborns or fetuses with a family history of tuberous sclerosis should be evaluated for cardiac rhabdomyomas [99].

The clinical picture of rhabdomyomas depends on the number, size, and location of these tumors. The most common initial features are cardiac murmur, symptoms of cardiac obstruction, or arrhythmia. Patients with small tumors are generally asymptomatic. Jozwiak *et al*. analyzed 154 patients with tuberous sclerosis and found 74 patients with a cardiac rhabdomyoma. Most (61%) of these tumors were clinically silent [91]. Larger tumors may obstruct the cardiac cavity or associated valves, leading to significant hemodynamic compromise [15,25,74] (Plate 39.5, see plate section opposite p. 594). Subaortic stenosis caused by a pedunculated tumor is a common finding in infants with cardiac rhabdomyoma [26]. Tumors obstructing the right or left AV valve can simulate tricuspid or mitral valve stenosis/atresia. Obstruction of the tricuspid valve may also lead to right-to-left shunting at the level of the foramen ovale, resulting in cyanosis. Involvement of the conduction system may yield serious arrhythmias, including almost any type of atrial or ventricular dysrhythmia including pre-excitation, sinus node dysfunction, and complete AV block [24,26,92].

Many authors consider the combination of the following criteria highly suspicious for the diagnosis of a rhabdomyoma: tumor morphology and location (multiple tumors, located in the ventricles); presence of a single tumor plus involvement of other organs (central nervous system, skin, kidney); and/or a family history of tuberous sclerosis [15,25,27,79]. On echocardiography, rhabdomyomas appear as solid intramyocardial tumors, often involving multiple areas of myocardium. Their structure is homogeneous, representing echo bright densities of varying size (Plate 39.1, see plate section opposite p. 594). Large rhabdomyomas may cause right or left ventricular outflow or inflow obstruction (Plate 39.5, see plate section opposite p. 594). Pericardial effusions have not been reported.

Spontaneous regression of rhabdomyomas is well documented and is reported to be more frequent in younger patients and in those with smaller tumors [26]. Of these patients, 50–100% show partial or complete regression [15,29,78–80]. Farooki and associates, analyzed five patients with cardiac rhabdomyoma associated with tuberous sclerosis and determined a regression rate of 0.9–6 mm/month [80].

Asymptomatic children with cardiac rhabdomyomas can be simply followed with serial echocardiographic examinations. Surgery is indicated in patients with medically refractory arrhythmias and hemodynamically significant obstruction. This is the case in up to 23% of children [15,29,74]. In the study of Beghetti *et al*., nine out of 44 patients exhibited a gradient in the left or right ventricular outflow tract, four with a gradient of >40 mmHg underwent surgery [15]. Critically ill neonates with severe mechanical obstruction and heart failure may be stabilized preoperatively with a prostaglandin E1 infusion to maintain patency of the ductus arteriosus. The primary goal of surgical resection is to excise the tumor. This often mandates only partial tumor excision, when a complete excision would sacrifice vital structures or a critical portion of the myocardial mass [15,24,74,83]. Typically, the remaining rhabdomyomatous tissue will regress spontaneously and cause no further sequelae. This management strategy in children with rhabdomyomas is associated with excellent short-term and long-term prognoses [15,24,29]. Tumor-related reoperations are very rare [15,29].

Fibromas

Cardiac fibromas are the second most common primary cardiac tumors in infants and children, comprising up to 20% [13,15,18,24,30]. Although most fibromas are diagnosed within the first few years of life, some remain quiescent and undiscovered until adolescence or adulthood. Fibromas are benign white, firm, well circumscribed, not encapsulated tumors predominantly located in the left ventricular free wall or the interventricular septum [13,18,20,26] (Plate 39.2, see plate section opposite p. 594). Right ventricular free wall and atrial involvement are rare [26]. In contrast to rhabdomyomas, which tend to be multiple, fibromas generally appear as single tumors [26]. These tumors infiltrate the myocardium. Fibromas may grow to a large size and cause outflow tract obstruction and compression or obliteration of cardiac chambers [24,73,100]. Pericardial effusions have not been reported. According to Freedom *et al*. their average size is about 5 cm in diameter [26]. Cystic degeneration and focal calcification is frequent and is an important diagnostic imaging feature [59]. Neither spontaneous regression nor malignant transformation of fibromas has been reported. A characteristic whorled

appearance is featured on their cut surface and is reminiscent of a uterine leiomyoma. The histologic features of fibromas consist of relatively avascular dense connective tissue in the central portion, with fibroblasts and collagen interspersed with normal cardiac myocytes near the periphery.

As with all cardiac tumors, the initial clinical features of cardiac fibromas are largely dependent on their size and location. Because of their propensity to invade the interventricular septum and conduction system, fibromas often are associated with life-threatening arrhythmias or sudden death [15,56]. In infants with extremely large intramural tumors, severe congestive heart failure from mechanical intracavitary or valvar obstruction may be the primary mode of expression. Occasionally, fibromas may grow to great sizes in older children and yet remain clinically silent, with their presence revealed only by the incidental detection of a heart murmur or cardiomegaly on plain radiography.

On echocardiography, fibromas appear as solid intramural tumors (i.e., homogeneous, echo-bright masses) ranging from a few millimeters to several centimeters in diameter (Plate 39.2, see plate section opposite p. 594). Very large fibromas may herniate into the outflow tract of the right or left ventricle, causing severe outflow obstruction. Embolic events are rare. The indication for operative treatment of fibromas is very similar to the one described for rhabdomyomas. Even though fibromas do not apparently regress, their presence in an asymptomatic individual does not mandate surgical resection. Although complete resection is the primary surgical goal in treating symptomatic fibromas, contraindications to complete resection include situations in which the conduction system may be violated or a critical mass of ventricular myocardium would be sacrificed [24]. In such cases, partial resection has resulted in immediate clinical improvement and favorable long-term survival [24,73,77,85]. However, in some cases of massive fibroma infiltrating cardiac walls, cardiac transplantation may be the only treatment [86,101].

Myxomas

Myxoma is the most common primary benign cardiac tumor in adults and represents 50% of all benign tumors [13,18,20]. According to MacGowan and colleagues, who reviewed all patients admitted to the national cardiac surgical unit of the Republic of Ireland, the incidence is estimated to be 0.5 per 1 000 000 population per year [102]. Myxomas are rare (0–5%) in pediatric patients and are usually diagnosed in older children and adolescents [15,24,25,29,41]. However, incidental reports describe their occurrence in neonates [48].

An autosomal dominant mode of familial inheritance is discovered in approximately 10% of patients with myxomas as part of the Carney complex [103]. About 75% of myxomas originate in the left atrium and 15–20% in the right atrium [26,104]. Most myxomas arise from the endocardium of the interatrial septum at the border of the fossa ovalis. However, attachments to the posterior or anterior atrial wall and to the atrial appendage have also been described. They may arise from a broad attachment base or be pedunculated [26,104]. Only about 3–4% are located in the right or left ventricle [104]. Although myxomas are generally solitary tumors, multiple and biatrial myxomas have been identified [105]. Multiple tumors and atypical locations are more frequent in cases of familial predisposition [106]. Macroscopically, cardiac myxomas appear as polypoid, often pedunculated, round or oval, white, gray-white, yellowish, or brown masses, with a smooth or gently lobulated surface (Plate 39.6, see plate section opposite p. 594). Polypoid myxomas are compact and show little tendency toward spontaneous fragmentation. The less common villous or papillary myxomas are characterized by a surface with multiple fine villous extensions, which tend to fractionate [104]. Histologically, myxomas consist of a myxoid mucopolysaccharide matrix. Polygonal cells with eosinophilic cytoplasm are dispersed one at a time or in small clusters in the myxoid stroma [26,104]. Myxomas often contain cysts and areas of hemorrhage [104]. About 10% of the tumors show calcification with occasional foci of metaplastic bone [18,35,48,107]. Traditionally, myxomas were believed to be thrombotic in origin. However, most evidence suggests that these tumors actually arise from multipotential mesenchymal cells in the subendocardial region [108].

Although generally regarded as benign, some myxomas have been classified as malignant on the basis of local invasion or tumor recurrence at primary or embolic sites [109]. However, the true malignant potential of this neoplasm remains a controversial issue. There are two groups of patients with tumor recurrence: those with recurrent cardiac myxoma resulting from inadequate surgical excision and those with tumor recurrence at multiple sites. The latter group exhibits a poor prognosis, with a mortality of approximately 50% [26].

Most children with cardiac myxomas are symptomatic, and many suffer from the classic clinical triad of cardiac obstructive symptoms, emboli, and constitutional symptoms. Depending on their size and mobility, myxomas may obstruct the mitral or tricuspid valve during diastole (Plate 39.3, see plate section opposite p. 594) and mimic mitral or tricuspid valve stenosis with subsequent symptoms of congestive heart failure, recurrent pulmonary edema, syncope, or sudden death [110,111]. The extent of the valvar obstruction may vary with the body position [112]. In the typical situation in which a left atrial myxoma intermittently obstructs the mitral valve, symptoms may occur only in an upright position, while recumbency may cause these symptoms to subside. A mobile atrial tumor moving forward and backward across the AV valve into the ventricle can

affect mitral or tricuspid valve closure and cause regurgitation. A tumor with a long pedicle may even prolapse through the AV valve and obstruct blood flow across the aortic or pulmonic valve.

Systolic or diastolic murmurs may be heard in more than half of the patients with myxomas. Diastolic murmurs result from obstructed filling of the left or right ventricle. On auscultation, a mid-diastolic murmur or characteristic "tumor plop" may be evident, the latter of which occurs during prolapse of the tumor through the mitral valve during diastole. Systolic murmurs occur when the tumor interferes with valve closure [104].

The embolic capacity of tumor fragments or thrombotic material overlying a cardiac myxoma is well described. Although most emboli originate in the left atrium and involve the systemic circulation, right-sided atrial myxomas may yield pulmonary emboli or paradoxical emboli through a patent interatrial communication [48,50]. An infant or child who sustains an unexplained embolic event must be evaluated by echocardiography for a cardiac myxoma; in such individuals it is also wise to submit the extracted embolic material for histopathologic analysis. Constitutional symptoms account for the third component of the clinical triad associated with myxomas. Such vague symptoms, which include fever, weight loss, malaise, myalgias, and arthralgias, are often attributed erroneously to a rheumatologic disorder.

An immunologic response to the tumor has been proposed as the basis for these systemic symptoms. Associated laboratory abnormalities include evidence of hemolytic anemia, thrombocytopenia, and an elevated sedimentation rate and C reactive protein level.

On echocardiography, myxomas appear as lobulated intracavitary masses attached by long pedicles to adjacent endocardium (Plate 39.3, see plate section opposite p. 594). Echocardiographic evaluation of left atrial myxomas should include careful M-mode and Doppler evaluation of the mitral valve and its potential involvement.

Right atrial myxomas exhibit corresponding symptoms to left atrial myxomas, necessitating comprehensive interrogation of the tricuspid valve and right ventricular inflow hemodynamics. In addition, because embolic events are common with myxomas, evaluation of all right heart myxomas should include Doppler echocardiographic estimation of pulmonary artery pressures to estimate pulmonary hypertension resulting from recurrent pulmonary emboli. Ventricular myxomas are rarely encountered. Myxomas in the left ventricle commonly attach to the interventricular septum or left ventricular apex by long pedicles, allowing prolapse of the tumor mass, eventually causing dynamic left ventricular outflow obstruction. Right ventricular myxomas arise from pedicles attached to the outflow tract or to the free wall and may cause right ventricular outflow tract obstruction. Broad-based attachments to adjacent right ventricular myocardium should suggest a diagnosis other than myxoma.

The diagnosis of a cardiac myxoma is in general an indication for its surgical removal. Left untreated, many asymptomatic patients with myxomas may suffer an unexpected embolic event. Right and left atrial myxomas are approached through the right atrium via full sternotomy or right anterolateral minithoracotomy. The septum is incised at the fossa ovalis and the base of the tumor identified. Because these tumors are prone to local recurrence, it is essential to excise the tumor completely, along with a rim of normal endocardium around its base. To prevent intraoperative embolization of fragments from these friable tumors, one should avoid undue manipulation of the heart until initiation of cardiopulmonary bypass and application of the aortic cross-clamp.

Intrapericardial Teratomas

Intrapericardial teratomas are composed of multiple tissues of all three germ layers [10,18] and may contain elements of muscle, cartilage, gastrointestinal, respiratory, and neural tissue. In clinical series they represent 8–12% of all tumors [18,25,29,41] and constitute the fourth most common group of primary cardiac tumors in pediatric patients.

About two-thirds of tumors are diagnosed within the first year of life and 50% are discovered within the first month of life [18,113–115]. Approximately 20% of cardiac teratomas are malignant [116].

The majority of teratomas have an extracardial but intrapericardial location. Intracardial teratomas are extremely rare [18,37,117]. Teratomas are large, solitary, cystic, encapsulated tumors (Plate 39.7, see plate section opposite p. 594), which often are attached to the root of the aorta or pulmonary artery by a narrow pedicle [18]. They are usually located anteriorly and to the right side of the mediastinum, nestled between the aorta and superior vena cava [118,119]. Occasionally, intrapericardial teratomas attach to the left side of the ascending aorta, lying over the left atrium and left ventricle [114,120]. Uncommonly, these tumors may arise posterior to the aorta [120]. Older infants and children usually present with small tumors. In neonates and young infants, however, intrapericardial teratomas are rather large.

Because intrapericardial teratomas tend to be very large, they often cause obstruction of the great vessels (superior vena cava, ascending aorta, and pulmonary artery), external compression of the cardiac chambers (right atrium and right ventricle), and pulmonary parenchyma. Furthermore, as opposed to most other benign cardiac tumors, intrapericardial teratomas usually are associated with a voluminous serous pericardial effusion [119].

As a result of these features, the clinical picture is often one of neonatal respiratory distress, heart failure, and

cardiac tamponade, ultimately progressing to death if timely treatment is not undertaken [114,121].

The diagnosis of intrapericardial teratomas is made easily and accurately by two-dimensional echocardiography in both the fetus [118] and infant [122–125]. These tumors appear as single, nonhomogeneous, pedunculated masses within the pericardial sac. Intrapericardial teratomas contain multiple cysts and calcifications, appearing as echolucent and echogenic foci, respectively, on two-dimensional echocardiography (Plate 39.4, see plate section opposite p. 594). Clinically significant pericardial effusions are commonly present in the critically ill neonate or infant [124,126] and are diagnosed by two-dimensional echocardiography. Ultrasonographically guided evacuation of pericardial fluid can be lifesaving for critically ill patients with evidence of cardiac tamponade. However, recurrence of pericardial effusion is the rule if the teratoma is not resected [126]. *In utero* detection of intrapericardial teratomas allows advanced planning and expeditious postnatal surgical resection before the neonate develops severe cardiorespiratory distress [127].

Because all intrapericardial teratomas eventually become symptomatic [119], complete surgical excision should be undertaken as soon as the diagnosis is made. This involves separation of the tumor from the epicardium of the cardiac chambers, as well as division of the pedicle connecting the tumor to the great vessels. Because intrapericardial teratomas normally receive their blood supply from the vasa vasorum of the aorta and pulmonary artery, one should exercise caution when dissecting the pedicle. The great majority of these tumors are completely extracardiac; therefore, cardiopulmonary bypass is rarely necessary for their removal. Early surgical excision of benign intrapericardial teratomas is considered both lifesaving and curative, because to our knowledge recurrence of these lesions has not been reported [128].

Angiomas

Tumors that form vascular channels, such as hemangiomas, lymphangiomas, and other tumors, are benign and rarely involve the heart. Hemangiomas are red, hemorrhagic tumors comprised of endothelium-lined vascular channels of various sizes and contain blood. They may occur in any chamber of the heart, visible as multiple, echolucent areas within the myocardium on two-dimensional echocardiography. Similar to the intrapericardial teratomas, these tumors are often associated with a serous pericardial effusion. Although most of these benign neoplasms are incidental findings, some may produce rhythm disturbances or obstructive symptoms. Surgical resection is indicated for small, well circumscribed, symptomatic hemangiomas [129]. In the absence of symptoms, hemangiomas of all sizes may be monitored with serial echocardiographic examinations [130,131]. However, in symptomatic patients with diffuse tumorous myocardial involvement, even cardiac transplantation may be required.

Hamartomas

The origin of myocardial hamartomas is controversial [27]. This is reflected by the various terms that have been introduced to describe this abnormality (e.g., histiocytoid cardiomyopathy, Purkinje cell tumor, foamy myocardial transformation) [27]. Myocardial hamartomas appear as grayish white nodules primarily involving the endocardial or epicardial surface of the left ventricle [24]. Histologically, the tumor cells resemble modified cardiac myocytes [57]. The individual tumor cells have large numbers of mitochondria [24]. Most of these tumors are diagnosed because the patients experience refractory life-threatening ventricular tachycardia within the first year of life [24,27,51,57,132]. A 2:1 female preponderance was reported in one series [57]. Because myocardial hamartomas are only a few cells thick, these tumors are generally below the threshold of detection by echocardiography [24]. Electrophysiologic studies and intraoperative inspection of the epicardial and endocardial surfaces are the only means of diagnosis. Intraoperative mapping, tumor excision, and cryoablation of the margins of the excision site yield cure and sustained freedom from tachyarrhythmias [24,57,132]. However, in the series of Takach *et al*., 3 of 16 patients required a reoperation within 24 hours because of recurrent ventricular tachycardia [24].

Other Primary Benign Cardiac Tumors

Other exceedingly rare benign pediatric cardiac tumors include lipomas, papillary fibroelastomas, mesotheliomas, and neurofibromas.

In addition, a few cases of so-called cardiac pseudotumors in pediatric patients have been described [133]. These interesting entities, which are considered a benign proliferative response to an unknown stimulus, contain a preponderance of plasma cells and are thus most aptly termed inflammatory pseudotumors. On echocardiography, these tumors appear as homogeneous intracavitary masses, often growing to fill entire cardiac chambers. Although not believed to be truly neoplastic, these lesions may form a tumor-like mass and produce cardiac symptoms identical to those caused by true cardiac tumors. As a result, surgical resection is the preferred treatment in symptomatic individuals. In asymptomatic patients monitored with serial echocardiographic examinations, spontaneous regression usually is observed.

Papillary fibroelastomas, the second most common tumor in adult patients [18,134], are very rare in the pediatric population. Gowda and colleagues reviewed the

literature and identified 725 cases with histologically confirmed fibroelastoma. Only nine patients were children <10 years [134]. Familial occurrence has been reported. These tumors are benign endocardial papillomas with a characteristic flower-like appearance predominantly located on the valvar surface. The aortic valve (36.5%) is the valve most commonly involved, followed by the mitral valve (29.5%) and nonvalvar sites [134]. The tumors vary in size from 2–70 mm. Transient ischemic attack or stroke as well as angina or myocardial infarction are the most common clinical presentation. On echocardiography the tumor appears as a small, mobile, pedunculated or sessile valvar or endocardial mass [134]. The diagnosis of a fibroelastoma is in general an indication for its surgical removal. Surgery is recommended for symptomatic patients as well as asymptomatic patients with a mobile tumor.

Primary Malignant Cardiac Tumors

Primary malignant cardiac tumors are extremely rare accounting for less than 10% of primary cardiac tumors in the pediatric population [18,25,24,29,30]. The majority of these malignant neoplasms represent various types of sarcomas including angiosarcomas, rhabdomyosarcomas, leiomyosarcomas, and fibrosarcomas. Of these, angiosarcomas are the most frequently encountered (Plate 39.8, see plate section opposite p. 594) [19,22,24,33,40,135]. However, in neonates rhabdomyosarcoma seems to be more frequent [28]. Much of the literature describing malignant tumors has been limited to case reports, and there are only a limited number of studies comprising larger series of mainly adult patients [19,33,85,88].

Malignant cardiac tumors often remain asymptomatic until they reach an advanced stage [21]. About one-third of patients exhibit metastatic disease at the time of presentation [33]. Symptomatic patients complain about a variety of symptoms such as dyspnea, atypical chest pain, or congestive heart failure. Pericardial effusions are common. The tumors can arise in any part of the heart [21,33]. On echocardiography, sarcomas are single, homogenous intramural tumors, with extension into adjacent cardiac chambers generally present at the time of diagnosis (Figures 39.1, 39.3).

The prognosis of patients diagnosed with malignant cardiac tumor remains poor. Expected survival in untreated patients is less than 1 year [136]. Metastases to the lungs, liver, and brain are common [33]. In patients with unresectable tumors, a combined chemotherapy (vincristine, ifosfamide, etoposide) and radiotherapy did not improve survival [137]. Patients, who present with metastatic disease, have a median survival of 5 months compared with 15 months for patients without metastatic disease [33]. Even with complete surgical excision the median survival does not exceed 2 years [19,33,135,138].

Figure 39.3 Left atrial myosarcoma, computed tomography. (LA, left atrium; Ao, aorta; LCA, left coronary artery.) (Courtesy of Dr Albrecht Will, Department of Radiology, German Heart Center, Munich, Germany.)

Tumor recurrence is frequent [33]. The role of adjuvant chemotherapy and/or radiotherapy after surgical resection remains controversial. Several studies have failed to demonstrate any benefit [33,138,139,140]. Others, however, have found chemotherapy or radiation to be efficacious in treating primary cardiac sarcomas [141,142]. In an isolated case of a 24-year-old patient with a leiomyosarcoma, Pessotto and associates could achieve complete tumor remission with combined chemotherapy and radiotherapy after surgical excision [143]. The role of cardiac transplantation for treatment of nonmetastatic cardiac sarcoma in infants and children remains controversial [87]. Talbot *et al*. performed a combined heart and lung transplantation in four patients aged 37–45 years with primary cardiac sarcoma [88]. All of these patients had tumor recurrence, and the median survival was only 31 months despite this aggressive approach [88].

Secondary Cardiac Tumors

Secondary involvement of the pediatric heart by extracardiac malignancies is more common than primary cardiac tumors [30]. Chan and associates reviewed clinical and autopsy records of 3641 infants and children with malignant solid tumors and identified 59 patients with secondary cardiac tumors [30]. Forty-five of these presented with metastases from a distant tumor site, and 14 children with a tumor extending directly into the great veins and cardiac chambers [30]. The most common malignancies in

childhood with metastatic spread to the heart are lymphomas, neuroblastomas, and extracardiac sarcomas [30]. Direct tumor extension to the right atrium via the inferior vena cava may occur with primary renal (Wilms' tumor) and hepatic malignancies [30,144]. The clinical symptoms and the tumor appearance are usually dominated by the nature of the primary malignancy. Features directly attributable to cardiac involvement include hemorrhagic pericardial effusions, cardiac compression, and arrhythmias. Aside from resection of Wilms' tumors with intracaval or intracardiac extension or both, the role of surgical intervention for usually incurable malignancies with secondary cardiac invasion is limited. In patients with Wilms' tumors who have thrombus extension into the right atrium, a planned approach using cardiopulmonary bypass and intracardiac exposure has proven safe and effective [145,146]. Initial treatment with chemotherapy has resulted in complete resolution of tumor thrombus in some patients; in others, surgical management was facilitated because of reduction in the size of the tumor thrombus [145,146].

Acknowledgments

The authors wish to thank Richard Henze, MD (Institute of Anesthesiology); Manfred Vogt, MD, (Department of Pediatric Cardiology); and Albrecht Will, MD (Institute of Radiology) for their assistance in providing echocardiographic and MRIs used in this chapter.

CHAPTER 40

Diseases of the Pericardium

Victor O. Morell[1,2] and Ergin Kocyildirim[2]

[1]University of Pittsburgh Medical Center Heart and Vascular Institute, Children's Hospital of Pittsburgh, Pittsburgh, PA, USA
[2]McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Historical Perspectives

The heart is surrounded by a fibroserous sac known as the pericardium, a term derived from the Greek words *peri*, "around", and *kardia*, "heart". It was a Graeco-Roman physician, Claudius Galen, who first described and named this anatomical structure in 160 AD. He was also the first to recognize the deleterious effects of a pericardial effusion on cardiac function. In 1653 the Parisian surgeon, Jean Riolan, recommended aspiration of the pericardial fluid in patients with effusions and proposed trephining of the sternum to provide exposure to the pericardium. In 1749, when the first comprehensive book on cardiac anatomy, physiology, and pathology was published by Jean-Baptiste Senac, a French physician, there was a full chapter dedicated to the pericardium and its diseases.

One of the first clinicians to document the feasibility of surgical interventions in the heart was Louis Rhen, in Germany, who in 1913 performed the repair of a cardiac laceration with evacuation of clots from the pericardial space on a patient who was dying from cardiac tamponade after suffering a stab wound to the chest. His success stimulated other surgeons to pursue surgical approaches for the management of pericardial diseases, like French surgeon Paul Hollopeau, who in 1921 performed the first partial pericardiectomy for the management of constrictive pericarditis.

Embryology and Anatomy

In the human embryo, between week 5 and 7 of gestation, the pericardial cavity is created from the subdivision of the embryonic coelom [1]. Fusion of the pleuropericardial membranes with the foregut mesenchyme posteriorly divides the thoracic cavity into a ventral pericardial cavity and two dorsolateral pleural cavities. Abnormal development of the pleuropericardial membranes results in defects in the pericardial wall [2].

The pericardium is a bilayered sac consisting of a thick stiff outer fibrous layer and a thin inner serous layer. The fibrous outer capsule is mainly made up of collagen and elastin fibers and the serous layer of a thin elastic membrane of mesothelial cells, which envelop the inner aspect of the fibrous pericardium (serous parietal pericardium) and also the myocardium (serous visceral pericardium or epicardium). Between the two layers of the serous pericardium there is a potential space known as the pericardial cavity, which is normally lubricated by a thin layer of fluid (pericardial fluid) (Plate 40.1, see plate section opposite p. 594).

Within the pericardial cavity there are two recesses, the transverse and oblique sinuses, representing reflections of the serous pericardium between the great vessels at the base of the heart (Plate 40.2, see plate section opposite p. 594) [3]. The transverse sinus lies behind the aorta and main pulmonary artery and the oblique sinus extends behind the left atrium in the region between all four pulmonary veins. In order to provide structural support to the heart and prevent excessive cardiac motion within the thoracic cavity, the pericardium is connected to the undersurface of the sternum by the superior and inferior sternopericardial ligaments and to the posterior mediastinal structures by loose connective tissue. Also, the pericardium is attached to the central tendon of the diaphragm.

The main vascular arterial supply to the pericardium is provided by the pericardiophrenic artery, a branch of the internal mammary artery and the venous drainage is via the pericardiophrenic veins, which are tributaries of the

brachiocephalic veins. The phrenic nerves provide the sensory enervation and the sympathetic trunks the vasomotor enervation.

Diseases of the Pericardium

Pericardial disease is defined as a structural or functional abnormality of the visceral or parietal pericardium that may, or may not, have a significant impact on cardiac function. The International Congenital Heart Surgery Nomenclature and Database Project described 12 types of disease processes affecting the pericardium. They were classified as effusive pericarditis (pericardial effusion), constructive pericarditis, cardiac tamponade, postoperative pericardial effusion, postoperative cardiac tamponade, postpericardiotomy syndrome, congenital defect, neoplastic process, benign mass, pericardial cyst, pneumopericardium, and chylopericardium [4,5]. Each group will be discussed briefly with common causes, diagnosis, and medical and surgical treatments.

Effusive Pericarditis

Effusive pericarditis (pericardial effusion) is defined as an inflammatory stimulation of the pericardium that results in the accumulation of appreciable amounts of pericardial fluid. It may be caused by many disorders including idiopathic, viral, uremic, tuberculous, purulent, neoplastic, traumatic, and drug induced. Pericardial effusion may be serous, purulent, or hemorrhagic.

Idiopathic pericardial effusions are quite common in the pediatric population, representing up to 37% of cases in some series [6]. In these patients there is no identifiable cause for the pericardial process. Viral effusions are often, but not always, associated with other signs and symptoms of an acute viral infection. Agents commonly responsible for the development of viral pericarditis include Coxsackie virus, adenovirus, enteric cytopathogenic human orphan (ECHO) virus, influenza virus, mumps virus, varicella virus, Epstein-Barr virus, and human immunodeficiency virus [7,8]. They are characterized by a small to large effusion occurring in children with a pericardial friction rub, which is the most common physical finding. Patients with uremic effusions commonly suffer from renal disease. Approximately 20% of uremic patients requiring chronic dialysis will develop a pericardial effusion during their lifetime [9]. The association between uremia and pericardial effusions has been well described and is recognized as one of the indicators of end-stage renal disease. However, the causes of uremic pericarditis remain uncertain [10].

Bacterial pericarditis can be primary, resulting from contiguous spread of bacteria from a mediastinal and/or pleural source, or secondary, resulting from septicemic spread from a remote source. *Staphylococcus aureus* is the most common organism identified, followed by *Haemophilus influenza* type B. Other bacteria responsible for purulent pericarditis include *Pseudomonas aeruginosa*, *Neisseria meningitides*, *Salmonella* species, *Neisseria gonorrhoeae*, *Listeria monocytogenes*, *Escherichia coli*, *Brucella*, *Yersinia*, *Gemella morbillorum*. Tuberculosis may be associated with a serosanguineous pericardial effusion with predominance of lymphocytes. Purulent pericardial effusions can be life-threatening and occasionally require emergency interventions.

Although primary tumors of the pericardium are rare, neoplastic pericardial effusions are frequently observed in patients with neoplastic diseases and may result from local tumor invasion of the pericardium or from metastatic seeding. Occasionally, it can develop from metastatic spread to the pericardial fluid itself. Blunt or penetrating trauma, including cardiac massage during resuscitation may cause a hemorrhagic pericardial effusion. Minoxidil, anticoagulants, thrombolytics, drugs causing a lupus-like syndrome such as chlorpromazine (Thorazine), hydralazine, isoniazid, minocycline, methyldopa, procainamide and quinidine can be the causes of drug-induced pericardial effusion [11].

Pericardial effusions can be diagnosed based on the history and physical examination, electrocardiography, chest roentgenography, echocardiography, computed tomography (CT), and/or magnetic resonance imaging (MRI). The clinical presentation is determined by the primary etiology and the speed of accumulation of the pericardial fluid. If the effusion develops slowly it can be asymptomatic, while a relatively smaller but rapidly accumulating effusion can present with severe hemodynamic compromise. Large effusions may cause cough and dyspnea owing to compression of adjacent lung tissue and on auscultation distant heart sounds are present. In pericarditis there may be a friction rub, which is best heard on the left border of sternum or in the midclavicular line, between the second and the fourth intercostal space. Large effusions are usually related to neoplastic, tuberculous, or uremic processes.

On chest roentgenography an enlarged cardiac silhouette can be observed in the presence of a large effusion, but a normal cardiothoracic ratio does not rule out smaller effusions (Figure 40.1). The diagnosis is best confirmed by echocardiography, which also documents cardiac filling and ventricular function, determining the presence or absence of cardiac tamponade physiology (Plate 40.3, see plate section opposite p. 594). Computed tomography can easily detect pericardial effusions and is also useful in identifying the characteristics of the fluid (blood, chyle, transudate, etc.). Low voltage on the electrocardiogram (ECG) is a typical finding in patients with pericardial effusions.

The management of pericardial effusions includes both medical and surgical options. In the absence of hemodynamic compromise some of the pericardial effusion may

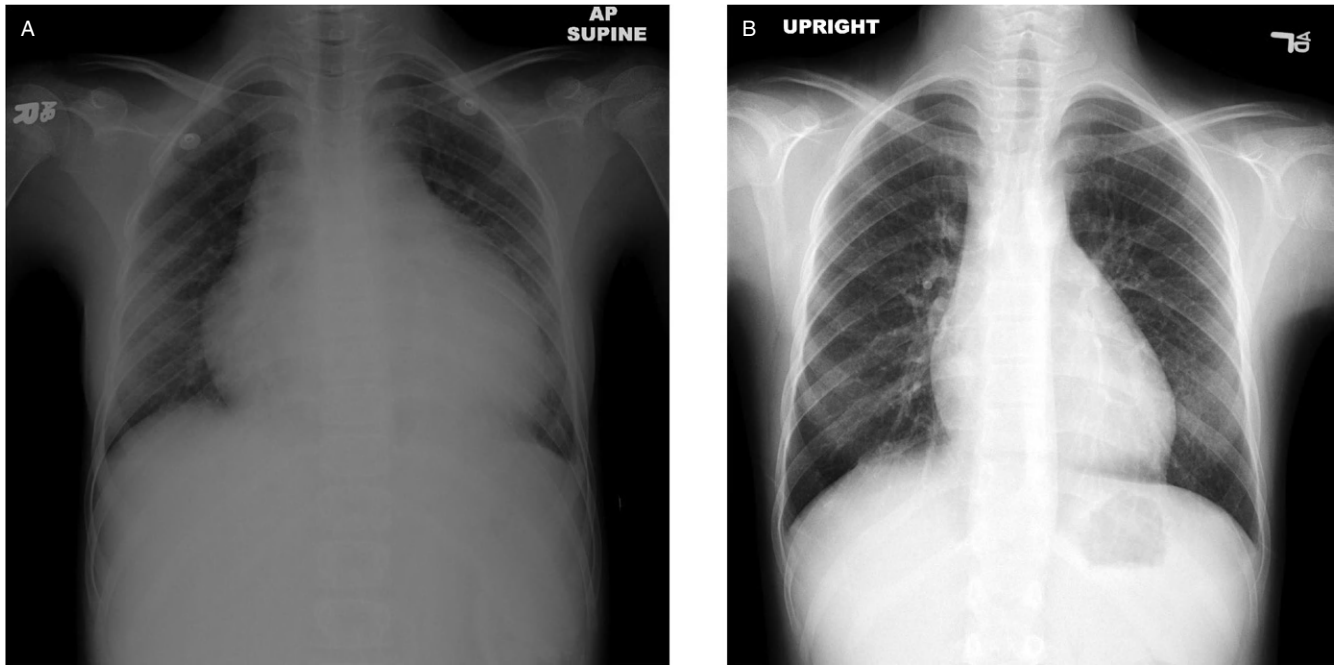

Figure 40.1 Chest roentgenography of a patient presenting with a large pericardial effusion. **A,** On admission. **B,** After pericardiocentesis.

resolve with medical management without the need for fluid analysis. Idiopathic or viral effusions usually have a benign course and tend to improve with bed rest and the use of nonsteroidal anti-inflammatory drugs such as indomethacin or salicylates. Steroids may be needed occasionally for recurrent or refractory cases.

Uremic effusions are frequently managed with nonsteroidal anti-inflammatory agents and diuretics. In these patients dialysis can also effectively treat the pericardial effusion. Uremic effusion can be quite large and may lead to cardiac tamponade requiring urgent drainage. Drainage is also indicated if the effusion persists after a 2-week course of aggressive dialysis [12,13].

Bacterial pericarditis should be managed with both antimicrobial therapy and surgical drainage, which has shown to reduced the mortality and morbidity associated with this illness [14]. Tuberculosis is the most common cause of constrictive pericarditis, therefore patients with tuberculous pericarditis may benefit from early pericardiectomy. Neoplastic pericardial effusions are often asymptomatic requiring no specific treatment but, when symptomatic, they can be managed by palliative pericardiocentesis or extended catheter drainage [15]. In recurrent cases a subxiphoid pericardiostomy and tube drainage is the preferred option. For the management of chronic recurrent malignant effusions the intrapericardial delivery of sclerosing agents (tetracycline or bleomycin) has been used with apparent success, but no controlled trials are available [16–19].

The most common surgical techniques used in the management of pericardial effusions consist of pericardiocentesis, subxyphoid pericardiostomy and video-assisted thoracoscopy. Pericardiocentesis involves placing a needle 1–2 cm below the xiphoid process, at a 45-degree angle with the skin, directed towards the tip of the left scapula and then advancing it into the pericardial space (Figure 40.2). Once the needle is in the pericardial space, a guide wire is inserted through it and a drainage catheter is advanced. The drainage catheter is then connected to a closed drainage system. The pericardial fluid should be sent for cell count, chemistry, culture, and cytology.

If the aspirated fluid is grossly bloody, it is important to rule out intracardiac placement of the needle. Therefore, an aliquot of 3–5 mL is drawn on to a clean sponge to document clotting: blood withdrawn from the pericardial space will not clot because of fibrinolysis. The risk of cardiac injury can be reduced by performing the procedure under echocardiographic guidance. Also, an ECG lead can be attached to the needle to allow for continuous ECG monitoring. As the needle is advanced, ST segment elevations suggested ventricular epicardial contact and PR segment elevation will be observed with the atrial contact. Certainly, all these patients should have normal coagulation parameters at the time of the procedure to avoid bleeding complications.

The subxiphoid pericardiostomy (pericardial window) (Figure 40.3) is usually performed under general anesthesia and requires a small vertical midline incision, extending

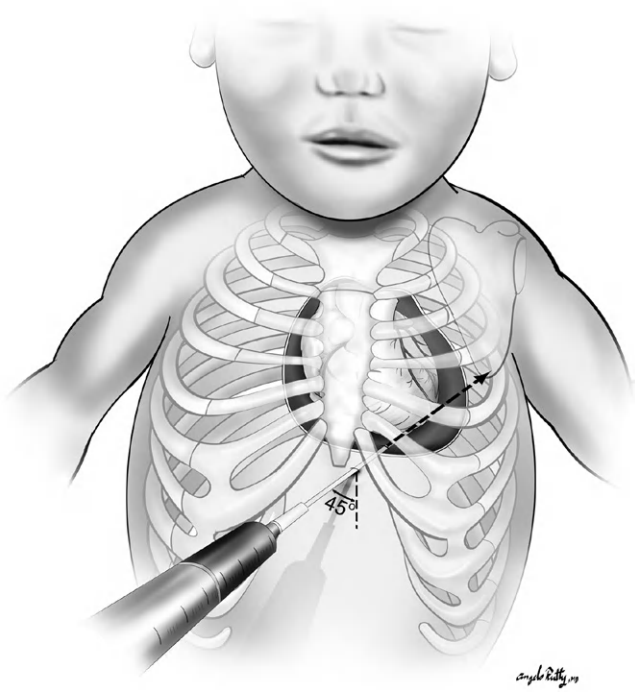

Figure 40.2 Pericardiocentesis technique. The needle is advanced at a 45-degree angle with the skin and directed towards the tip of the left scapula.

from the xiphisternal junction to just below the xiphoid process. Then the linea alba is divided and the sternum retracted allowing for visualization of the anterior pericardium. In patients with significant effusion, immediately on pericardial entry there is a fluid outrush, which should be associated with a rise in systemic blood pressure and a decrease in the heart rate. In the event of any cardiac injury and massive bleeding, the opposite will occur [20]. An advantage to this approach is that a piece of pericardium can be excised and sent to the pathology lab for examination. A pericardial drainage tube is placed through a separate skin incision and secured at skin level. Complications of subxiphoid pericardiostomy are rare but include bleeding, infection, incisional hernia, anesthetic complications, and cardiac injury [21].

Video-assisted thoracoscopic surgery is another safe and effective technique for the creation of a pericardial window (Figure 40.4) [22]. With the patient in a lateral decubitis position and through three small incisions in the chest, the endoscopic trocars are inserted in the pleural space. Under single-lung ventilation a thoracoscope and two thoracoscopic instruments are inserted allowing for bimanual dissection. Once the phrenic nerve is visualized, the pericardium is grasped and a window is created allowing for drainage of the pericardial fluid into the pleural space.

Constrictive Pericarditis

Constrictive pericarditis is defined as an inflammatory process of the fibrous and serous layers of the pericardium

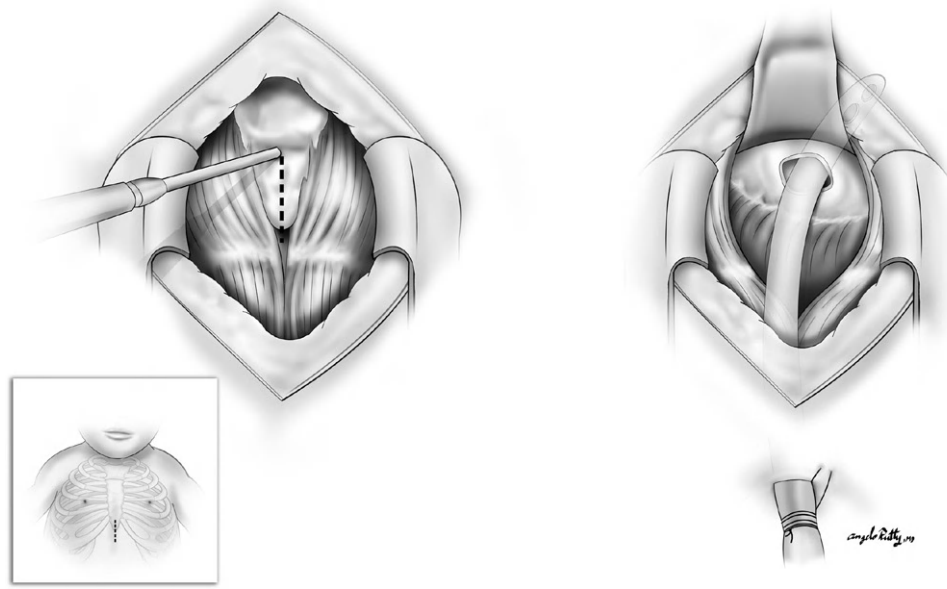

Figure 40.3 Subxiphoid pericardiostomy technique. First, an incision over the xiphoid process is made. After excising or dividing the xiphoid process and with upward retraction of the distal sternum, the pericardium is visualized and entered. This approach allows for open pericardial drainage and/or biopsy.

that leads to pericardial thickening and compression of the cardiac chambers, ultimately resulting in a significant reduction in cardiac function [5]. Although tuberculous pericarditis remains the leading cause of constrictive pericarditis worldwide, its incidence has declined in western countries [23]. Presently, idiopathic constrictive pericarditis is the most common etiology in the western world, followed by postcardiotomy and postmediastinal irradiation.

Physiologically, the thickened adherent pericardium decreases ventricular compliance and restricts cardiac filling in late diastole. Normally, the decrease in intrathoracic pressure that occurs with inspiration is transmitted to all cardiac chambers and therefore the pressure gradient between the pulmonary veins and the left-sided chambers remains unchanged. With constrictive pericarditis, the thickened pericardium isolates the cardiac chambers from intrathoracic pressure changes resulting in a decrease in the pressure gradient between the systemic and pulmonary veins and the cardiac chambers. This results in a reduction in the filling of all cardiac chambers [24].

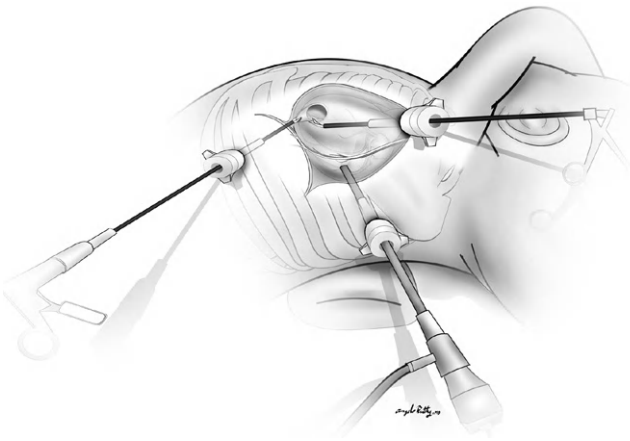

Figure 40.4 Video-assisted thoracoscopic pericardial window. After careful placement of the three trocars into the left pleural space, placement of the video camera and two endoscopic instruments allows for the creation of a pericardial window.

Symptoms and signs include fatigue, exercise intolerance, pedal edema, and in extreme cases syncope on exertion, hepatic congestion, and ascites. Jugular venous distention with inspiration (*Kussmaul's sign*) is present. On auscultation muffled heart sounds, a prominent S3 gallop, and/or a pericardial knock are common findings. The chest X-ray may show pericardial calcifications and a normal cardiac silhouette in a patient with right-sided heart failure symptoms. Echocardiography may demonstrate the pericardial thickening. Computed tomography and MRI provide excellent additional information for the diagnosis.

Cardiac catheterization remains a very useful diagnostic tool in the management of constrictive pericarditis, especially when ruling out the presence of a restrictive cardiomyopathy. The significant factor leading to altered pathophysiology is the presence of the thickened inelastic pericardium interfering with ventricular expansion during diastole, particularly the latter two-thirds of diastole. Both left and right ventricular diastolic pressure waveforms show an early diastolic dip followed by a plateau *(square root* sign). There is usually equilibration of the mean right atrial pressure, pulmonary artery wedge pressure, and the right and left ventricular end-diastolic pressures (Figure 40.5). Pulmonary arterial systolic pressure is usually normal or slightly elevated and usually not greater than 40 mmHg. Also, myocardial biopsy could be helpful in documenting findings suggestive of restrictive cardiomyopathy (myocyte hypertrophy, interstitial fibrosis, myocytolysis, and endocardial sclerosis).

The surgical management of constrictive pericarditis involves the complete removal of the pericardium, which is usually performed through a midline sternotomy approach (Figure 40.6). First, the pericardium is incised longitudinally with a scalpel and once in the correct plane it is removed first from the left ventricle and left atrium. Bleeding during dissection can be controlled by gentle compression with warm saline or fine sutures. Human fibrin glue can also be considered to stop the bleeding [25]. Extra care must be taken to mobilize and preserve the phrenic nerves. After the resection of the right atrial and

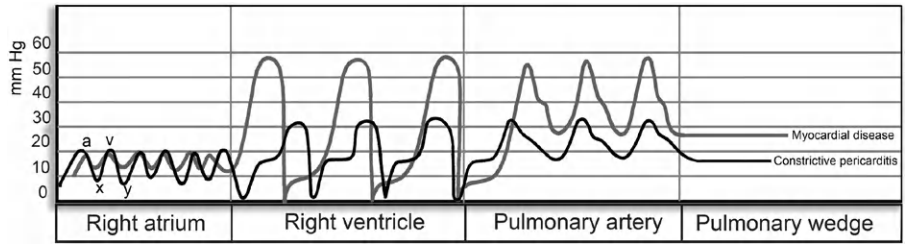

Figure 40.5 Pressure tracings in constrictive pericarditis and myocardial disease.
Note the plateaued end-diastolic pressure of the right ventricle and equalization of diastolic pressures in all cardiac chambers with constrictive pericarditis.

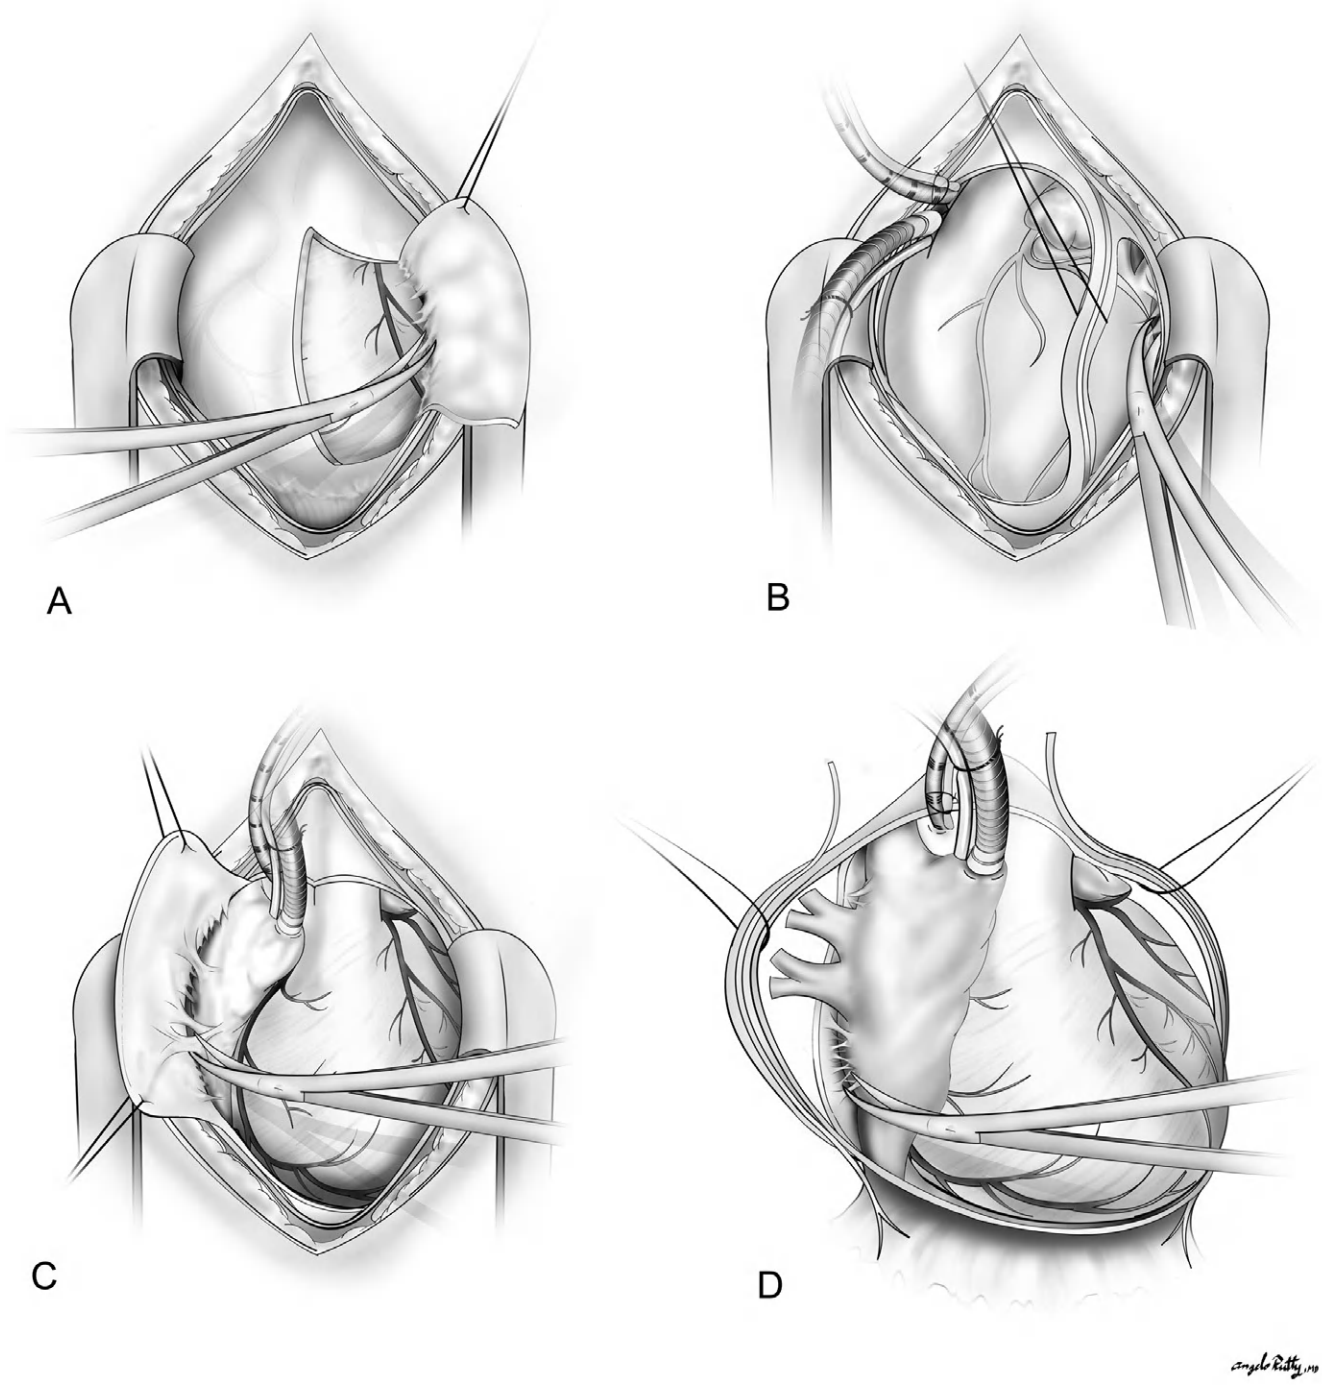

Figure 40.6 Total pericardiectomy. **A,** The pericardium over the left ventricle and left atrium is first removed, followed by the pericardium over the right ventricle. **B,** The phrenic nerves are preserved but the pericardium posterior to the nerves should also be resected. **C,** The pericardium over the right atrium and (**D**) pulmonary veins should also be resected.

right ventricular pericardium, the dissection of the pericardium around the aorta, pulmonary artery, superior vena cava and inferior vena cava is completed.

Constrictive pericarditis is a rare condition in children. Surgical treatment offers good short- and long-term results [26]. The complete removal of the pericardium is very important because incomplete removal could result in persistent symptoms. The outcomes are not as good in patients with radiation-induced constrictive pericarditis because there is usually a component of myocardial injury. Early

surgical treatment should be considered in tuberculous constrictive pericarditis [27].

Cardiac Tamponade

Cardiac tamponade can be defined as cardiac compression [5] and it occurs when enough fluid, air, pus, or tumor accumulates in the pericardial space to cause a significant increase in the intrapericardial pressure that results in impaired cardiac filling. As a direct result of the elevated intrapericardial pressure there is a rise in the ventricular end-diastolic pressure, which equalizes with the central venous pressure. This hemodynamic abnormality results in a reduction of the ventricular diastolic filling, stroke volume, and cardiac output.

Beck's triad is a collection of physical signs frequently observed in patients with cardiac tamponade and consists of an elevated central venous pressure, a decreased arterial blood pressure, and muffled heart sounds. *Kussmaul's sign*, a rise in the central venous pressure with spontaneous inspiration, is frequently present in patients with cardiac tamponade or constrictive pericarditis. *Pulsus paradoxus*, a drop in the systolic arterial blood pressure greater than 10 mmHg with inspiration, is also commonly observed in these patients.

The diagnosis of cardiac tamponade could be challenging. A chest X-ray often shows mediastinal enlargement, but a normal cardiothoracic ratio does not rule out the diagnosis. Echocardiography is very useful because it also provides physiologic data. Echocardiographic features of the cardiac tamponade include late diastolic right atrial collapse, diastolic right ventricular collapse, and large respiratory variation of flow velocity through the heart valves [28–31]. On cardiac catheterization there is near equality of the diastolic pressures in all cardiac chambers and the pulmonary artery, with an elevated central venous pressure.

Pericardial fluid removal is the definitive treatment. If there is a suspicion of cardiac tamponade pericardiocentesis is a method of both diagnosis and treatment. Aspiration of a few milliliters of fluid in a newborn or only 10–15 mL in an adult patient can be a life-saving procedure [32]. Open surgical drainage may be necessary in some cases, especially in postoperative patients with active mediastinal bleeding.

Postoperative Pericardial Effusion

Postoperative pericardial effusions have been reported to develop in up to 85% of patients after cardiac surgery [33,34]. Pericardial effusions that present during the immediate perioperative period (less than 30 days) are considered "early" effusions. The patient's exposure to the cardiopulmonary bypass circuit, with its adverse effects (systemic inflammatory response and coagulopathy), certainly plays a role in their development. "Late" effusions present at a time removed from the immediate perioperative period (more than 30 days) and their etiology appears to be multifactorial.

The location, size, and rate of accumulation of these effusions play a significant role in the patient's clinical presentation. Most are asymptomatic and the effusions are detected in a routine follow-up examination, but postoperative pericardial effusions may lead to cardiac tamponade. Medical treatment with diuretic and nonsteroidal anti-inflammatory agents is the first option for patients with small to moderate effusions without hemodynamic instability. Steroid therapy is usually reserved for persistent or recurrent cases. Surgical intervention in the form of percutaneous or open drainage is indicated in cases of large effusions or in patients that have failed medical management.

Postoperative Cardiac Tamponade

Pericardial effusions resulting in cardiac tamponade have been reported in up to 8.8% of patients after open heart surgery [33,34]. Early cardiac tamponade is one that develops within 30 days of surgery and is usually associated with the presence of postoperative bleeding or coagulopathy. Even with an open pericardial cavity the acute accumulation of a moderate amount of blood can readily cause cardiac tamponade. On chest X-ray the presence of an enlarged cardiac silhouette is suggestive of the diagnosis. Echocardiography is very useful in documenting the size and location of the effusion and the presence of diastolic right atrial or ventricular collapse. The differential diagnosis with hemodynamic parameters is presented in Table 40.1 [32]. The management of this condition usually requires urgent mediastinal exploration with the evacuation of blood and clots and control of the bleeding. In an emergency, opening of the lower end of the sternotomy

Table 40.1 Differential diagnosis of postoperative cardiac tamponade.

	Right atrial pressure	Left atrial pressure	Pulmonary artery pressure	Systemic pressure
Hypovolemia	↓	↓	↓	↓
Acute tamponade	↑	↓	→	↓
Myocardial dysfunction	↑	↑	↑	↓
Acute pulmonary hypertension	↑	↓	↑	↓

incision with partial evacuation of the mediastinal hematoma can be life saving [25].

Late postoperative cardiac tamponade is one that presents at a time removed from the immediate perioperative period (more than 30 days) [5]. The etiology of this condition appears to be multifactorial and is related to factors like the presence of prolonged postoperative mediastinal drainage and the development of postpericardiotomy syndrome [35,36]. Because of its insidious nature patients often present with minimal symptoms and without obvious clinical signs of cardiac tamponade. Therefore, the diagnosis can be easily missed. These "late" effusions respond well to percutaneous drainage under fluoroscopic or echocardiographic guidance but occasionally open surgical drainage is required, especially for loculated posterior effusions.

Postpericardiotomy Syndrome

Postpericardiotomy syndrome is a febrile illness observed in patients after a surgical procedure that involved opening the pericardium. Symptoms tend to develop weeks to months after pericardiotomy and include fever, pericardial or pleuritic pain, friction rubs, pericardial or pleural effusions, and electrocardiographic changes. The etiology is still unclear, but the underlying mechanism is thought to be an immunologic process characterized by the development of anticardiac antibodies [37]. Approximately two-thirds of patients have been found to have a marked increase in antibody titers to a variety of viral agents including coxsackie B, adenovirus, and cytomegalovirus, suggestive of a viral etiology [38]. However, a prospective study by Webber and associates found no evidence to support this theory and concluded that the use of viral titers in the setting of cardiopulmonary bypass and recent blood transfusions is unreliable [39].

The incidence of postpericardiotomy syndrome after cardiac surgery is approximately 30%, but patients under 2 years of age seem to be less affected [38,40]. Medical management consists of the use of anti-inflammatory agents including aspirin, indomethacin, and other nonsteroidal anti-inflammatory agents. Steroid therapy is effective and dramatically hastens the recovery. Pericardiocentesis is reserved for the management of large pericardial effusions. A surgically created pericardial window may be necessary in refractory cases.

Congenital Defects of Pericardium

Congenital defects of the pericardium are rare and include complete absence of the pericardium and partial left- or right-sided defects. Most pericardial defects (86%) occur on the left side and result from premature atrophy of the left duct of Cuvier during embryologic development [2]. In 30% of cases, congenital pericardial defects are associated with cardiovascular or pulmonary congenital anomalies including atrial septal defect, tetralogy of Fallot, patent ductus arteriosus, pulmonary sequestration, bronchogenic cyst, and diaphragmatic defects [41]. Although mostly asymptomatic, congenital pericardial defects may present with syncope, chest pain, or arrhythmias [42,43]. Also, cardiac herniation through the defect could lead to incarceration of the myocardium, torsion of the great arteries, and sudden death [44]. A combination of chest X-ray, echocardiography, CT, and/or MRI is useful in establishing the diagnosis but frequently these defects are identified incidentally at autopsy or during surgery.

Asymptomatic patients with complete absence of the pericardium or with small defects require no surgical intervention. Moderate-sized defects are rarely of clinical significance and, despite the potential for cardiac chamber herniation, most authors advise leaving them untreated. Therefore surgical intervention is reserved for symptomatic patients [32]. Surgical repair consists of primary closure or pericardioplasty. During repair, care must be taken to avoid injuring the phrenic nerve, which usually runs along the anterior border of the defect.

Pericardial Neoplasia

Malignant diseases of the pericardium include lymphoma, leukemia, thymoma, mesothelioma, teratoma, angiosarcoma, rhabdomyosarcoma, or metastatic disease [5]. They are quite rare in children. The most common primary pericardial malignancy is mesothelioma, but the majority of pericardial malignant tumors are metastatic in nature. Early diagnosis is often difficult owing to the lack of symptoms. As the disease advances patients often develop signs and symptoms of cardiac tamponade owing to the presence of a large pericardial effusion or because of cardiac compression by the tumor mass. Diagnostic studies include chest X-ray, echocardiography, CT or MRI, and pericardiocentesis for cytology. A pericardial biopsy is often necessary to establish the diagnosis. Surgical resection of the primary pericardial tumor with or without chemotherapy and/or radiation is the preferred treatment. The management of malignant pericardial effusions has been previously discussed in this chapter.

Benign Pericardial Mass

Benign primary tumors of the pericardium include lipomas, fibrous polyps, hemangiomas, and dermoid tumors [5,25]. Patients are usually asymptomatic, but when symptoms develop they are usually related to cardiac compression. The diagnosis is made by chest X-ray, echocardiography, CT, and/or MRI. Surgical resection is the treatment of choice.

Pericardial Cyst

A pericardial cyst is defined as a sac enclosing fluid or semisolid matter found in close proximity to the pericardium, although rarely communicating with the pericardium, and they can be intrapericardial or extrapericardial [5]. The most common locations for these cysts are the right periphrenic angle (Figure 40.7), the left periphrenic angle, and the anterior mediastinum. Pericardial cysts are rare and usually asymptomatic, however they may cause cardiac compression, chronic inflammatory symptoms, or cardiac chamber erosion [25]. Pericardial cysts are usually discovered on a routine chest X-ray but echocardiography, CT, or MRI are useful diagnostic studies. Surgical excision is recommended to confirm the diagnosis.

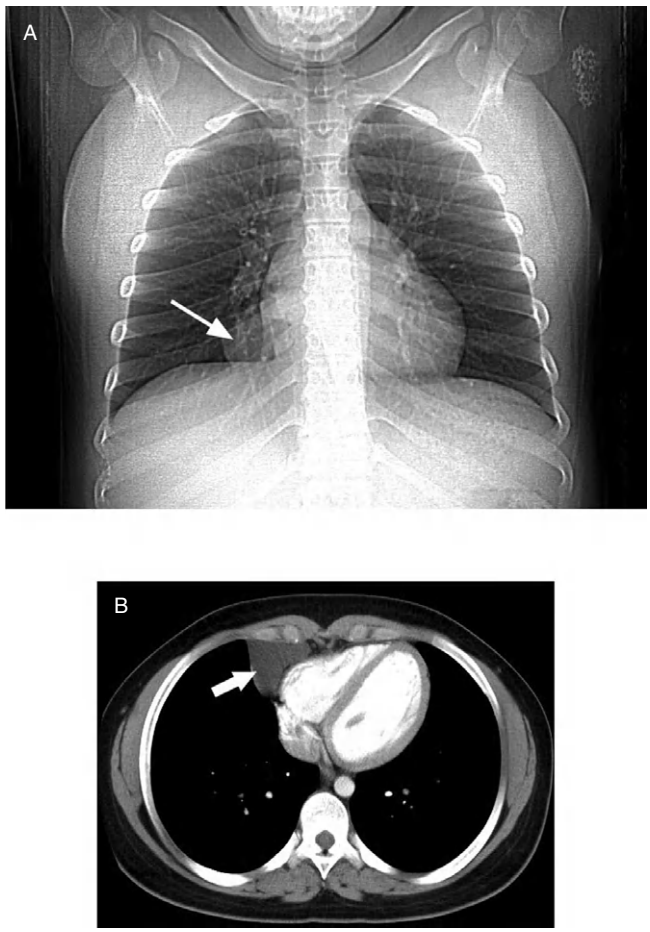

Figure 40.7 Images of a patient with a pericardial cyst. **A,** Chest roentgenography reveals an abnormal shadow in the right periphrenic angle (arrow). **B,** A chest computed tomography scan confirms the presence of a cystic mass at the right periphrenic angle (arrow).

Pneumopericardium

Pneumopericardium is defined as the presence of air within the pericardial cavity and it can be idiopathic, traumatic, or infectious in origin [5]. Idiopathic pneumopericardium is believed to result from the rupture of terminal alveoli releasing air that courses along the bronchi into the tissue planes leading into the pericardium. It is usually self-limited and resolves spontaneously. In rare cases, it can lead to the development of a tension pneumopericardium with signs and symptoms of cardiac tamponade.

Neonatal pneumopericardium is a rare clinical condition that can be life threatening and is seen in neonates with existing lung pathology requiring mechanical ventilation [45–47]. It may be associated with other air leak syndromes such as pneumomediastinum, pneumothorax, and pneumoperitoneum. Neonatal pneumopericardium can be successfully treated by the nitrogen washout technique [48].

Traumatic pneumopericardium is a rare condition, whose significance lies in the possibility of developing a tension pneumopericardium. The most common cause is penetrating chest trauma but it is also seen after blunt trauma. The presence of a pneumopericardium in a patient with a penetrating chest injury should raise concerns of the possibility of cardiac injury, and hence it should be considered a relative indication for surgical intervention. Tracheal and esophageal injuries could also be present.

Infectious pneumopericardium can be seen in patients with a secondary fistulous communication between the pericardium and an infected contiguous organ or with a primary pericardial infection with a gas-forming organism. The medical management is directed to the eradication of the infection.

Chylopericardium

Chylopericardium is defined as a chylous effusive process of the pericardium. It can be idiopathic, posttraumatic, post thoracic surgery, postcardiotomy, or neoplastic in origin [5] and may present with signs of cardiac tamponade. Patients with increased superior vena cava pressures are at risk for the development of a chylopericardium, and that includes single ventricle patients with a Fontan circulation and patients with superior vena cava obstruction or thrombosis. Neoplastic processes or surgical trauma affecting the thoracic lymphatic drainage can also result in the formation of a chylous pericardial effusion.

The initial management of a chylopericardium consists of drainage of the pericardial fluid and the institution of low-fat enteral nutrition with medium-chain triglycerides. If persistent, total parenteral nutrition is then indicated. Also, the use of octreotide has been reported with some success [49]. In the presence of caval obstruction, strong consideration should be given at re-establishing unob-

structed superior vena cava flow. Surgical ligation of the thoracic duct is performed in patients in whom conservative medical management failed.

Evolving Role of Surgical Therapy

Historical Considerations

The definitive cure of arrhythmias originated with the surgical elimination of accessory connections performed by Sealy and colleagues at Duke University in 1968 [1], culminating in the impressive surgical results by Cox *et al*. in successful elimination of accessory connection function in more than 90% of operated patients [1–3]. Success with the ablation of accessory connections led to atrioventricular node modification for atrioventricular nodal re-entry tachycardia (AVNRT) [4], atrial isolation techniques for automatic atrial tachycardia [5], and ablative surgery in association with endocardial resection for ventricular tachycardia [6,7]. The technique of surgical interruption of these arrhythmia circuits was subsequently studied extensively in the dog model and resulted in the development of the highly successful Cox-maze procedure for elimination of atrial fibrillation, again with success rates over 90% [8–16]. Guiraudon successfully performed ablation of the right atrial isthmus as treatment for right atrial flutter [17], and subsequently Josephson and colleagues developed mapping and resection techniques for ventricular tachycardia, particularly those associated with ventricular scar or aneurysms secondary to ischemic disease [18]. Williams and others [19] applied these techniques to the therapy of ventricular tachycardia complicating repaired congenital heart disease, particularly tetralogy of Fallot. These impressive surgical arrhythmia results were supplanted by the development of catheter ablation techniques in the electrophysiology laboratory beginning in the 1990s, initially for atrioventricular nodal re-entry and accessory connections, and extending to most arrhythmia substrates including atrial fibrillation, relegating surgical therapy to a largely historical category [20–28]. Danielson and colleagues at the Mayo clinic persisted in the application of the right atrial isthmus ablation to surgical repairs of patients with atrial arrhythmias with congenital heart disease, particularly Ebstein anomaly [29]. The high success rates for the transcatheter ablation of arrhythmias largely replaced the techniques of surgical intervention as newer mapping technologies and ablation energies were refined, and defibrillator therapy supplanted ventricular arrhythmia surgery. During the first 20 years of transcatheter ablation the knowledge of arrhythmia circuits was considerably advanced, while the cumbersome custom epicardial mapping systems used in the operating room languished.

As the subset of patients with congenital heart disease gained markedly improved survival rates following surgery, the development of late postoperative arrhythmias increased and resulted in significant late morbidity and mortality. Lesions such as tetralogy of Fallot, atrial septal defects, transposition of the great arteries, Ebstein anomaly, and single-ventricle physiology were associated with the highest risk of developing late arrhythmias. The recognition of the development of arrhythmias as an "electromechanical" problem was first proposed by Gatzoulis and colleagues [30] in patients with repaired tetralogy of Fallot; isolated intervention for arrhythmias with the transcatheter approach did not address the ongoing progression of hemodynamic complications. The correlation of the need for reoperations with the high risk of arrhythmia development in certain congenital lesions emphasizes the complex interaction of hemodynamics with arrhythmia development (Table 41.1). Using the integration of knowledge gained with catheter ablation into the surgical repair of congenital lesions, Mavroudis and colleagues in Chicago re-initiated the surgical techniques of arrhythmia intervention beginning in 1994 [31–41]. Initial results with

conversion of the atriopulmonary Fontan to an extracardiac total cavopulmonary connection associated with right and later left atrial arrhythmia surgery resulted in often dramatic improvements in hemodynamic status, and reduced the midterm recurrence of arrhythmias to less than 20% in this most difficult population. These techniques were then applied to subsequently more challenging anatomical substrates including ventricular inversion and heterotaxy syndromes, neonates, and patients with severe congestive heart failure secondary to arrhythmias. The use of arrhythmia surgery techniques was then applied to the prophylactic prevention of arrhythmia development in patients known to be at risk, such as patients undergoing re-do operations for conduit changes or late repairs of atrial septal defects. The ease of incorporation of arrhythmia surgery techniques into the operative repair of congenital heart disease emphasizes the need for a comprehensive electrical and mechanical approach to the repair of congenital heart disease, and provides a standard and a challenge for the operative repairs of the next decades.

This chapter will review the indications for arrhythmia surgery, the presently available operative techniques and results based on the mechanism of arrhythmia, the collaborative roles of the electrophysiologist and the surgeon in the planning and performance of arrhythmia surgery, the indications and techniques of pacemaker and antitachycardia device therapy, and the management of early postoperative arrhythmias. The goal is to understand the available techniques for arrhythmia surgery and current success rates based on arrhythmia substrate in order to appropriately guide patient selection and evaluation.

Indications for Arrhythmia Surgery

Table 41.2 summarizes current indications for arrhythmia surgery in our institutions. In 1983 Cox wrote "the selection of patients for the surgical treatment of cardiac arrhythmias is based on several variables. These variables include the patient's age and general condition, the nature of the presenting arrhythmia, its response to medical treatment, and the presence of associated anomalies that may require additional surgical correction" [42]. The results achieved over the last 2 decades in arrhythmia surgery indicate that age and complexity of anatomical substrate are no longer important hurdles to successful arrhythmia surgery. Rather, an awareness of preexisting arrhythmias, suitability of the arrhythmia substrate to current surgical techniques versus catheter ablation, and intervention to limit the development of later arrhythmias are important determinants of the decision to perform arrhythmia surgery. In the early phase of the current era of arrhythmia surgery, only patients who had failed multiple attempts at catheter ablation techniques with structurally normal hearts were referred for surgery as a last resort; the improvement in catheter ablation techniques has limited this occurrence to very few patients. However, in patients requiring concomitant arrhythmia surgery where catheter ablation techniques are difficult, such as Ebstein anomaly or heterotaxy syndrome, or where catheter ablation techniques require prolonged procedures with less than optimal success rates, high arrhythmia recurrences, or risk of complications, a more streamlined therapeutic approach would be to appropriately map the arrhythmia substrate and proceed to arrhythmia surgery if initial catheter attempts are unsuccessful. Arrhythmia surgery in the setting of congenital heart disease offers certain powerful advantages compared to

Table 41.3 Techniques for arrhythmia surgery.

Technique	Substrate
Resection or dissection	AV groove accessory connection
Focal substrates	Atrial wall tissue, appendages
	Endocardial fibrosis or scar
	Aneurysm
Ablation	Accessory connection
	Areas of early activation, scar
	Connection between anatomic barriers
Maze procedures	Modified right atrial maze
Macro re-entrant circuits	Left atrial maze
	Cox-maze IIII procedure
Denervation	Left cervical ganglion sympathectomy

the transcatheter approach, including direct visualization of the anatomy and the ability to rapidly perform complete lines of block between difficult to access anatomic barriers. The high success rates and low risk of recurrence of tachycardia in addition to improved hemodynamic outcomes provide a standard of comparison for the optimal selection of intervention, such as atrial fibrillation in the setting of complex heart disease, or tachycardia associated with single-ventricle physiology.

The techniques we currently use for arrhythmia surgery are summarized in Table 41.3, and the operative techniques are discussed in detail in subsequent sections. Knowledge of the mechanisms of tachycardia is essential to the appropriate application of arrhythmia surgery techniques. The fundamental distinction to be made when planning a surgical approach is to identify either macro re-entrant circuits and their constituent parts, or a focal tachycardia: macro re-entry circuits are treated with either dissection or ablation of an accessory connection or a maze procedure, and focal tachycardia is approached with either resection or localized ablation; the distinction is of critical importance as a maze procedure will not effectively treat focal atrial tachycardia. Macro re-entrant circuits require a circuit with unidirectional block in one limb, and slowed conduction in the other limb allowing re-entry to occur, and may be initiated and terminated with pacing techniques, allowing elucidation of the substrate. Elimination of conduction through a critical part of the re-entrant circuit will terminate tachycardia. The keys to success in arrhythmia surgery are the accurate identification of the arrhythmia mechanism and its anatomic substrate, and the appropriate delivery of incisions, ablative lesions, or resection; the limitations are thus the accuracy of electrical mapping, anatomic exposure, and ablation techniques (Table 41.4).

Table 41.4 Mechanisms of supraventricular tachycardia commonly associated with congenital heart lesions.

Supraventricular tachycardia	Congenital heart disease
Accessory connection-mediated	Ebstein anomaly
	Atrial septal defect
	Congenitally corrected transposition of the great arteries
	Hypertrophic cardiomyopathy
Atrial re-entry	Atrial septal defect
	Single ventricle following atriopulmonary repairs
	Transposition of the great arteries with Mustard/Senning repairs
	Atrioventricular septal defects
	Tetralogy of Fallot
	Total anomalous pulmonary venous connections
Atrioventricular nodal re-entry	Mustard/Senning repairs of transposition of the great arteries
	Left ventricular outflow obstructive lesions
Atrial fibrillation	Mitral valve disorders
	Ebstein anomaly of tricuspid valve
	Single ventricle, especially tricuspid atresia
	Atrial septal defects
	Tetralogy of Fallot
	Hypertrophic cardiomyopathy
	Eisenmenger's syndrome

Operative Planning

The success of a surgical arrhythmia strategy begins with appropriate patient selection, based on the anticipated success rates of arrhythmia surgery, the complexity of anatomic repair, and the ability of the patient to tolerate the combined surgical procedures safely. A thorough understanding of the anatomy of the congenital heart disease and prior surgical repairs provides valuable information regarding the potential arrhythmia substrates, supplemented by careful review of the tracings obtained during clinical arrhythmias. Obtaining medical records of a patient's extended history is often difficult, particularly in older patients with repaired congenital heart disease whose original surgeries were performed remotely in time and geography. Detailed review of prior operative reports is important, and may identify surgeon-specific variations in technique that will impact the surgical approach, such as the deviation of the atrial septum to the left atrium in atriopulmonary repairs of single ventricle; knowledge of these surgical variations will require modification of the standard right atrial surgery. A realistic assessment of

the time and exposure required to appropriately perform arrhythmia surgery in complicated cases, and the ability of impaired ventricular function to withstand surgery, is needed.

The careful delineation of the arrhythmia mechanism and critical anatomic components usually necessitates preoperative invasive electrophysiologic study; the exception to this is isolated atrial fibrillation, as the need to perform right and left atrial maze surgery is clear. Patients with congenital heart disease may not uncommonly have more than one arrhythmia mechanism, such as accessory connection-mediated tachycardia or AVNRT in addition to atrial flutter. In these cases a stepwise approach may be employed, using transcatheter ablation preoperatively for one mechanism, and reliance on surgery for a technically more challenging arrhythmia. It has been our preference to attempt transcatheter ablation of accessory connections preoperatively whenever possible, using surgery in this situation for multiple accessory connections or in the setting of Ebstein anomaly. The presence of right atrial thrombus, right-to-left shunts, or hemodynamic instability during tachycardia will restrict the ability to perform preoperative studies. Visual reproductions of the anatomy as defined in the catheterization laboratory using angiography or three-dimensional reconstructions, with superimposition of the electrophysiologic target, are valuable to provide the surgeon with appropriate landmarks. Reliance on only intraoperative mapping of tachycardia mechanism is not optimal, as tachycardia may not be inducible under situations of anesthesia with the chest open.

Intraoperative electrophysiologic mapping is used in the following settings: to confirm anatomic landmarks important to the arrhythmia circuit, to assess efficacy of surgical techniques particularly when multiple arrhythmia mechanisms are present, mapping when vascular access is restricted, and mapping when provision of cardiopulmonary bypass for hemodynamically unstable arrhythmias is needed. Patients with atrial baffles or patches over the right-sided atrioventricular valve may have restricted access to the critical atrial isthmus between the coronary sinus and the inferior vena cava; successful ablation of the arrhythmia circuit requires baffle or patch removal in order to apply the lesions. The anatomy of Ebstein anomaly or ventricular inversion, particularly in the presence of dextrocardia, is not always readily mapped in the catheterization laboratory, and such complex anatomy may benefit from correlation of anatomic landmarks under visual inspection with the target of ablation. The ability of the operative team to cooperate with electrophysiologic mapping becomes imperative in the setting of hemodynamically unstable tachycardia, such as incessant atrial tachycardia resulting in severe congestive heart failure. In this setting, mapping and elimination of tachycardia can avoid the need for implantation of mechanical circulatory support devices and may be life saving.

Intraoperative mapping systems historically have relied on custom-developed multiple electrode arrays, which were not commercially available, and were designed to lay on the epicardial surface of the atrium or ventricle. Use of these systems also required sophisticated engineering support for the display of the electrical signals. The complexity of these systems posed a significant deterrent to widespread acceptance of surgical mapping. However, the advances of catheter ablation technology resulted in the manufacture of many configurations of multiple electrode array catheters with steerable handles, which can be adapted for use in the operating room using standard mapping display systems. In addition, placement of an esophageal electrogram at the start of the procedure provides additional anatomic information and an atrial reference electrogram throughout the surgery.

After cannulation but before commencement of bypass, a reference bipolar electrode is sutured to either the atrial or ventricular surface, and is used as a stable reference and as a pacing electrode. For mapping of accessory connections, a steerable deca-polar catheter can then be positioned along the atrioventricular groove, with sterile connectors to the electrophysiology recording computer. Atrial mapping can be performed with one or more deca-polar catheters secured to the atrial surface of interest with sutures or wet gauze. Ventricular mapping of the epicardial surface can be performed with either more than one catheter in place, or sequential positioning of a catheter. Due to ventricular wall thickness, epicardial ventricular mapping may differ from the earliest site of endocardial electrical activity by as much as 1.5 cm, limiting accuracy. Right ventricular endocardial mapping may or may not be feasible, depending on tachycardia inducibility on bypass. Some centers have developed custom-made "plunge" needle electrodes to record across the depth of the ventricular muscle to overcome this limitation.

Clarity of electrode anatomical positioning must be communicated with precision from the surgeon to the electrophysiologist, recognizing that surgical anatomic relationships are typically described with different spatial terms than the standard electrophysiology nomenclature developed using fluoroscopy. It has been our practice for the surgeon to draw a map of the anatomy, with the electrode positions delineated. Miscommunication, or misinterpretation, at this point will result in inaccurate mapping and inaccurate guidance for lesion placement. The importance of this step cannot be overstated. With electrodes in place, the quality of electrograms is verified, with catheter repositioning as necessary to obtain good contact with the epicardial surface. Before pacing is initiated to induce tachycardia, an understanding of the process for hemodynamic support and tachycardia termination must be agreed on.

Typically, tachycardia induction and electrogram recording can be performed in less than 20 minutes. Catheters may be repositioned sequentially during tachycardia to obtain sufficient electrograms to determine earliest activation and circuit delineation. After termination of tachycardia, the electrophysiologist can proceed with review of electrograms and clarification of activation sequences while surgery progresses. Once more, it is our practice to frequently produce a visual representation of the tachycardia focus or circuit superimposed on anatomic landmarks, often as a drawing, to assure that the spatial target is clearly understood by both the electrophysiologist and the surgeon.

Clear communication between the electrophysiologist and the surgeon before surgery is essential, with agreement on the proposed mapping and ablative approach and the alternatives as dictated by anatomic considerations. The need for more mapping information needs to be weighed and reassessed versus the hazards of surgical dissection and exposure of anatomy that may not be easily accessible. Certain types of arrhythmia surgery may require repeat pacing and mapping during surgery to verify efficacy of the ablative technique. Inducibility of the clinical arrhythmia following initial ablation may require additional efforts at ablation, taking into account the safety of further operative efforts. Finally, integration of device therapy needs to be considered, including the potential for resynchronization therapy or defibrillator as well as antibradycardia or antitachycardia pacing.

Acute postoperative care frequently involves atrial pacing at rates higher than the intrinsic rhythm, to maintain a stable rhythm and limit atrial ectopy. In patients undergoing surgery for atrial fibrillation, early postoperative atrial tachycardia can occur in 30–40% of patients following the left atrial maze procedure. To avoid this high incidence of recurrent atrial tachycardia, intravenous antiarrhythmic medication, amiodarone, is infused until oral medications are tolerated. Antiarrhythmic medication is continued for 3 months postoperatively in patients with atrial fibrillation, in gradually decreasing dosages. For all other patients undergoing arrhythmia surgery for re-entrant tachycardias, repeat electrophysiology testing is performed without antiarrhythmic medication prior to hospital discharge, to assess both efficacy of the procedure and potential proarrhythmic effects. Testing is performed in the baseline state and with infusion of catecholamines, usually isoproterenol. In patients with inducible arrhythmia, appropriate medication or antitachycardia pacing algorithms are instituted. Patients with inducible ventricular tachycardia undergo defibrillator implantation prior to hospital discharge. For the majority of patients without inducible postoperative arrhythmias, following electrophysiology study beta-blocking medications are administered for 3 months postoperatively.

Accessory Connection-Mediated Atrial Tachycardia

Mechanism

Wolff-Parkinson-White (WPW) syndrome is the association of episodes of tachycardia with the appearance of a delta wave on electrocardiography (pre-excitation) [37]. During sinus rhythm with pre-excitation, conduction proceeds simultaneously from the sinus node to the ventricles over two routes, the atrioventricular node and the accessory connection. The electrical wave front traverses the accessory connection and depolarizes ventricular tissue first, because of intrinsic slowing of conduction at the atrioventricular node. This is the manifest form of accessory connections (pre-excitation, or WPW). In order for a re-entrant tachycardia to occur, there must be unidirectional block in one pathway with slowed conduction in the other. Plate 41.1 (see plate section opposite p. 594) shows unidirectional block in the AV node, with conduction proceeding antegrade to the ventricles via the accessory connection [37,41]. The ventricular muscle is responsible for conduction delay, allowing the wave front to proceed retrogradely up the atrioventricular node (which has had time to regain conduction) to the atrium. This re-entrant circuit is termed antidromic reciprocating tachycardia; the re-entrant circuit includes the atria, accessory connection, ventricles, and the atrioventricular node. The more common form of tachycardia in association with an accessory connection is called orthodromic reciprocating tachycardia. Plate 41.2 (see plate section opposite p. 594) illustrates conduction block in the accessory connection, thus resulting in loss of the delta wave [37,41]. Conduction proceeds normally through the atrioventricular node to the ventricle. The delay encountered in the atrioventricular node and ventricular muscle allows the accessory connection to regain electrical conductivity, and the electrical wavefront then enters the atria from the opposite direction. This re-entrant circuit is similar to antidromic reciprocating atrial tachycardia except that the electrical pathways are reversed and pre-excitation is concealed.

Surgical Therapy of Accessory Connection-Mediated Tachycardia

Indications

Surgical ablation of accessory connections achieved success rates of 95% or greater before being supplanted by the widespread application of the radiofrequency catheter ablation technique [2,11–15]. Presently, surgical ablation of supraventricular tachycardia (SVT) is performed for patients failing both medical and catheter ablation techniques and for patients with complex congenital heart disease undergoing surgical repair. Certain accessory

connections, especially in the posteroseptal region, may have an epicardial course [43], limiting the success of ablation using an endocardial catheter approach. Right-sided accessory connections in patients with Ebstein anomaly tend to be multiple, with an increased likelihood of antidromic reciprocating tachycardia posing a therapeutic challenge. Recurrence risks for pre-excitation due to right-sided accessory connections are significantly higher following ablation procedures than for accessory connections in other locations [44,45] and often require multiple ablation procedures. The decision as to whether to persist with multiple ablation procedures or opt for surgical repair is individualized.

In patients with manifest accessory connections and congenital heart disease undergoing surgical repair, current recommendations are to assess the characteristics of the accessory connection and to perform preoperative ablation in patients with inducible SVT and rapidly conducting accessory connections [46,47], owing to the risk of refractory tachycardia during the early postoperative period. With complex congenital heart disease, the ablation procedure may pose technical difficulties, which require prolonged fluoroscopy times or more than one ablation procedure [48–51]. For patients requiring surgical intervention for their structural heart disease, decisions must be made on an individual basis as to the optimal way to manage both problems, minimizing the number and extent of procedures and the risk to the patient.

Over the past decade, electrophysiologic mapping and catheter ablation have improved to the point where surgical ablation is rarely necessary. Nevertheless, for those rare occasions where concomitant cryoablation for accessory connections becomes necessary, a comprehensive review of the surgical dissections are presented herein.

Surgical Technique

Following a comprehensive preoperative electrophysiologic study [19], intraoperative epicardial or endocardial mapping, or both, are performed during surgery to confirm the preoperative electrophysiologic findings and to assess the immediate postoperative result. The technique of intraoperative mapping has been previously discussed. The general goal of surgical therapy for the WPW syndrome or concealed bypass tract is to divide or cryoablate accessory connections, which are responsible for the re-entry phenomenon and clinical tachycardia. Two surgical techniques, the endocardial and epicardial techniques, were developed (Figure 41.1) [52]. The endocardial technique [2,11,14] requires cardiopulmonary bypass and is performed within the right atrium or left atrium, depending on the anatomic location of the bypass tract. The epicardial technique [12,13,15] may or may not require cardiopulmonary bypass, depending on the location of the accessory connection and is performed on the epicardial surface of the heart at the atrioventricular junction by dividing the atrial end of the connection. Excellent results are achieved by both techniques, the choice being surgeon dependent and institution dependent.

Left Free-Wall Accessory Connections

Ablation of left free-wall accessory connections is usually performed by the *endocardial* technique from within the left atrium using cardiopulmonary bypass and cardioplegic arrest. The exposure is through a left atriotomy, usually performed at the interatrial (Sondergaard's) groove, similar to that for mitral valve repair/replacement. After proper exposure, a curvilinear incision is made parallel to and 2 mm away from the posterior mitral annulus, extending from the left fibrous trigone to the posterior septum (Figure 41.2) [53]. A dissection plane is then developed between the fat pad of the atrioventricular groove and the superior portion of the left ventricle, extending to the epicardial reflection throughout the entire length of the initial incision (Figure 41.2) [53]. The dissection is completed by extending the ends of the incision and the dissection, "squaring off" to the mitral annulus to divide any accessory connection, which might be located at the juxta-annular area [11]. This dissection exposes the entire left free-wall space to the respective boundaries, thereby ensuring division of any or all accessory connections. The endocardial incision is then sutured to complete the procedure.

The *epicardial* approach (Figure 41.3) [53] for left free-wall accessory connections requires upward and rightward cardiac retraction for proper exposure, which frequently results in severe hemodynamic instability. As a result, most surgeons employing this technique prefer to use cardiopulmonary bypass, although no intracavitary exposure is required for this technique. Once exposure is achieved, the epicardial reflection of the atrium is entered and a plane of dissection is established between the atrioventricular groove fat pad and the atrial wall. Coronary sinus tributaries often require ligation and division, and care must be taken to avoid coronary artery injury. The dissection plane is extended to the level of the posterior mitral valve annulus and carried slightly onto the top of the posterior left ventricle. This maneuver divides the atrial end of all accessory connections in this area except for those which lie immediately adjacent to the mitral valve annulus. If present, these juxta-annular connections can be interrupted by a cryosurgical probe that is placed at the level of the mitral valve annulus. The atrial epicardial reflection is then reapproximated by suture technique. Both techniques have their respective advantages and disadvantages [11,12] and can be applied selectively, depending on the anatomic circumstances governing the operation. Anatomic variation may be especially important in simultaneous repair of congenital heart disease and ablation of accessory connections. Under these circumstances, the

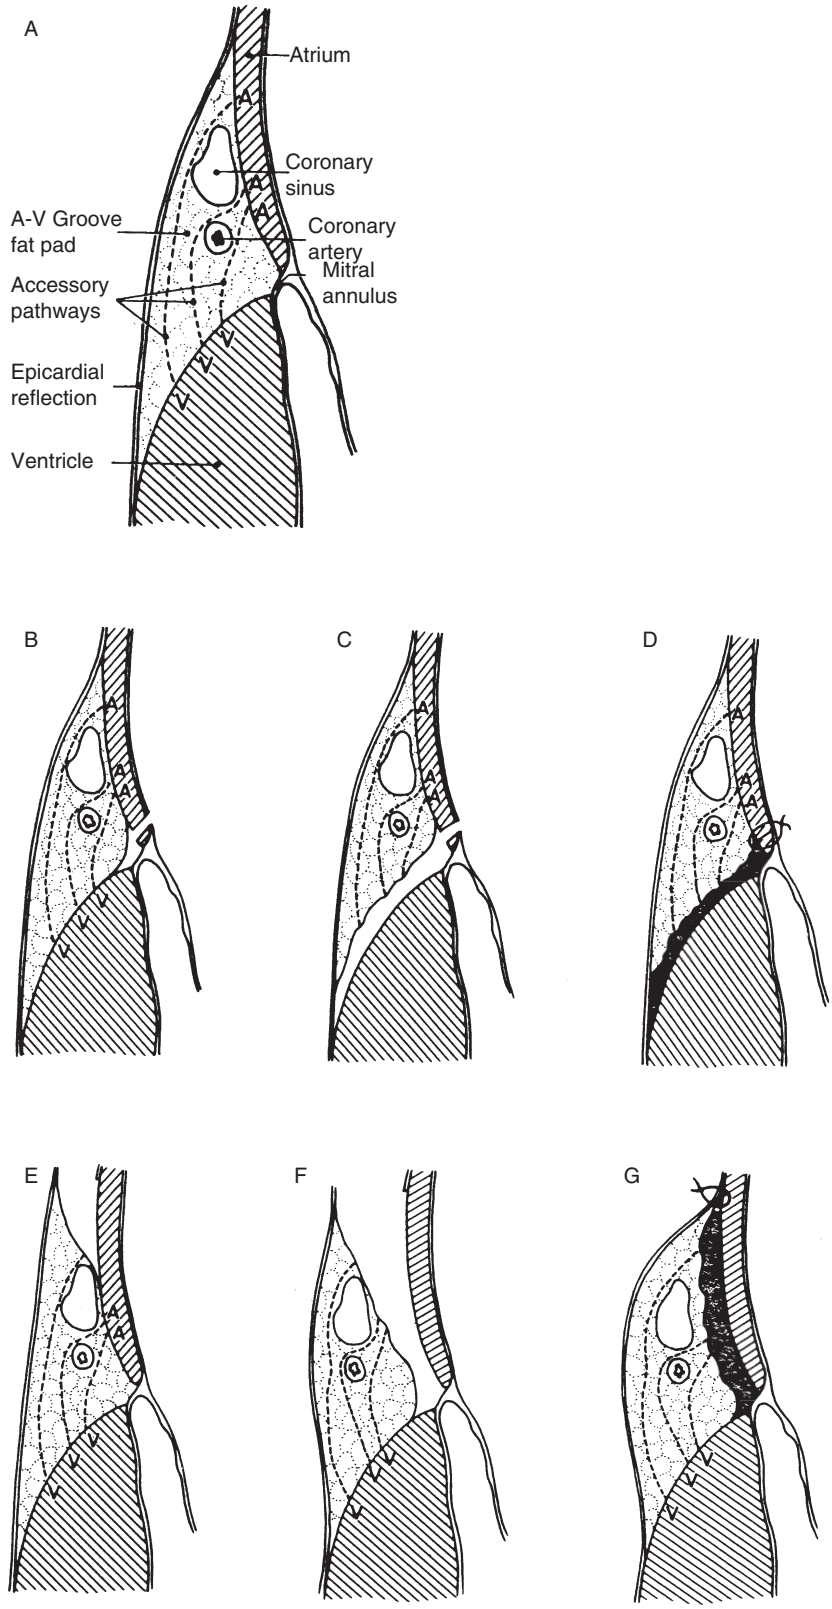

Figure 41.1 Diagrammatic representation of a cross-section of the posterior left heart. **A,** The different depths at which left free-wall connections can be located in relation to the mitral annulus and epicardial reflection are shown. **B–D,** The endocardial surgical technique. **E–G,** The epicardial technique. (Reproduced with permission from Cox [52].)

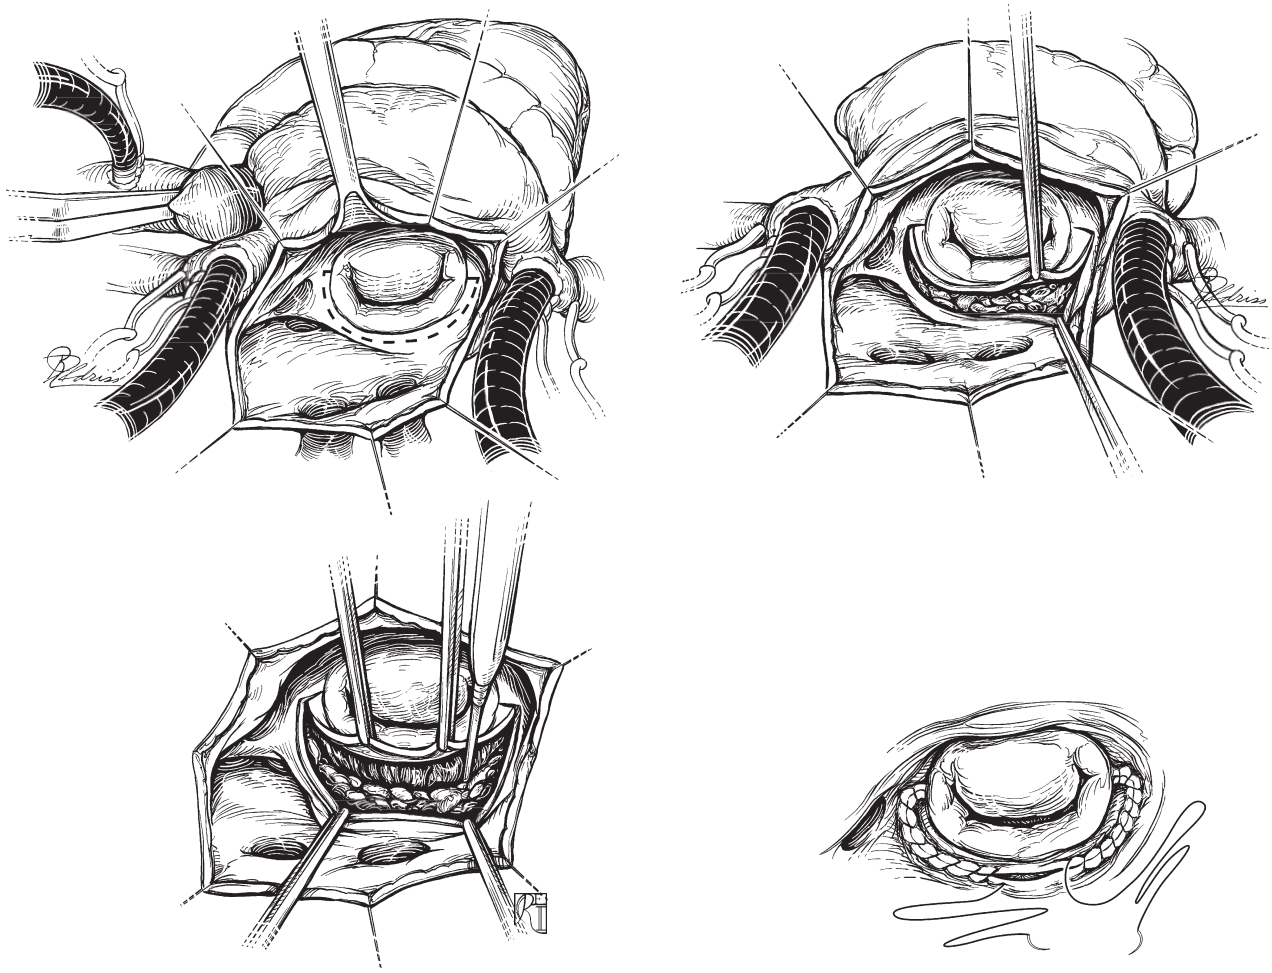

Figure 41.2 Endocardial technique for dividing left free-wall accessory connections in Wolff-Parkinson-White syndrome.

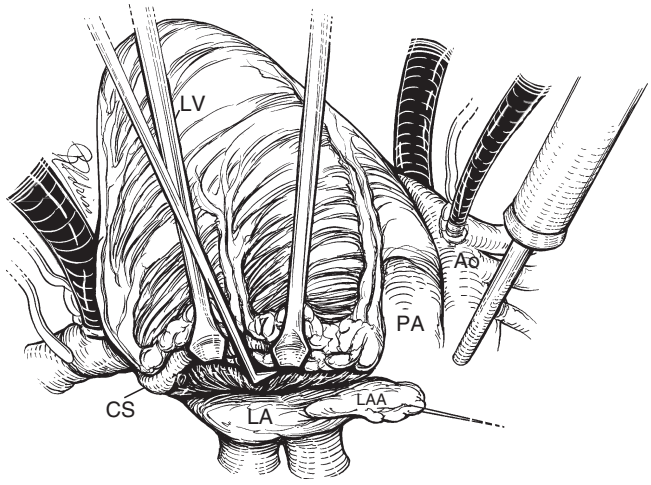

Figure 41.3 The epicardial approach to left free-wall accessory connections. A schematic of the left ventricle, viewed from an operative position. The fat pad is mobilized and the atrioventricular junction exposed. (Ao, aorta; CS, coronary sinus; LA, left atrium; LAA, left atrial appendage; LV, left ventricle; PA, pulmonary artery.)

atrioventricular anatomic connections may vary, especially when there is a subaortic muscular conus, atrioventricular discordance, and juxtaposition of the atrial appendages. The surgeon should be familiar with both techniques and be ready to alter the procedure depending on the pathoanatomy.

Posterior Septal Accessory Connections

The *endocardial* approach to posterior septal connections is through the right atrium. Normothermic cardiopulmonary bypass usually is used with certain precautions, which include closure of any intracardiac shunts before proceeding with the operation. Preoperative evaluation, particularly transthoracic echocardiography, may not always detect the presence of a patent foramen ovale. Care then is taken to fibrillate the heart shortly after cardiopulmonary bypass and before right atrial entry in order to check for, and close, a patent foramen ovale. This maneuver will ensure that no air is introduced into the left ventricle during a beating cardiac cycle. After complete patent foramen

ovale closure, the heart can be defibrillated and the operation continued.

After completion of the endocardial mapping, a supra-annular incision is made 2 mm above the posterior medial tricuspid valve annulus, beginning at least 1 cm posterior to the His bundle (Figure 41.4) [2,53]. The supra-annular incision is extended counterclockwise onto the posterior right atrial free wall. This incision provides exposure to the posterior septal space near the left ventricle and the epicardial reflection at the posterior right ventricle near the crux of the heart. The posterior septal space fat pad is then dissected away from the top of the posterior ventricular septum while the heart is beating or during hypothermic cardioplegic arrest, depending on the vascularity of the dissection plane and the preference of the surgeon.

The *epicardial* approach to posterior septal accessory connections is very similar to that for the left free-wall connections except of course for the location. The posterior septal accessory connections are divided by developing a dissection plane between the fat pad and the top of the posterior ventricular septum, following the mitral annulus over to the posterior superior process of the left ventricle, and following the epicardial reflection from the posterior right ventricle, across the crux, onto the posterior left ventricle. Cryolesions are placed at regular intervals around the annulus to ensure complete division of all accessory connections.

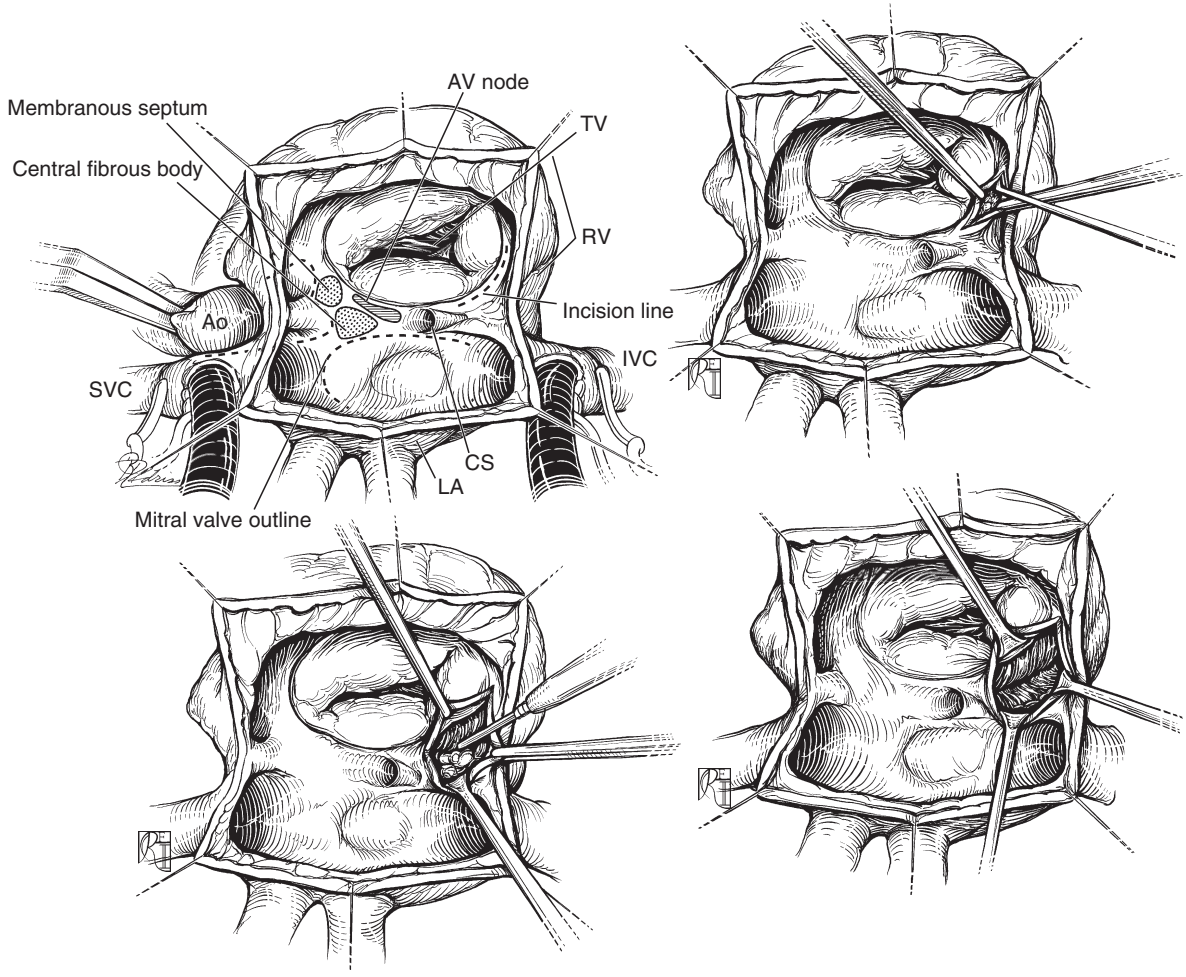

Figure 41.4 Endocardial technique for surgical division of posterior septal accessory connections in Wolff-Parkinson-White syndrome. The junction of the posterior medial mitral and tricuspid valve annuli forms an inverted V at the posterior edge of the central fibrous body, and the fat pad comes to a point at the apex of that V. The apex of the V is always posterior to the His bundle, although the distance between the apex of the V and the His bundle may vary. As long as the dissection in this region remains posterior to the central fibrous body, the His bundle will not be damaged. After the anterior point of the fat pad is gently dissected away from the apex of the V (i.e., away from the posterior edge of the central fibrous body), the mitral valve annulus comes into view at the point where it joins the tricuspid valve to form the central fibrous body. (Ao, aorta; AV, atrioventricular node; CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve.)

Right Free-Wall Accessory Connections

The *epicardial* dissection for right free-wall accessory connections can be performed without cardiopulmonary bypass in the majority of cases. An incision is made in the epicardium, establishing a dissection plane between the right atrial wall and the atrioventricular groove fat pad to the tricuspid valve annulus (Figure 41.5) [53] throughout the entire length of the right atrial free wall. Cryolesions at appropriate intervals can ensure complete accessory connection ablation.

The *endocardial* technique can be used if there is concern about epicardial bleeding or if a concomitant intracardiac repair is necessary. Under cardioplegic arrest, a supra-annular incision is placed 2 mm above the tricuspid valve annulus, extending around the entire right free-wall. A dissection plane is then established between the underlying atrioventricular groove fat pad and the top of the right ventricle throughout the length of the supra-annular incision. The dissection is extended to the epicardial reflection off the ventricle, thereby dividing all the penetrating fibers in this area. The incision can then be closed.

Anterior Septal Accessory Connections

The *epicardial* approach to anterior septal accessory connections was less successful than the *endocardial* approach, leading most surgeons to use the endocardial exposure for this connection [13]. The endocardial dissection is similar to that for the right free-wall lesions except for location. A supra-annular incision is made just anterior to the His bundle, 2 mm above the tricuspid annulus and extended in a clockwise direction onto the right anterior free-wall. The dissection plane is established between the fat pad occupying the anterior septal space and the top of the right ventricle and developed to the aorta medially and to the epicardial reflection off the ventricle anteriorly. Great care is required to avoid injury of the right coronary artery, which courses through the fat pad in this area, and the aortic wall at the right coronary sinus of Valsalva.

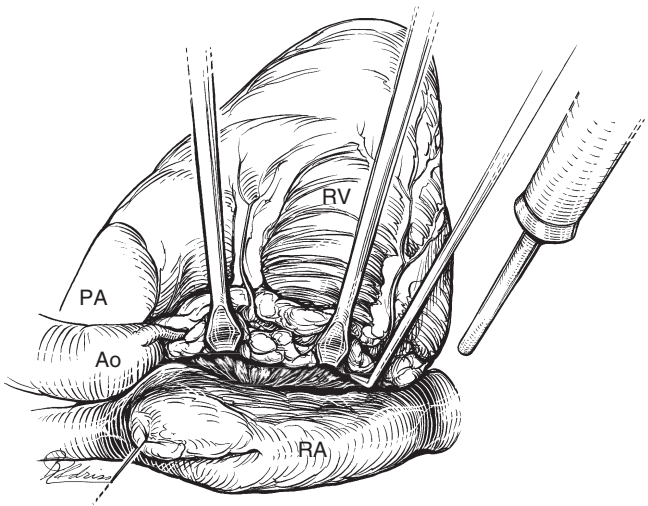

Figure 41.5 Epicardial approach for right free-wall accessory connections. A schematic view of the exposure of the right coronary fossa and anterior right ventricular atrioventricular sulcus. (AO, aorta; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.)

Special Considerations

Accessory connections are frequently present in patients with Ebstein anomaly of the tricuspid valve and in patients with congenitally corrected transposition of the great arteries who have associated Ebstein malformation of the systemic tricuspid valve. These connections tend to be multiple and due to the abnormal anatomy of the atrioventricular groove, are sometimes technically difficult to completely eliminate with the transcatheter approach, and have a higher risk of recurrence following an initially successful ablation. In this setting, operative dissection of the atrioventricular groove provides a technical advantage.

Macro Re-Entrant Atrial Tachycardia (Atrial Re-Entry Tachycardia, Atrial Flutter)

Mechanism

Macro re-entrant atrial tachycardia is a large tachycardia circuit present in either the right or left atrium (Plate 41.3, see plate section opposite p. 594) [37,41,54–56]. The re-entrant circuit requires unidirectional block and an area of slow conduction in order to sustain tachycardia. A premature atrial contraction can propagate an electrical wave front that encounters unidirectional block near the atrial septum and is redirected inferiorly by an alternative route, to the right atrial free-wall. The electrical wave front encounters an area of slow conduction, usually at the area between the inferior vena cava, tricuspid valve, and the coronary sinus. The electrophysiologic delay allows the area of unidirectional block to recover conduction. The electrical wave front now enters opposite the area of unidirectional block that establishes the re-entrant circuit. Cryoablation lesions are used to interrupt this circuit at the inferior isthmus, defined as the area between the coronary sinus, tricuspid annulus, and the inferior vena cava. The cryoablation lesion, therefore, transforms an area of slow conduction to an area of no conduction, thereby eliminating the circuit. Multiple areas of slow conduction may exist in patients with congenital heart disease from prior incisions, patches, or wall stress.

Indications for Surgery

Patients with refractory atrial tachycardia failing catheter ablation procedures, and patients with tachycardia requiring repair of associated intracardiac defects, are considered candidates for surgical arrhythmia intervention. Success rates for eliminating right atrial macro re-entrant surgery using the modified right atrial maze procedure are over 95% [31–33,35,37,40,41,55,56]. In rare cases of tachycardia in the neonate with structural heart disease, in which the ablation procedure poses significant risk to the infant, surgical ablation may be performed safely. In patients who have had Fontan surgery, transcatheter ablation therapy has limited success because of the frequent association of coexisting hemodynamic abnormalities. Those centers that have recognized this problem have achieved excellent results with a combined approach of repair of associated lesions in combination with Fontan conversion and arrhythmia surgery [35,39,40,57].

Structurally Normal Hearts

In the structurally normal heart, atrial re-entry tachycardia is uncommon and usually is amenable to radiofrequency catheter ablation procedures. If the area of re-entry encompasses a wide area of atrial tissue, the catheter technique may not be successful, and resection coupled with cryoablation may be effective. We have operated successfully on an 11-year-old girl who had paroxysmal sinoatrial re-entry tachycardia since infancy, refractory to virtually all antiarrhythmic therapy, and failing two ablation procedures. Endocardial mapping localized tachycardia to the posterolateral right atrium; during surgery, repeat activation mapping indicated additional involvement of the posterior left atrium. Resection of the posterolateral right atrium was performed, with an encircling incision around the pulmonary veins. The child had no recurrence of the atrial re-entrant tachycardia in 4 years, but she developed late sinus bradycardia requiring an atrial pacemaker 3 years postoperatively.

Concomitant Repair of Congenital Heart Disease

A small population of patients with congenital heart disease will have atrial tachycardia identified before any surgical intervention; arrhythmia management may be incorporated into single-stage therapy at the time of surgery without limitations of patient weight or complexity of anatomy [57–59].

We have experience with a few patients with atrial re-entry tachycardia originating near the rim of an unrepaired atrial primum or secundum septal defect. Because of the need for atrial surgery, we elected not to perform catheter ablation but to ablate under direct vision intraoperatively. After mapping the tachycardia preoperatively, surgical repair includes excision of the rim of the atrial defect, with localized cryoablation of the involved perimeter of the defect. Anatomic ablation of the inferomedial right atrial isthmus, between the os of the coronary sinus and the inferior vena cava, may treat atrial flutter successfully. We have performed right atrial cryoablation for an infant with recurrent atrial flutter at the time of initial repair of tetralogy of Fallot.

More commonly, atrial tachycardia occurs as a late sequelae of intracardiac repair of congenital heart disease. Atrial re-entry tachycardia occurs in 20–50% of postoperative Mustard or Senning patients [60,61], more than 40–50% of Fontan patients [62,63], and 34% of tetralogy of Fallot patients [64]. In the absence of hemodynamic problems, particularly in the non-Fontan patient, such arrhythmias most often are treated successfully using radiofrequency catheter ablation [65,66]. However, if patients have residual hemodynamic abnormalities, or in Fontan patients with atriopulmonary repairs, consideration should be given to integration of the principles of catheter ablation into the surgical repair to minimize interventions for the patient. In contrast to nonsustained ventricular arrhythmias, which may improve after repair of residual hemodynamic problems, atrial arrhythmias tend to persist after surgery. Direct intervention for atrial arrhythmias during surgery is highly effective and relies on four techniques; inferomedial right atrial ablation for typical atrial flutter, a modified right atrial maze procedure for multiple atrial re-entrant circuits, a Cox-maze III procedure for atrial fibrillation, and atrial pacemaker implantation, either to avoid bradycardia or as an antitachycardia device.

Atrial re-entry tachycardia following the Mustard or Senning procedure is amenable to catheter ablation, although a retrograde catheter approach via the aorta and across the tricuspid valve into the pulmonary venous atrium is often necessary [50,67], with the attendant risk of creating aortic insufficiency. If the patient requires reoperation for hemodynamic problems, such as atrial baffle leak repair, direct surgical cryoablation between identified anatomic barriers can be performed successfully with minimal prolongation of the surgical repair, in contrast to lengthy fluoroscopy time. We have used this approach successfully in two patients.

Atrial Re-Entry Tachycardia in Fontan Patients

Catheter ablation of atrial re-entry tachycardia following surgical repair of congenital heart disease has acute success rates of 30–80% [68,69], with short-term recurrence rates for single-ventricle patients greater than 50% [70]. The catheter approach is more likely to fail in hearts with residual

hemodynamic problems and markedly thickened atria [71]. The Fontan population is particularly problematic because significant atrial arrhythmias occur in at least 50% of patients during long-term follow-up [62,63] and because of limited success of the catheter approach with high recurrence of tachycardia [70,72]. Factors contributing to the disappointing results of the catheter approach include chronic atrial hypertension and dilation, distorted anatomy, multiple re-entrant circuits, restricted catheter access, particularly following lateral tunnel-type repairs, and the inability to deliver ablation lesions of sufficient depth to create a line of block. The ability to perform three-dimensional mapping of the multiple re-entrant circuits and to track the continuity of the ablation lines of block [73–75], coupled with newer types of energy delivery enabling deeper lesions, may improve the results of catheter ablation in patients with lateral tunnel type repairs [76].

Most atriopulmonary Fontan patients with disabling atrial arrhythmias have significant hemodynamic abnormalities, including obstruction of the right atrium-to-pulmonary artery connection, pulmonary venous obstruction, and massively dilated right atria with sluggish venous flow, predisposing to atrial thrombosis [63]. In addition, in some patients recurrent atrial re-entry tachycardia may progress to atrial fibrillation, which is not amenable to catheter ablation in this population. The loss of atrial contractility is particularly debilitating in patients with single-ventricle physiology. We and clinicians in other centers initially attempted to treat the disabling arrhythmias with surgical revision of the Fontan anastomosis, without direct intervention for the arrhythmia substrate [36,77–83]. This approach resulted in improved hemodynamics but almost uniform recurrence of atrial tachycardia [36,77–83].

The association of hemodynamic abnormalities and recurrent tachycardia following surgical repair led us to combine a surgical approach to arrhythmia therapy with revision of the Fontan hemodynamics in postoperative Fontan patients with refractory atrial tachycardia [36,39,40]. We have now performed 127 Fontan revisions in combination with arrhythmia surgery over the last 15 years. Patients with atrial macro re-entry tachycardia undergo a modified right atrial maze procedure (Figure 41.6) [59], while patients with atrial fibrillation undergo the modified right atrial maze in addition to a left atrial Cox-maze III procedure. The modified right atrial maze is designed to interrupt critical areas of re-entry specific to the Fontan patient which are: the atriotomy scar, the rim of the atrial septal defect and the lateral right atrial wall, the right atrial isthmus, and the prior atriopulmonary connection. Patients with atrial fibrillation undergo the Cox-maze III procedure involving the right and left atria (Figure 41.7) [59].

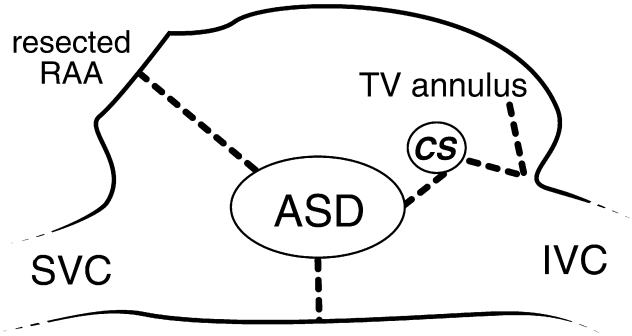

Figure 41.6 Modified right atrial maze procedure for atrial re-entry tachycardia. Large section of anterior right atrial wall is resected, including incision from SVC to IVC. Cryoablation lesions are indicated by dotted lines. (ASD, atrial septal defect; CS, coronary sinus; IVC, inferior vena cava; RAA, right atrial appendage; SVC, superior vena cava; TV, tricuspid valve.) (Reproduced with permission from Deal *et al.* [59].)

Maze Surgical Technique

The modified right atrial maze procedure and the modified Cox-maze III procedure were developed to repair re-entrant atrial circuits that tend to be multiple in patients with varying anatomy and complex congenital heart disease (Plate 41.4, see plate section opposite p. 594; Figures 41.8–41.12) [8,37,38,41,84,85]. Plate 41.4, see plate section opposite p. 594, demonstrates the possible lines of ablation that can be used to treat macro re-entrant atrial tachycardia in the presence of various atrial anomalies [37,41]. These include juxtaposition of the atrial appendages, total anomalous pulmonary venous connection, separate atrial entry of the

hepatic veins, persistent left superior vena cava, and absence of the coronary sinus. The most common anatomic variances of single ventricle that require adaptation of the right-sided maze procedure are tricuspid atresia, mitral atresia, and common atrioventricular valve. Figures 41.8, 41.9, and 41.10 show the cryoablation lesions that are applied to areas of slow conduction in these patients [85]. In addition, the Cox-maze III procedure treats atrial fibrillation and has been modified for patients with single ventricle, as noted in Figures 41.11 and 41.12 [37,84,85].

Conduct of Fontan Conversion

Three basic types of existing first time anatomic connections undergoing revision are atrial compartmentalization with right atrium-to-pulmonary artery anastomosis, classic right Glenn operation and an atrium-to-left pulmonary artery anastomosis, and a total cavopulmonary artery reconstruction.

At the time of Fontan conversion, or any re-do congenital heart operation, adhesions from previous operations, dilated right atria, long-standing abnormal physiology of the atriopulmonary circuit, and right ventricular-to-pulmonary artery conduit or anterior aorta all contribute to the difficulty of sternal re-entry [37]. In rare cases, the femoral vessels can be dissected before the resternotomy for rapid cannulation and institution of cardiopulmonary bypass when there is high risk for cavitary entry. Early identification of the aorta and atrium is achieved so that rapid institution of cardiopulmonary bypass can be accomplished in the event of unwanted mishaps during dissection. To avoid injury to the phrenic nerves the dissection plane should remain medial to the pericardium and entry into the cardiac chambers is to be avoided to reduce the risk of paradoxical air embolus occurring through residual

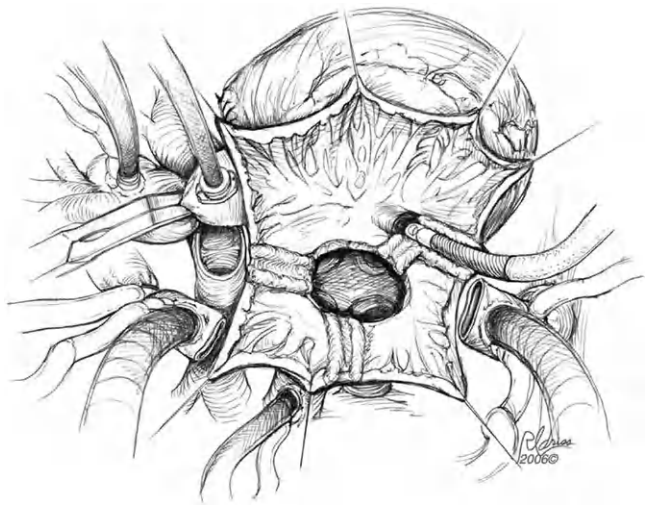

Figure 41.8 Atrial view of a patient with tricuspid atresia who had an atriopulmonary Fontan operation after aortic cross-clamping and cardioplegic arrest. The inferior and superior venae cavae have been transected, the atrial wall excision has been performed, and the atrial septal patch has been removed. No measures are taken to preserve the sinoatrial node, which is nonfunctional in a significant number of patients. Cryoablation lesions are placed in four areas to complete the modified right-sided maze procedure. The first two cryoablation lesions are standard for all anatomic substrates and are performed by connecting (1) the superior portion of the atrial septal ridge with the incised area of the right atrial appendage and (2) the posterior portion of the atrial septal ridge with the posterior cut edge of the atrial wall, which extends through the crista terminalis. The next part is the isthmus ablation. These lines of block are dependent on the anatomic substrate. In patients with tricuspid atresia, as noted here, the cryoablation lesion is placed to connect (3) the posteroinferior portion of the coronary sinus os with the transected inferior vena cava os. The last lesion (4) connects the coronary sinus os with the inferior edge of the atrial septal defect. (Reproduced with permission from Mavroudis *et al.* [85].)

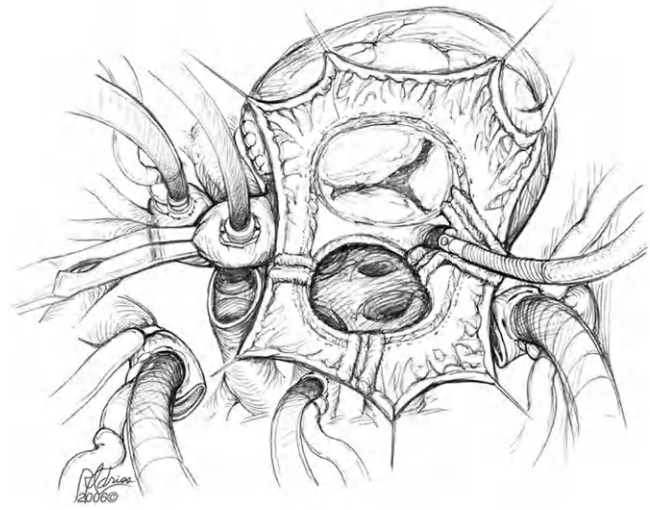

Figure 41.9 This drawing demonstrates the modified right-sided maze procedure in a patient with double-outlet right ventricle and mitral atresia. As noted in Figure 41.8, the two standard cryoablation lesions connecting the rim of the atrial septal defect with (1) the incised area of the right atrial appendage and (2) the posterior cut edge of the atrial wall, respectively, are shown. The isthmus block is accomplished by creating cryoablation lesions (3) to connect the posteroinferior portion of the coronary sinus os with the transected inferior vena cava os, and (4) to connect the tricuspid valve annulus with the transected inferior vena cava os. These isthmus block lesions are usually placed across the ridge of the resected atrial compartmentalization patch. An additional lesion (5) connects the coronary sinus os with the inferior edge of the atrial septal defect. (Reproduced with permission from Mavroudis *et al.* [85].)

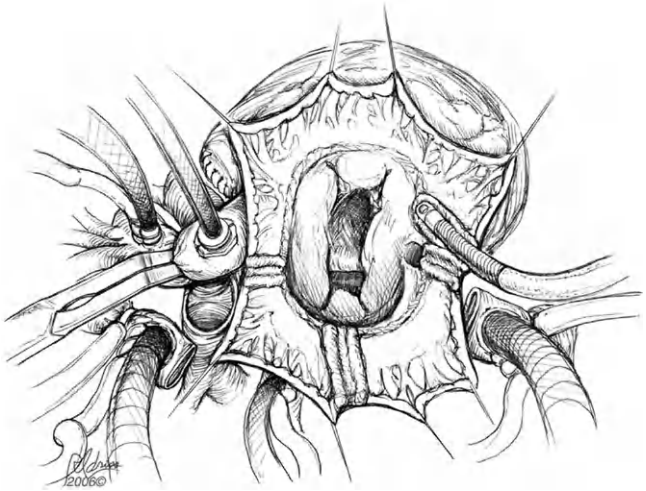

Figure 41.10 This drawing demonstrates the modified right-sided maze procedure in a patient with single-ventricle and unbalanced atrioventricular canal. As noted in Figure 41.8, the two standard cryoablation lesions connecting the rim of the atrial septal defect with (1) the incised area of the right atrial appendage and (2) the posterior cut edge of the atrial wall, respectively, are shown. The isthmus block is accomplished by creating cryoablation lesions (3) to connect the posteroinferior portion of the coronary sinus os with the transected inferior vena cava os and (4) to connect the common atrioventricular valve annulus with the transected inferior vena cava os. These isthmus block lesions are usually placed across the ridge of the resected atrial compartmentalization patch. The lesion connecting the coronary sinus os with the atrial septal defect is not performed because the anatomic ridge is not usually absent. (Reproduced with permission from Mavroudis *et al.* [85].)

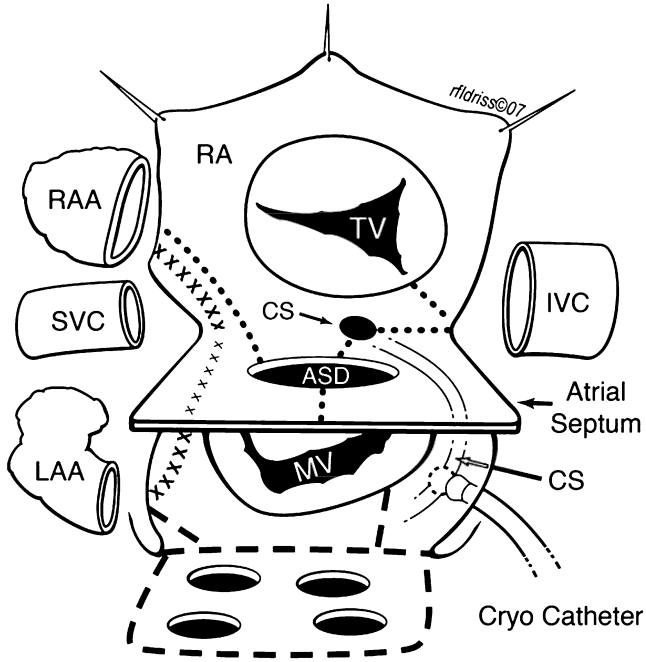

Figure 41.11 Diagrammatic representation of the modified right-sided maze procedure for right atrial re-entry tachycardia (dotted lines) and the left atrial Cox-maze procedure (dashed lines) for atrial fibrillation and left atrial re-entry tachycardia. Additional cryoablation lines are: (1) coronary sinus (CS) to atrial septal defect (ASD) for modified right-sided maze procedure, and (2) base of the right atrial appendage (RAA) to the base of the left atrial appendage (LAA) across the domes of the right and left atria for the left atrial Cox-maze procedure. The addition of the coronary sinus-to-atrial septal defect lesion did not change what we call the modified right-sided maze procedure; however, the addition of the right atrial appendage-to-left atrial appendage lesion caused us to change the name of the left-sided operation to left atrial Cox-maze procedure which infers that we use this same operation for both left atrial re-entry tachycardia and atrial fibrillation. (ASD, atrial septal defect; AVN, atrioventricular node; CS, coronary sinus; FO, foramen ovale; HV, hepatic vein; IVC, inferior vena cava; LAA, left atrial appendage; LSVC, left superior vena cava; MV, mitral valve; PV, pulmonary valve; RA, right atrium; RAA, right atrial appendage; RSVC, right superior vena cava; SVC, superior vena cava; TAPVR, total anomalous pulmonary venous return; TV, tricuspid valve.) (Reproduced with permission from Mavroudis *et al.* [37,84].)

intracardiac shunts. Careful preoperative planning and extreme caution during the resternotomy should insure a safe outcome for the patient [86].

Once the sternum is opened we proceed to aortic and direct vena cava cannulation using right-angled cannulas inserted high in the superior vena cava and straight cannulas in the inferior vena cava [37]. After the commencement of cardiopulmonary bypass the inferior vena cava is transected and anastomosed to a 24 mm Gore-Tex (W.L. Gore & Associates, Flagstaff, AZ) tube graft. A vent is placed in the right superior pulmonary vein, the aorta is cross-clamped, and cold blood cardioplegia is delivered. With the heart arrested, an atrial septectomy and resection of the right atrial appendage are performed. Linear cryoablation lesions for the right-sided maze procedure are placed with a Surgifrost device (CryoCath Inc., Kirkland, Quebec, Canada) applied at –160 °C for 1 minute. The lesions extend from the base of the right atrial appendage to the cut edge of the atrial septal defect, across the crista terminalis from the cut edge of the atrium to the atrial septal defect, and from the transected inferior vena cava to the coronary sinus. In addition, if a tricuspid valvar orifice is present, a lesion is created from the inferior vena cava to the annulus of the tricuspid valve. A lesion is placed to prevent macro re-entrant circuits extending from the coronary sinus to the edge of the atrial septal defect. In patients with atrial fibrillation, the Cox-maze III procedure is performed. The left atrial appendage is excised and an encircling pulmonary venous isolation is performed using

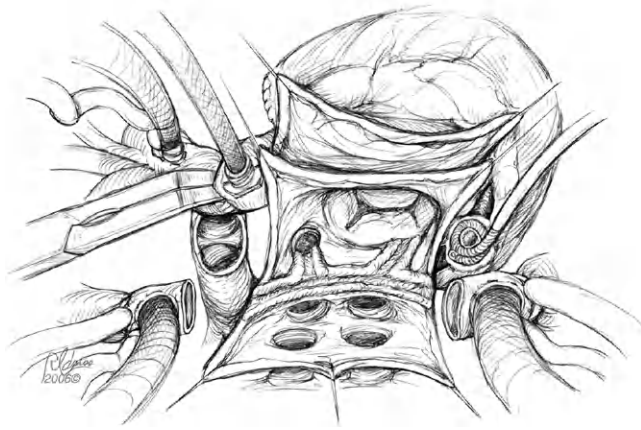

Figure 41.12 Left atrial view of a univentricular heart that shows the standard incisions, excisions, and cryoablation lesions which, when combined with the right atrial component, complete the Cox-maze III procedure. The incisions include a partial encircling pulmonary vein isolation and a left atrial appendage resection. Standard cryoablation lesions (–60°C for 60 seconds) are placed to complete the pulmonary vein isolation, to create a cryoablation lesion from the isolated pulmonary veins toward the posterior mitral (P3 or medial mitral scallop) or tricuspid valve annulus, and to extend the pulmonary vein isolation to the cut edge of left atrial appendage base. A cryoablation lesion is placed on the coronary sinus (–60°C for 120 seconds). (Reproduced with permission from Mavroudis *et al.* [85].)

cryoablation and/or incisional techniques. A cryoablation lesion is placed from the cut portion of the excised left atrial appendage to the confluence of the pulmonary veins. An additional lesion is placed from the encircling atriotomy lesion to the annulus of the mitral valve, directing it at the inferomedial scallop. A circular lesion, created for 2 minutes, is placed on the epicardial surface of the coronary sinus directly opposite the endocardial lesion involving the mitral valve. At the conclusion of the Cox-maze III procedure, the right atrium is closed with running polypropylene, the heart de-aired, and the cross-clamp removed. This sequence can be altered in the event that other left-sided lesions require surgical repair.

For patients with atriopulmonary anastomoses, a standard total cavopulmonary artery connection is accomplished using a lateral tunnel or an extracardiac technique [87–90]. Pulmonary artery reconstruction, when necessary, is performed at that time. In patients with a prior right Glenn procedure and an atrium-to-left pulmonary artery anastomosis, more creative pulmonary artery reconstructions are required. Left-sided (systemic circulation) procedures are performed under cardioplegic arrest; they include prosthetic atrial patch resection, valvar reconstructions, and completion of left atrial cryoablative lesions when needed. After atriorrhaphy and removal of the aortic cross-clamp, total cavopulmonary connection is then completed, using a polytetrafluoroethylene conduit for the inferior vena cava connection to the pulmonary artery. Earlier in our experience, transmural atrial wires were implanted using the technique reported by Hoyer and associates [91,92]. Presently the epicardial approach is used for the atrial pacemaker leads. Initially, an atrial antitachycardia pacemaker was used. With subsequent use of the more extensive modified right atrial maze procedure, tachycardia recurrence is rare, and an atrial rate-responsive pacemaker is preferred. Separation from cardiopulmonary bypass is followed by transesophageal echocardiographic assessment.

Pacemaker Implantation

Achievement of acceptable pacing thresholds in the atrium may be challenging because of the extensive resection, reconstruction, and ablative lesions [37,85]. Typically, epicardial bipolar steroid eluting leads are placed on the right atrium near the atrioventricular groove anterior to the atriotomy. The technique of lead implantation is illustrated in Figures 41.13 and 41.14 [93]. It is important to find a portion of atrium relatively free of adhesions. In difficult situations, these leads can be placed on the dome of the left atrium or at the base of the left atrial appendage. Device selection has evolved over the years to the current use of epicardial dual chamber antitachycardia pacing systems. Ventricular leads are placed on the ventricular diaphragmatic surface or the anterior ventricular wall according to optimal threshold measurements. Placement of ventricular leads will minimize the effects of atrial lead far field R wave sensing, and will provide the capability of dual-chamber pacing should atrioventricular block develop with time. For the ventricular lead we have tried to use the steroid eluting bipolar epicardial leads, but when there is a large amount of scar tissue or fat on the ventricle we have used two screw-in leads attached in a "Y" configuration for bipolar sensing. Multisite ventricular pacing has been used in the setting of marked QRS prolongation to achieve ventricular synchrony and improved cardiac function [84,85]. In the rare setting of prior cardiac arrest because of ventricular arrhythmia, implantation of epicardial defibrillator patches or subcutaneous coils has been performed.

Anatomic and Electrophysiologic Variations of Fontan Conversion

Takedown of Right Atrial-to-Right Ventricular Bjork Modification

In the setting of surgical conversion of a Bjork–Fontan modification to a total cavopulmonary artery connection, the dilemma arises of what to do with the right ventricle [85]. Disconnecting the main pulmonary artery and leaving the right ventricle, however small, without an egress of

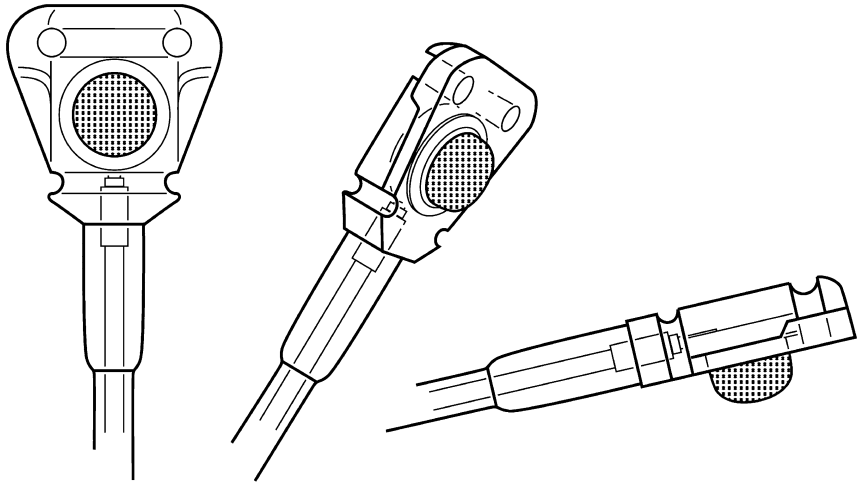

Figure 41.13 Steroid eluting lead. Medtronics model #4965. The round protruding portion is the porous-tipped electrode platinized with platinum black and coated with dexamethasone. At the proximal portion of the lead there is a groove for the retaining suture. At the distal portion of the lead there are two holes for the other retaining suture to pass through. (Reproduced with permission from Dodge-Khatami *et al.* [93].)

blood flow has the potential problems of right ventricular dilatation and leftward interventricular septal deviation caused by accumulation of thebesian blood flow. We have performed Fontan conversion with arrhythmia surgery on 14 patients (14/109; 12.8%) with tricuspid atresia (n = 13) and unbalanced atrioventricular canal (n = 1) who had a previous right atrial to right ventricular Bjork-Fontan connection with (Figure 41.15; n = 2) [85] and without (Figure 41.16; n = 12) [85] an interposition bioprosthetic valve [85]. The distinct surgical considerations in this setting are: 1) takedown of the Bjork-Fontan anastomosis, and 2) management of the right ventricle. Most of the patients without the bioprosthetic valve interposition graft had a communication that was formed by a posterior reversed right atrial flap and an anterior prosthetic patch that formed the right atrial to right ventricular connection. Takedown of these connections involves a careful and extensive dissection of the right atrioventricular grove to facilitate right atrial appendage amputation, right atrial wall reduction, epicardial pacemaker lead placement, and adequate right ventricular wall patch closure. The dissection of the right atrioventricular groove is commenced near the ascending aorta where an undissected plane is readily achieved (Figures 41.17, 41.18) [85]. The dissection is continued as far as possible toward the posteroseptal area as long as the dissection plane safely allows (Figure 41.19) [85]. Care must be taken not to enter the right coronary artery, which occurred in two patients in this series (1.8%). Because the injury was caused by electrocautery dissection in one, cardioplegic arrest and Gore-Tex patch (W.L. Gore & Associates,

Figure 41.19 Artist's depiction of completed electrocautery dissection of the entire atrioventricular groove. The amount of atrium freed from this maneuver allows for a larger atrial reduction and provides unscarred atrial tissue for the atrial pacemaker leads that are placed at the end of the Fontan conversion. (Reproduced with permission from Mavroudis *et al*. [85].)

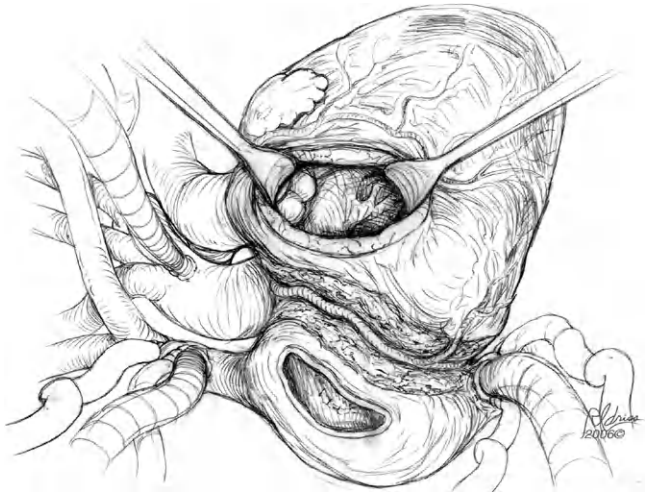

Figure 41.20 The right ventricle to pulmonary artery connection is prescribed to prevent the unwanted condition of a myocardial chamber without an outflow. The figure shows the intact pulmonary valve in continuity with the diminutive right ventricle and the downsized right atrial wall before atrial closure. (Reproduced with permission from Mavroudis *et al*. [85].)

Flagstaff, AZ) arterioplasty were performed without sequelae. The other injury was caused by sharp dissection and was repaired with cardioplegic arrest and interrupted suture technique without sequelae. Our approach to the remaining right ventricle is to preserve the right ventricular to main pulmonary artery connection to allow easy egress of blood into the pulmonary arteries (Figures 41.20, 41.21) [85]. We have found that the developed right ventricular pressure is low under these circumstances because of decreased right ventricular preload and does not affect the nonpulsatile blood flow established by the extracardiac total cavopulmonary connection (TCPC). Figure 41.22 shows a right ventricular patch and right atrial closure in association with the extracardiac total cavopulmonary connection [85]. The extensive atrioventricular groove dissection has aided the right atrial wall reduction and allowed for unscarred atrial wall for optimal epicardial pacemaker lead placement.

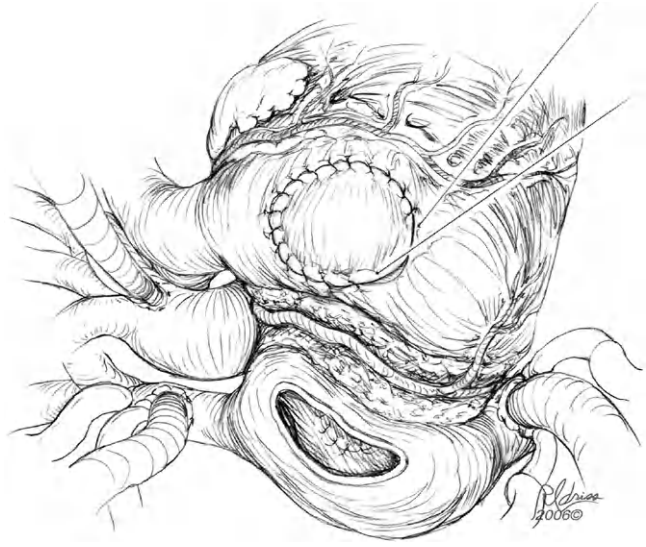

Figure 41.21 The diminutive right ventricular free wall is closed with a Gore-Tex patch allowing free egress of right ventricular blood (largely thebesian flow) to the main pulmonary artery. (Reproduced with permission from Mavroudis *et al*. [85].)

Takedown of Atrioventricular Valve Isolation Patch for Right-Sided Maze Procedure

In the developing era of Fontan procedures for complex diagnoses such as double-inlet ventricles, criss-cross hearts, and straddling atrioventricular valves, the smaller right-sided atrioventricular valve was oftentimes isolated with a patch when the left-sided atrioventricular valve was large enough and functional [37,85]. Patching of this valve accomplished separation of the circulations by performing an atriopulmonary connection together with an atrial septal defect closure. The important anatomic and electrophysiologic considerations relate to the distance of the patch to the annulus and the partitioning of the coronary sinus. Oftentimes, the isolation was performed to leave the coronary sinus on the ventricular side to avoid complete heart block (Figure 41.23), which means that the right-sided

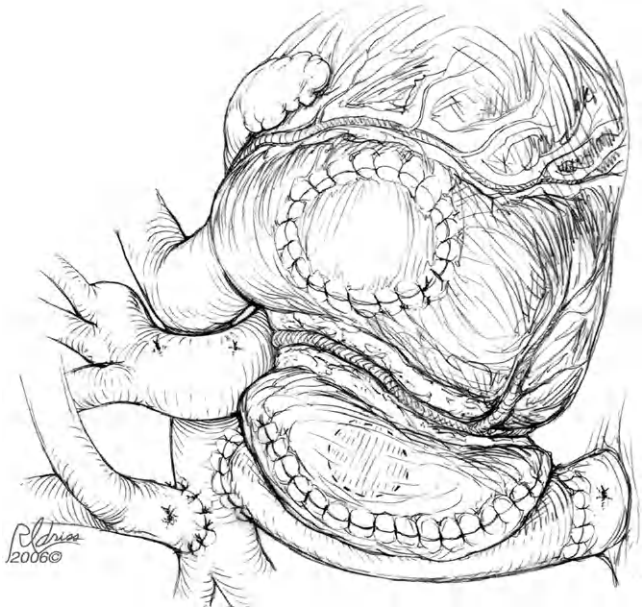

Figure 41.22 The completed extracardiac connections are shown. Right atrial wall reduction and closure is noted by the long atrial suture line. Right ventricular to main pulmonary artery continuity is maintained by a right ventricular patch, thus insuring outflow of thebesian venous flow and avoidance of right ventricular dilatation. (Reproduced with permission from Mavroudis *et al.* [85].)

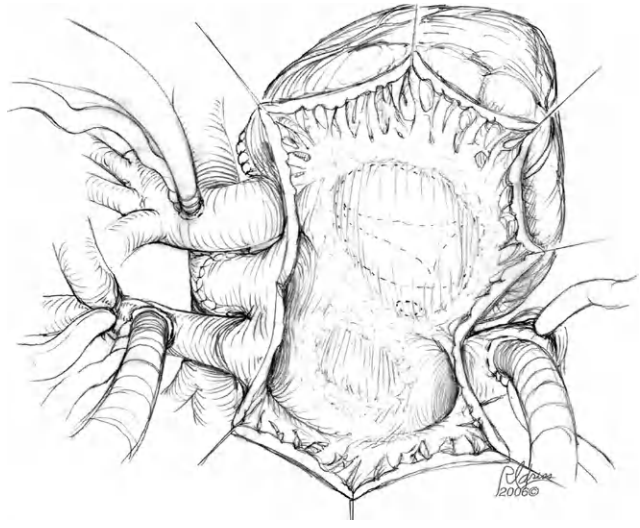

Figure 41.23 Right atrial view of a patient with double-inlet ventricle who had an atriopulmonary Fontan with tricuspid valve isolation and atrial septal defect closure. (Reproduced with permission from Mavroudis *et al.* [85].)

Figure 41.24 The isolation patch is sharply removed to uncover the tricuspid valve and the coronary sinus to perform the right-sided maze procedure. The atrial septal defect patch is also being removed. (Reproduced with permission from Mavroudis *et al.* [85].)

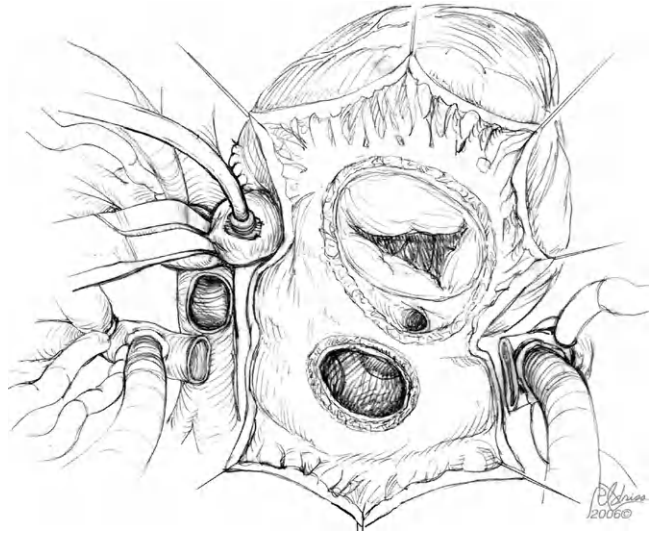

Figure 41.25 Right atrial view showing the results of isolation patch removal and atrial septal defect creation. The anatomic landmarks for application of the cryoablation lesions are now manifest. (Reproduced with permission from Mavroudis *et al.* [85].)

arrhythmia circuit might be partitioned to the pulmonary venous atrium. Under these circumstances, the right-sided maze cannot be safely performed because the traditional landmarks, namely the coronary sinus and the tricuspid valve, are not exposed. Therefore, the patch must be removed to accomplish the cryoablation procedure. Figure 41.24 shows the technique of tricuspid valve and atrial septal patch removal, respectively [85]. Figure 41.25 depicts the dissection plane associated with tricuspid valve patch removal. The cryoablation lesions can now be performed with adequate landmark identification which will insure transmural cryoablation (Figure 41.26) [85]. This part of the operation would have been in question if the cryoablation

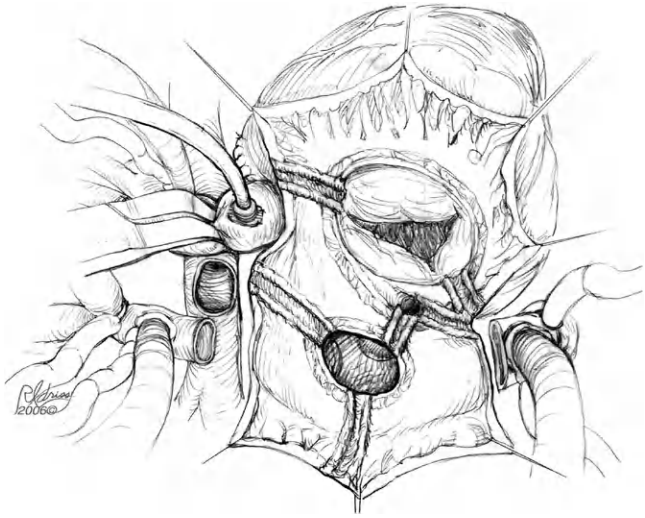

Figure 41.26 The cryoablation lesions are shown after proper identification of the tricuspid valve annulus and coronary sinus. The cryoablation lesion from the base of the right atrial appendage to the anterior tricuspid annulus is optional. (Reproduced with permission from Mavroudis *et al.* [85].)

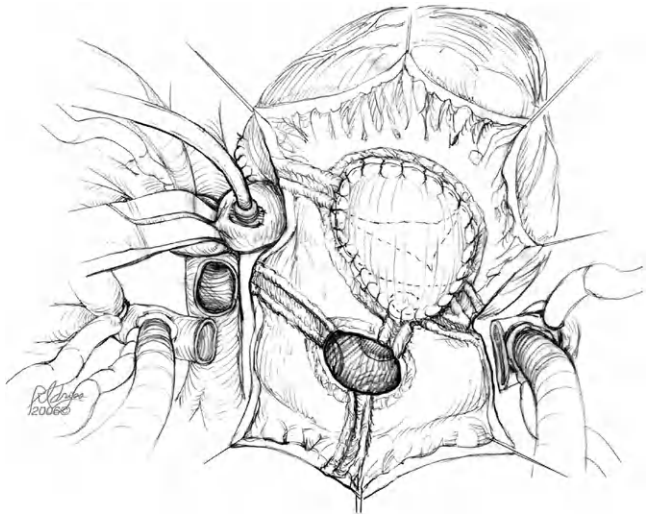

Figure 41.27 Right atrial view of Gore-Tex tricuspid valve isolation after cryoablation. The suture line for attachment is placed in the valve tissue near the annulus to avoid injury to the atrioventricular node. (Reproduced with permission from Mavroudis *et al.* [85].)

lesions were made on top of the prosthetic patch material. If the tricuspid valve is competent by bulb syringe testing, one can elect to allow the valve to function normally. If there is any question of valve competency or if there was antecedent valve dysfunction or injury, the valve can be isolated again with a Gore-Tex patch anchored to the leaflets of the tricuspid valve near the annulus (Figure 41.27) [85].

Right Atrial Cannulation in the Presence of a Right Atrial Clot

Approximately 5% of patients undergoing atriopulmonary to total cavopulmonary artery Fontan conversion can have right atrial clots, sometimes as a consequence of multiple transcatheter radiofrequency ablation attempts [94]. Fontan conversion in the setting of right atrial thrombus is fraught with hazards because of compromised cardiac output during sternotomy and dissection, the risk of clot dislodgement with cannulation, and the potential for venous catheter occlusion [85]. Preoperative evaluation using magnetic resonance imaging or computerized tomography to assess clot size and location can be complemented by epicardial echocardiography to guide safe atrial cannulation. Oftentimes, it is preferable to perform aorto-right atrial bypass to establish adequate cardiopulmonary bypass and improved perfusion while the dissection is completed which can lead to bicaval cannulation. During this time it is important to place the single atrial catheter away from the clot as shown in Figure 41.28 [85].

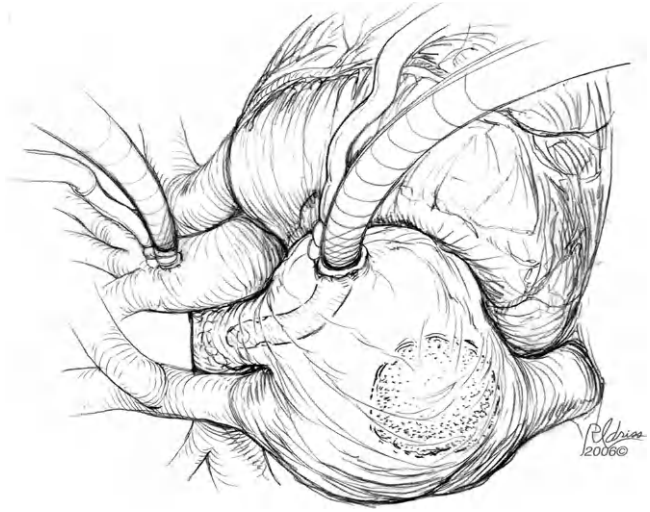

Figure 41.28 Global view of aorto-uniatrial cardiopulmonary bypass with the venous catheter placed away from the clot in the inferior portion of the right atrium where it was identified by epicardial echocardiography. Oftentimes, when the right atrium is large, single atrial cannulation for cardiopulmonary bypass can help with the completion of the dissection without causing hemodynamic instability. This can then be followed by conversion to bicaval cannulation. (Reproduced with permission from Mavroudis *et al.* [85].)

Distended Left Superior Vena Cava Causing Left Pulmonary Vein Stenosis

A distended left superior vena cava without circulatory egress may result in significant left pulmonary vein stenosis and compromise the Fontan circulation [85]. We have recognized and addressed this problem in two patients: one was caused by congenital orifice atresia in the right atrium and ill advised previous surgical ligation at the innominate vein connection, and the second was caused by coronary sinus occlusion because of lengthy radiofrequency catheter ablation. Both of these conditions resulted in an enlarging cardiac chamber caused by blood accumulation without egress anterior to the course of the left pulmonary veins, producing stenosis (Figure 41.29) [85]. During Fontan conversion and arrhythmia surgery, the coronary sinus was unroofed (Figure 41.30) in one patient and occlusive fibrous tissue/thrombus was resected in the other, relieving the pathway obstructions [85].

Discontinuous Pulmonary Arteries

Modification of the extracardiac Fontan may be used to convert patients with discontinuous pulmonary arteries resulting from the combination of a right classic Glenn procedure and a right atrial to left pulmonary artery connection [37]. Aortic homografts have a natural favorable curve to accomplish an end-to-end anastomosis between the distal homograft and left pulmonary artery, a side-to-side anastomosis between the homograft and the classic Glenn, and an end-to-end anastomosis between the proximal homograft and the inferior vena cava. Recognition of the possible need for future cardiac transplantation led us to modify our reconstructive procedures to avoid the use of allograft material, which has been shown to increase panel reactive antibody (PRA) levels and interfere with optimal immunosuppression. We now favor polytetrafluoroethylene grafts for reconstruction of discontinuous pulmonary arteries (Figure 41.31) [37,85].

Right Ventricular Hypertension and Tricuspid Regurgitation after Atriopulmonary Fontan for Pulmonary Atresia and Intact Ventricular Septum

In the setting of pulmonary atresia and intact ventricular septum, either the right ventricular to pulmonary artery connection is atretic or has been disconnected [37,85]. We have had experience with two patients with pulmonary atresia and intact ventricular septum who were treated with an atriopulmonary Fontan procedure and main pulmonary artery disconnection. Over the years, the right ventricle enlarged, became hypertrophied, and developed suprasystemic right ventricular pressure, resulting in right atrial hypertension and dilatation because of the significant tricuspid regurgitation. An extracardiac total cavopulmonary connection without addressing the tricuspid valve would increase the resultant common left atrial pressure and cause circulatory compromise. After performing the modified right-sided maze procedure, we isolated the tricuspid valve

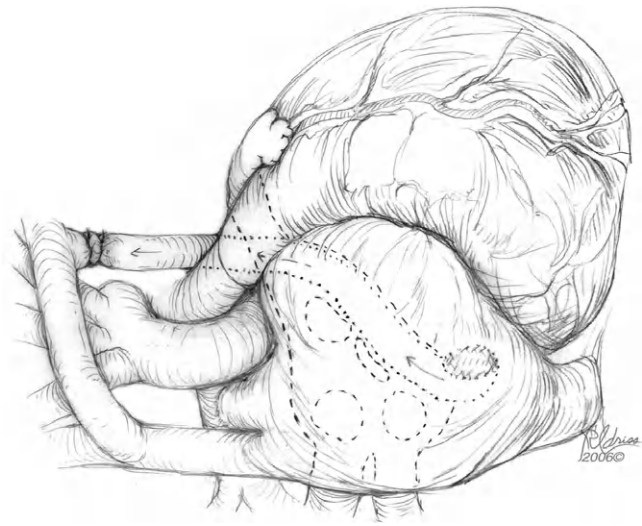

Figure 41.29 Drawing of a patient with double-inlet left ventricle, bulboventricular foramen, and L-transposition of the great arteries with bilateral superior venae cavae. The patient underwent ligation of the left superior vena cava in preparation for an eventual atriopulmonary Fontan without prior knowledge of orifice atresia of the coronary sinus. Lack of ebb flow from the coronary sinus caused sinus dilatation and obstruction of the left pulmonary veins as noted. (Reproduced with permission from Mavroudis *et al.* [85].)

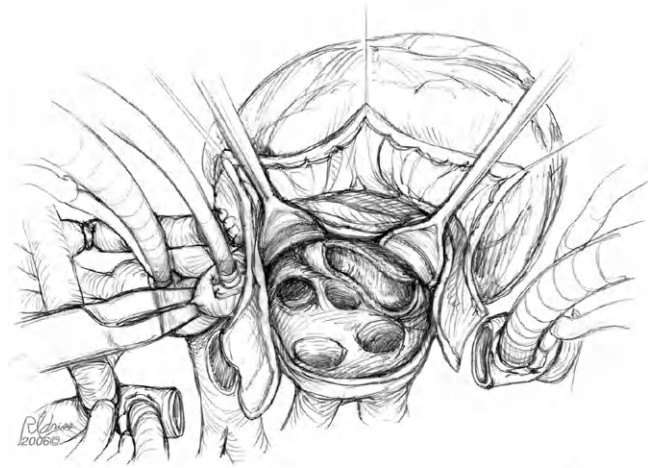

Figure 41.30 Left atrial view of a patient described in Figure 41.12. The large coronary sinus was unroofed, thereby establishing proper coronary sinus drainage and relief of the left pulmonary vein stenosis. (Reproduced with permission from Mavroudis *et al.* [85].)

Figure 41.31 Artist's representation of a patient who previously had a classic Glenn shunt to the right pulmonary artery connection who had reconnection of the pulmonary arteries using a Gore-Tex interposition graft and an extracardial inferior vena cava to pulmonary artery connection. Homografts are not used to avoid stimulation of preformed antibodies which could complicate cardiac transplantation should it become necessary. (Reproduced with permission from Mavroudis *et al*. [85].)

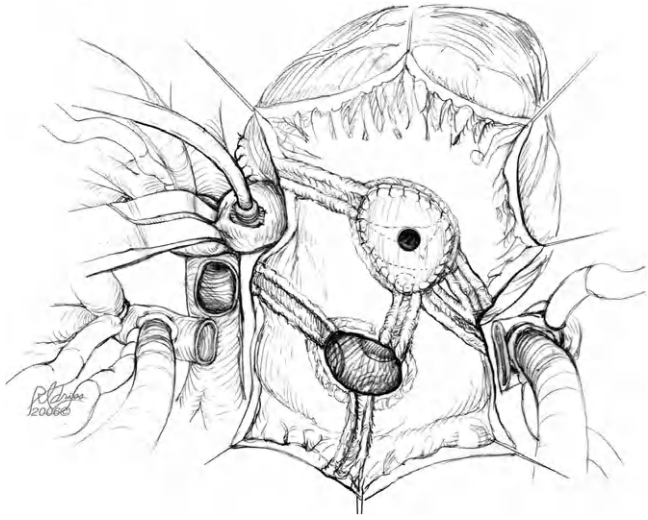

Figure 41.32 Right atrial view of a patient with pulmonary atresia and intact ventricular septum who had a prior atriopulmonary Fontan and presents now with arrhythmias and suprasystemic right ventricular pressure. The cryoablation lines are noted for the modified right-sided maze procedure as well as the fenestrated tricuspid valve isolation patch. The idea of the fenestration is to limit the inflow to the right ventricle in diastole, which will decrease the developed pressure of the right ventricle in systole. (Reproduced with permission from Mavroudis *et al*. [85].)

with a fenestrated (8 mm) Gore-Tex patch, which restricted blood flow into the right ventricle and decreased developed pressure by volume unloading the right ventricle. The fenestration also allowed blood egress into the common atrium during diastole (Figure 41.32) [85]. The developed right ventricular pressure in both patients postoperatively was significantly reduced and had no effect on the pulmonary venous atrial pressure.

Right Atrial Reduction in the Setting of a Systemic Right Ventricle Leading to Pulmonary Vein Stenosis

Right atrial wall reduction can be performed without hesitancy in patients with tricuspid atresia as long as the resultant anterior and posterior sides align without distortion [85]. The pulmonary veins are rarely compromised under these circumstances. However, complications can arise from overzealous right atrial wall reduction when the right ventricle is the dominant ventricle. Under these conditions, the right atrium must be large enough to direct blood flow from the pulmonary veins/left atrium, through the atrial septal defect, and then into the tricuspid valve. We have experience with one patient in whom an aggressive right atrial wall reduction (Figure 41.33) resulted in atrial septal defect compression and turbulence of pulmonary venous

Figure 41.33 Global view of the right atrium and single right ventricle after an overzealous right atrial wall reduction was performed. (Reproduced with permission from Mavroudis *et al*. [85].)

flow into the right ventricle (Figure 41.34) noted by transesophageal echocardiography [85]. The distortion was immediately repaired by a large Gore-Tex patch that relieved the turbulence and obstruction (Figure 41.35) [85]. We experienced a second case where we suspected the same problem would occur not from overzealous resection, but because of limited atrial tissue following the removal of a prosthetic anterior patch of the atriopulmonary con-

Figure 41.34 Global view of a completed extracardiac Fontan in a patient with a dominant right ventricle and tricuspid valve. The overzealous right atrial wall resection resulted in atrial septal compression and pulmonary venous obstruction to the right ventricle that was noted on transesophageal echocardiography. The compression of the atrial septum is noted within the right atrium. (Reproduced with permission from Mavroudis *et al.* [85].)

Figure 41.36 Artist's representation of a partially retracted transected cannulated inferior vena cava below the Rummel tourniquet. The end-to-end anastomosis between the extracardiac Gore-Tex tube and the inferior vena cava cannot be performed under these circumstances. (Reproduced with permission from Mavroudis *et al.* [85].)

nection. We placed an augmenting Gore-Tex patch prophylactically during atrial closure with no pulmonary venous flow obstruction noted.

Unwanted Inferior Vena Cava Retraction During the Extracardiac Connection

Occasionally, the transected inferior vena cava orifice retracts inferiad to the caval tourniquet making the end-to-end anastomosis impossible to perform unless the tourniquet is released (Figure 41.36) [85]. This problem is easily solved by clamping the inferior vena cava cannula, releasing the tourniquet, establishing sucker bypass, and performing an open end-to-end anastomosis (Figure 41.37) [85]. Once the anastomosis is completed the inferior vena cava catheter can be purged of air, the tourniquet can be replaced, and venous drainage can be resumed (Figure 41.38) [85]. We have found that this complication can be largely avoided by staged vena cava transection and strategic placement of traction sutures during the anastomosis,

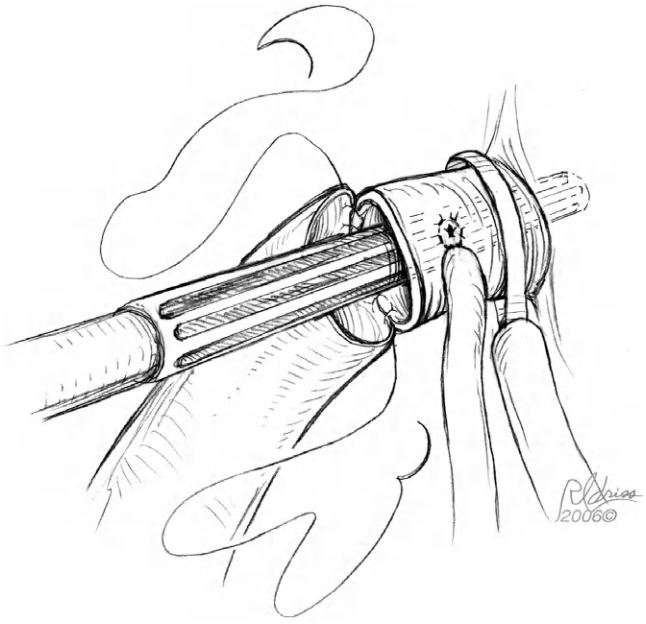

Figure 41.37 Artist's depiction of tourniquet removal, establishing of sucker bypass, and the end-to-end anastomosis in progress. (Reproduced with permission from Mavroudis *et al*. [85].)

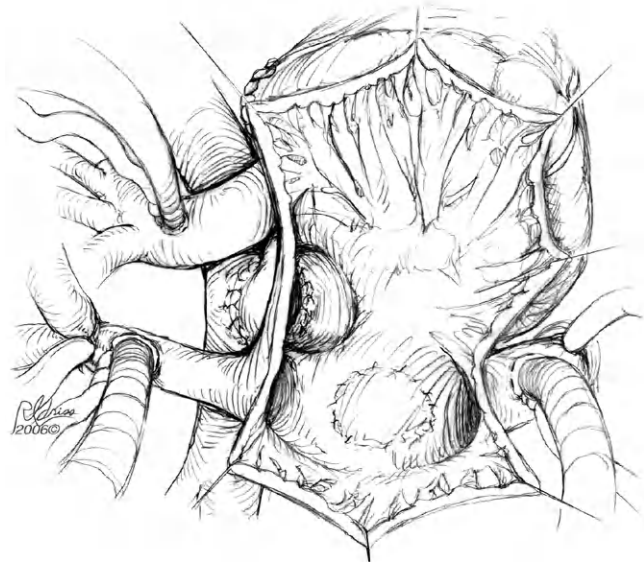

Figure 41.39 Right atrial view of a patient who underwent atriopulmonary Fontan by moving the atrial septum posteriorly which realigned the outflow of the right atrium to conform to the more posterior main pulmonary artery. This "dropped atrial septum" required a suture line in the left atrium which caused scarring and an area of slow conduction leading to atrial re-entry tachycardia. In addition, when this anastomosis was taken down, a significant moiety was created which required attention lest pulmonary venous obstruction be created. (Reproduced with permission from Mavroudis *et al.* [85].)

which will prevent inferior vena cava retraction beyond the caval tourniquet.

Surgical Translocation of Atrial Septal Alignment

Some surgeons hypothesized that because the pulmonary artery was more posterior to the right atrium, aligning the pulmonary artery directly with a revised translocated atrial outflow into the pulmonary artery would optimize blood flow [85]. Resecting a portion of the superior atrial septum and anastomosing the confluence of pulmonary arteries to the dome of the right and left atrium was performed in a subset of patients. The separation of the circulations was accomplished by a synthetic septal patch that in effect dropped the atrial septum into the left atrial dome, thereby aligning the pulmonary artery with the newly formed systemic atrium (Figure 41.39) [85]. We call this the "dropped atrial septum" technique, which has important arrhythmia implications. Some of these patients will have left atrial re-entry tachycardia based on the suture lines in the dome of the left atrium. Arrhythmia surgery in this setting will require left atrial resection with cryoablation lesions delivered in the left atrium. Atrial reconstruction will require a

Gore-Tex patch in the dome of the left atrium to prevent pulmonary vein stenosis (Figure 41.40) [85].

The Modified Right-Sided Maze Procedure for Various Single-Ventricle Pathology

Different types of modified right-sided maze procedures are performed based on the varying types of single-ventricle anatomy. The modified ablation lesions based on anatomy have been previously published [38]. Important variations include the presence of a right-sided atrioventricular valve, a common atrioventricular valve, and the absence of a coronary sinus associated with heterotaxy syndrome [85]. These conditions require modification of the right-sided maze procedure simply because the landmarks that determine the ablation lesions may or may not be present to interrupt the macro-re-entry circuits [59]. Figure 41.8 shows the cryoablation lesions that are used for tricuspid atresia patients with right atrial macro re-entry tachycardia [85]. Because there is no tricuspid valve, the standard lesion cannot be placed to connect the inferior vena cava os with the tricuspid valve. However, there are anatomic variants in which one can identify a "tricuspid valve dimple," which is thought to be a remnant of the tricuspid valve. It would seem intuitive to place the standard lesion from the inferior vena cava os to the tricuspid valve dimple. The difficulty with this action is that the atrioventricular node is in close proximity to this tricuspid valve dimple and therefore will likely cause heart block. We do not recommend placing this lesion for these reasons. Also noted in Figure 41.8 is a new lesion that connects the coronary sinus os with the atrial septal defect [85]. The rationale for this lesion is to interrupt any macro re-entrant circuits that may traverse this area. The other two lesions are standard and have been described before [38]. Figure 41.9 shows the right-sided lesions used in patients who have a dominant right ventricle and tricuspid valve [85]. In the presence of a right-sided atrioventricular valve, all the standard lesions can be performed. Figure 41.10 shows the right-sided lesions used in patients with a common atrioventricular valve and a present coronary sinus [85]. Some of these patients have heterotaxy syndrome and therefore may have absence of the coronary sinus. Under these circumstances, the usual lesion from the coronary sinus os to the inferior vena cava os cannot be performed. There can be other circumstances in which the modified right-sided maze procedure will have to be changed to accommodate the anatomic findings. In general, anatomic areas between large orifices tend to be involved with slowing of the atrial electrical impulse, which is a substrate for a re-entry circuit to take place. These areas will require cryoablation as long as the atrioventricular node is not in danger of injury. Figure 41.12 shows the cryoablation lesions and surgical incisions/excisions necessary for the left-sided maze procedure [85]. When the right- and left-sided lesions are performed in concert, we call this the modified Cox-maze III procedure. The lesion from the confluence of pulmonary veins to the mitral valve must align with the lesion placed on the epicardial surface of the coronary sinus to avoid recurrent atrial tachycardia caused by conduction via fibers within the coronary sinus. Therefore, we have changed the location of the intracardiac lesion from the confluence of the pulmonary veins to the mitral valve posterior leaflet middle scallop (P2 location) to the confluence of the pulmonary veins to the mitral valve posterior leaflet medial scallop (P3 location). Using this approach we have had no patient who has presented with recurrent atrial fibrillation.

Patient Population

From December 1994 until April 2009, 132 patients have undergone conversion from an atriopulmonary to a total cavopulmonary artery extracardiac Fontan with concomitant arrhythmia surgery and pacemaker placement at our institutions. All patients underwent preoperative cardiac catheterization with hemodynamic assessment and angiography for anatomic definition. Most underwent preoperative intracardiac electrophysiologic mapping; patients with atrial fibrillation, atrial thrombus, or poor vascular access were omitted. In the first nine procedures in our series isthmus cryoablation was used for arrhythmia control. The next 123 consecutive cases had variations of the modified right atrial maze for macro re-entrant atrial tachycardia and the Cox-maze III procedure for atrial fibrillation and left macro re-entrant atrial tachycardia.

Results

There were three (3/132, 2.3%) early and 12 (12/132, 9.1%) late deaths. Seven patients (7/132, 5.3%) required cardiac transplantation after Fontan conversion with arrhythmia surgery. Two patients (1.5%) underwent re-exploration for postoperative bleeding, mediastinitis occurred in three patients (2.3%), and nine patients (6.8%) had acute renal failure. The mean duration of chest tube placement was 9.0 ± 4.8 days. The mean postoperative hospital stay was 14.0 ± 12.0 days. The Kaplan-Meier curve (Plate 41.5, see plate section opposite p. 594) shows freedom from death in 126 patients who underwent Fontan conversion with arrhythmia surgery from 1994–2009 [37].

Atrioventricular Nodal Re-Entry Tachycardia

Mechanism

Atrioventricular nodal re-entry tachycardia is a re-entrant circuit in the area between the atrioventricular node, coronary sinus, and inferior vena cava associated with unidirectional block in one direction and an area of slowed conduction in the other (Plate 41.6, see plate section opposite p. 594) [37,41]. Atrioventricular conduction encounters unidirectional block in the normal fast pathway fibers superior to the atrioventricular node. The electrical wave front is redirected toward the atrial isthmus (between the coronary sinus and tricuspid valve) and encounters the slow pathway fibers of the atrioventricular node. After the impulse exits the isthmus, conduction now re-enters the fast pathway, anteriorly and superiorly, and establishes the re-entrant circuit. Cryoablation of the inferior isthmus region interrupts the re-entrant circuit.

Ablation of Atrioventricular Nodal Re-Entry Tachycardia

The concept that the perinodal region could be modified in patients with AVNRT was found inadvertently during an unsuccessful attempt at atrioventricular nodal ablation, which preserved nodal function but abolished the nodal tachycardia [4]. Holman and associates [5,95] subsequently showed that discrete cryolesions near the atrioventricular node could interrupt the tachycardia circuit while preserving atrioventricular conduction. Further support of this idea came from Ross and associates [96], who separated the perinodal connections from the compact node by dissection instead of cryoablation with excellent results. Extensive catheter ablation experience has demonstrated that an anatomic approach to slow pathway modification effectively treats AVNRT. Lesions are delivered inferior and anterior to the os of the coronary sinus, with slow pullback from the tricuspid annulus toward the inferior vena cava.

Currently, either the cryoablation or radiofrequency technique for patients with AVNRT is used [97]. A linear lesion is placed from the posterior inferior rim of the coronary sinus os to the inferior vena cava. In the presence of a right-sided atrioventricular valve, a linear lesion from the valve to the posterior os of the coronary sinus is delivered. The approach in a beating nonworking heart using discrete cryolesions [98,99] around the coronary sinus is no longer used. Results of radiofrequency catheter modification of the atrioventricular node slow pathway in the region of the coronary sinus os indicate that it is not desirable to attain prolongation of the PR interval as previously performed. The surgical cryoablation modification of the atrioventricular node as described previously requires less than 3 minutes. In patients with prior Mustard or Senning procedures undergoing reoperation, we have elected to perform ablation of AVNRT directly intraoperatively and avoid the retrograde catheter approach to the pulmonary venous atrium.

Focal (Automatic) Atrial Tachycardia

Mechanism

Focal atrial tachycardia is a localized area of electrical impulse generation [37] which may be due to either discrete micro re-entry or an automatic focus. Either form of focal tachycardia results in tachycardia occurring, independently of normal sinus function, which is inhibited (Plate 41.7, see plate section opposite p. 594) [37,41]. Electrical impulse conduction is propagated over the body of the atria, which results in stimulation of the atrioventricular node and ventricles. Cryoablative therapy and resection is used to obliterate or isolate this localized discrete area.

Ablation of Focal/Automatic Atrial Tachycardia

Surgical treatment of tachycardia localized to the atria may involve resection or cryoablation of atrial tissue; wider areas of focal tachycardia may require isolation. Some authors had good results with simple cryoablation and excision of automatic foci when found [100–102]. Multiple ectopic foci arrhythmia recurrence led surgeons to apply more extensive techniques [103] such as pulmonary vein isolation, left atrial isolation [104], right atrial isolation (Figure 41.41) [105], and His bundle cryoablation with pacemaker insertion in difficult cases. Automatic atrial foci, often localized to the right atrial appendage, may be directly resected intraoperatively. We have successfully resected automatic atrial tachycardia sites from the right atrial appendage in a neonate undergoing a Norwood procedure for hypoplastic left heart syndrome and in an older child undergoing closure of a primum atrial septal defect. In addition, a teenager presenting with cardiogenic shock secondary to tachycardia was taken to the operating room emergently for placement of a mechanical assist device; a focal right atrial tachycardia originating in the right atrial appendage was identified and resected, resulting in sinus

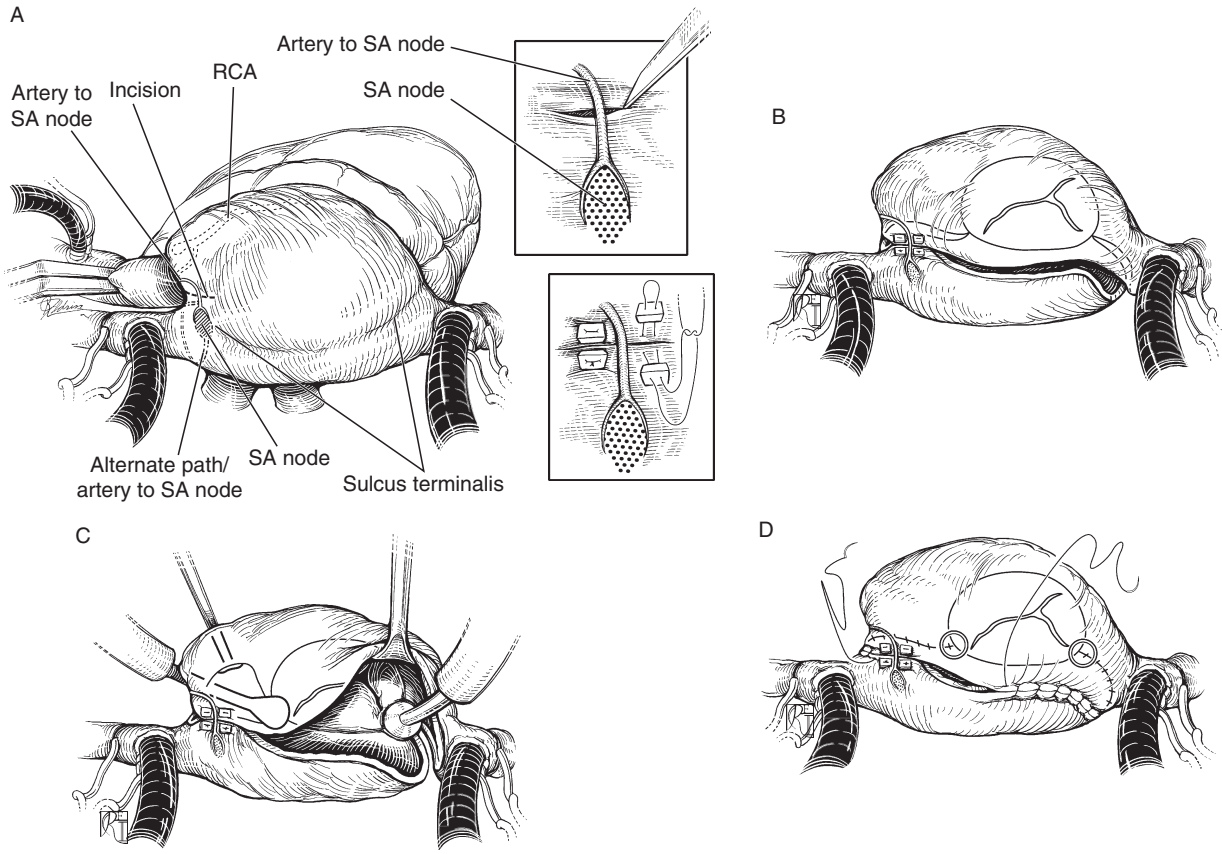

Figure 41.41 Right atrial isolation. **A**, The sinoatrial node (SAN) artery is dissected free from the atrial tissue 5 mm anterior to the crista terminalis. A 2-cm incision parallel to the crista terminalis is placed beneath the artery. **B**, The incision beneath the SAN artery is closed with a continuous nonabsorbable suture, and care is taken not to damage the artery. Small pledgets are used above and below the artery to reinforce the incision. The right atriotomy is then extended to a point anterior to the junction of the superior vena cava and the base of the right atrial appendage. **C**, The atriotomy is extended along the anterior limbus of the fossa ovalis to the anteromedial tricuspid valve annulus, just anterior to the membranous interatrial septum. **D**, Caudad extension of the right atriotomy around the posterior right atrial-inferior vena caval junction to the posterior–lateral tricuspid valve annulus. A cryolesion (–60 °C for 2 minutes) is placed at the end of the incision to ensure complete interruption of connecting atrial muscle fibers between the body of the right atrium and the remainder of the heart. The atriotomy is closed with a continuous 4-0 nonabsorbable suture. (Modified with permission from Harada *et al*. [105].)

rhythm. We avoided placement of an assist device in this patient, who was discharged within a week, and recovered normal ventricular function over a period of weeks. In general, refractory cases are rare and require an individualized treatment plan for accurate diagnosis and ablation.

Atrial Fibrillation

Mechanism

Atrial fibrillation is characterized by uncoordinated atrial activation with consequent deterioration of atrial mechanical function. On ECG, consistent P waves are replaced by rapid oscillations or fibrillatory waves that vary in amplitude, shape, and timing, associated with an irregular, frequently rapid ventricular response with variable atrioventricular conduction.

Ablation of Atrial Fibrillation

Atrial fibrillation typically occurs in markedly dilated left atria, usually with significant mitral regurgitation, either due to ventricular dysfunction or valve abnormalities. In adults with unoperated atrial septal defects, atrial flutter and fibrillation occurs in 14–22% of patients [106–108]. Atrial fibrillation will recur in a high percentage of patients following surgery [106–108] if direct arrhythmia intervention is not performed [109,110]. Performance of right atrial arrhythmia surgery is ineffective in preventing recurrence of atrial fibrillation. Therefore, careful evaluation of older patients undergoing atrial surgery is necessary to determine the presence of atrial fibrillation and to assess the need for left atrial arrhythmia surgery. As described previously, the Cox-maze III procedure is designed to eliminate atrial fibrillation while preserving intact atrioventricular

nodal conduction and atrial contractility. This procedure prevents atrial fibrillation recurrence in over 90% of adult patients, often in association with mitral valve repair [111–114], atrial septal defect closure [109,110], or coronary artery bypass surgery [115]. We have incorporated successfully the Cox-maze III procedure into repair of complex congenital heart disease, such as the Fontan conversion, atrial septal defect closure, and mitral valve repair in a 4-year-old girl with cardiomyopathy. We have had no late recurrence of atrial fibrillation in our patient population, using no antiarrhythmic medications. Use of a linear cryoablation probe or radiofrequency catheter intraoperatively instead of making atrial incisions shortens surgical time considerably. Attempts to duplicate these results using the transvenous catheter approach at electrophysiologic study are the subject of intense effort. Pulmonary vein stenosis is an infrequent but serious complication of this technique.

Ventricular Tachycardia

Mechanism

Ventricular tachycardia is an abnormal ventricular rhythm with a rate greater than 120 bpm in adolescents or adults, or a rate greater than 150 bpm in children [37]. This arrhythmia arises from various locations in either the left or right ventricles, and is usually re-entrant in nature. As there is no specific localized origin of ventricular tachycardia, treatment with cryoablative lesions or endocardial/epicardial resection must be individualized to the patient.

Surgery for Ventricular Tachycardia

Patients with ventricular tachycardia refractory to medications and transvenous catheter ablation techniques as well as patients undergoing concomitant repair of structural heart disease are considered for intraoperative ablation of ventricular tachycardia.

Structurally Normal Hearts

Incessant life-threatening ventricular tachycardia in infancy is associated with ventricular hamartomas or histiocytosis [116–118]. Before the availability of intravenous amiodarone, such infants underwent surgical resection of the left ventricular endomyocardium with some success [116–118]. In older patients, usually adolescents, idiopathic ventricular tachycardia in the ostensibly normal heart typically arises from either the right ventricular outflow tract (left bundle branch block, normal to rightward QRS axis morphology) or the septal surface of the left ventricle (right bundle branch block, left axis morphology). Both forms of idiopathic ventricular tachycardia are amenable to catheter ablation techniques, with success rates of 70–80% [26,119–121]. Rarely, ventricular tachycardia may originate from the epicardial surface of either the left or right ventricle, making the catheter ablation approach challenging.

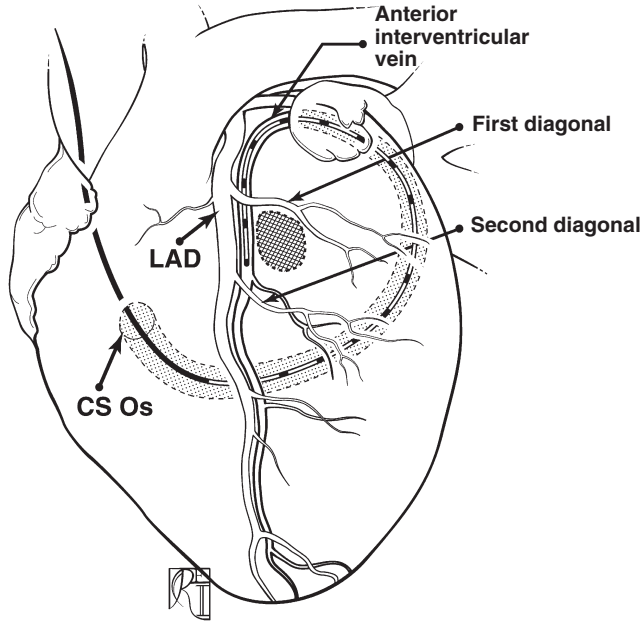

Figure 41.42 Ventricular tachycardia originating from epicardial surface of left ventricular outflow tract. Tachycardia could not be ablated successfully using endocardial catheter approach. Note proximity of tachycardia focus to left anterior descending (LAD) coronary artery. (CS, coronary sinus.) (Reproduced with permission from Deal *et al.* [59].)

Figure 41.42 illustrates the epicardial focus of ventricular tachycardia on the left ventricular outflow tract in a young boy with recurrent exertional syncope [59]. This rapid ventricular tachycardia was refractory to numerous medication combinations, and catheter ablations attempted at three institutions failed. Preoperative mapping using a small-diameter catheter in the anterior interventricular vein identified the epicardial origin on the high anterior left septal surface. Successful surgical cryoablation of the well circumscribed tachycardia focus was performed, using cardiopulmonary bypass to protect the left anterior descending artery. The patient has remained arrhythmia free without medication for over 14 years. Detailed preoperative and intraoperative mapping of the arrhythmia focus is essential to the successful performance of such procedures.

Structural Heart Disease

Patients with postoperative tetralogy of Fallot or double-outlet right ventricle are known to have late postoperative sustained ventricular tachycardia, with an incidence of 5–8% [30,122,123] and with a risk of late sudden death of 2–6% [124–126]. Risk factors for ventricular tachycardia include older age at initial repair, residual right ventricular hyperten-

sion, right ventricular outflow tract patch or aneurysm, significant pulmonary regurgitation, prolonged QRS duration over 180 msec on resting electrocardiogram, abnormal signal-averaged electrocardiogram, and longer duration of follow-up [30,122–126]. At least 15% of patients with repaired tetralogy of Fallot undergo reoperation for residual defects or late pulmonary valve regurgitation [127–129]. Because these patients are at increased risk for sustained ventricular tachycardia, they should undergo preoperative assessment for significant atrial and ventricular arrhythmias, with ambulatory electrocardiographic monitoring and exercise testing. Electrophysiologic studies are indicated for patients with symptoms of palpitations, syncope, cardiac arrest, sustained wide-QRS tachycardia, or QRS prolongation greater than 180 msec. Sustained ventricular tachycardia may be ablated preoperatively; should catheter ablation fail, direct endocardial resection and cryoablation may be performed intraoperatively. Physicians at our center and others [129–133] have performed surgical revision of residual hemodynamic abnormalities in the adult patient with tetralogy of Fallot at the same time as resection and cryoablation of the focus of ventricular tachycardia, sometimes eliminating the need for antiarrhythmic drugs or an implanted defibrillator. Careful preoperative and intraoperative mapping of tachycardia is necessary; common sites of arrhythmia origin are related to the ventriculotomy, outflow tract patch, and perimeter of the ventricular septal defect. Postoperative ventricular stimulation is necessary to determine efficacy, with defibrillator implantation performed if sustained ventricular tachycardia remains inducible. Successful surgical treatment of ventricular tachycardia in this setting ranges from 50–70% [37,123].

Rarely, patients with congenital heart disease may have sustained ventricular tachycardia before surgical repair. Two young patients with a membranous ventricular septal defect had recurrent ventricular tachycardia associated with syncope in one and dizziness in the other. During electrophysiologic study, the tachycardia was mapped to the anterior septal surface of the right ventricular outflow tract, opposite the jet of the ventricular shunt. Because surgical closure of the ventricular septal defect was necessary, catheter ablation was not performed. During surgery, large white plaque lesions were found, resected, and cryoablated. Ventricular tachycardia was not inducible during postoperative study in either patient.

Ventricular Tachycardia Associated with Ion Channelopathies

Mechanism

Ventricular tachycardia, either torsades des pointes due to long QT syndrome or catecholaminergic polymorphic ventricular tachycardia (CPVT) are inherited arrhythmogenic diseases due to ion channelopathies, typically due to sodium or potassium channel disorders (long QT syndrome); ryanodine receptors (RYR2) and calsequestrin (CASQ2) are identified causes of CPVT. Genetic testing is now commercially available and may identify the causative genes in up to 70% of patients currently. Tachycardia is characterized by episodic syncope that occurs during exercise or in association with an acute emotional response, startle, or during sleep in patients without structural cardiac abnormalities. Patients can undergo spontaneous recovery when these arrhythmias self-terminate or the arrhythmia may morph into ventricular fibrillation and sudden death. These forms of tachycardia may account for 10% of cases of sudden infant death syndrome and frequently present in the second decade of life. The mean age of onset of CPVT is between 7 and 9 years, although onset into the fourth decade of life has been reported [134–136]. Exercise stress testing or epinephrine infusion may reproduce the arrhythmia, with characteristic ECG features, which include an alternating 180 degree-QRS axis on a beat-to-beat basis, and an irregular polymorphic ventricular tachycardia without a stable QRS vector alternans. The two genes currently known to be associated with CPVT are RYR2 and CASQ2.

Medical and Surgical Therapeutic Options

Beta-blockers are the medical therapy of choice for most arrhythmias due to ion channel disorders. Implantable automatic internal cardio-defibrillators (AICD) have been used for primary or secondary prevention of cardiac arrest, or recurrent syncope. Left cardiac sympathetic denervation (LCSD) has been used to ablate the left thoracic sympathetic chain in order to reduce the surge of catecholamines due to sympathetic nervous system activation. Wilde and associates [137] have shown that LCSD proved to be effective in their three patients whose symptoms were not controlled by beta-blockade [137]. This surgical therapy can be considered for patients with intractable ventricular tachycardia in order to reduce the incidence of tachycardia episodes and limit the number of AICD shocks.

Prophylactic Arrhythmia Surgery

Initial concerns over the development of late arrhythmias following congenital heart disease focused on the risk of sudden death due to ventricular tachycardia in the tetralogy of Fallot population, occurring in 2–7% of patients. Over the last two decades, it has become clear that the risk of atrial tachycardia, while not typically fatal, occurs in a much higher percentage of patients following repair of congenital heart disease as their survival improves. Atrial tachycardia may result in syncope, congestive heart failure, atrial thrombi, thromboembolic events, and sudden death, and is the most common reason for hospitalization among older patients with repaired congenital heart disease. The

incidence of late atrial tachycardia ranges from 15% in patients with prior atrial septal defect closures, over 30% in repaired tetralogy of Fallot or atrial switch repairs for transposition of the great arteries, and is highest (over 50%) among patients with atriopulmonary Fontan repairs and Ebstein anomaly of the tricuspid valve. Many of these patients will undergo repeat surgeries over time. It is clear that efforts to reduce the incidence of late atrial tachycardia will result in major improvements in quality of life in patients with congenital heart disease, and efforts to minimize the opportunity for tachycardia development either at the initial or redo surgery should become routine. As described above, surgical arrhythmia techniques in the right atrium can reduce the recurrence of atrial macro re-entrant tachycardia in over 90% of patients. Efforts to limit the development of tachycardia include alteration or limitation of atrial incisions, prophylactic ablation of identified inducible atrial re-entrant circuits, atrial maze procedures or atrioventricular node modification in patients with clinical arrhythmias, and earlier pacing strategies to avoid bradycardia-related tachycardia.

Advances in surgical techniques have improved survival in patients undergoing a Fontan type repair of complex single-ventricle anatomy, with surgical mortality now less than 7–10% [138]. Early postoperative tachycardia is a significant contributor to early postoperative death, and the incidence of late atrial arrhythmia in Fontan patients escalates at 7–10 years of follow-up [139–141]. Staging procedures such as the hemi-Fontan may increase the incidence of sinus node dysfunction [142,143]. Variations in the surgical technique have been made in an attempt to decrease the incidence of late arrhythmia. Although initial results with the total cavopulmonary connection appear favorable compared with the atriopulmonary connection [144–146], the incidence of arrhythmia with longer-term follow-up may be similar [147].

Results of arrhythmia studies in both the animal model [148,149] and Fontan patients [36,69,75] have identified several anatomic and surgical barriers or incisions, which are critical to the atrial macro re-entrant tachycardia circuit. Critical sites included the atriotomy incision, the inferior right atrial isthmus between the coronary sinus os and atrioventricular valve or groove, the rim of the atrial septal defect, the site of the atriopulmonary connection, and the crista terminalis [36,69,75,148–151]. Studies in the dog model with lateral tunnel suture lines showed that extending the atriotomy scar with an incision to the right atrioventricular groove prevented the induction of atrial flutter postoperatively [149]. Performing this incision at the time of initial lateral tunnel repair might reduce the incidence of re-entry around the free wall atriotomy incision, although this lesion may also be arrhythmogenic by creating an additional zone of slowed conduction. In patients large enough to accommodate an extracardiac conduit, this approach is used in an attempt to limit atrial incisions and extensive suture lines [152]. In addition, because the re-entrant circuit involves the inferior isthmus, and preoperative studies may provoke atrial re-entry tachycardia in as many as 15% of patients [153], "prophylactic" cryoablation lesions can be made between the posterior rim of the coronary sinus and the inferior vena cava, and between the inferior vena cava and atrioventricular valve or groove in patients undergoing initial lateral tunnel cavopulmonary connections. Similarly, adult survivors of other forms of repaired congenital heart disease, such as tetralogy of Fallot and atrial septal defects, have a substantial incidence of late atrial tachycardia [64,106-108]. Should such patients undergo a repeat intracardiac repair, consideration should be given to surgical cryoablation of the inferior right atrial isthmus in an attempt to avoid episodes of typical atrial flutter. Karamlou and colleagues have shown that incorporation of atrial arrhythmia surgery into conduit revision surgery significantly reduces the incidence of late atrial tachycardia [154]. Adult patients undergoing surgical closure of atrial septal defects have a high incidence of atrial fibrillation, particularly if present before surgery [106–108]. Specific consideration should be given to the performance of the Cox-maze III procedure for atrial fibrillation at the time of atrial septal defect closure in older patients or those with a history of atrial tachycardia [108–110].

Finally, there is evidence that late postoperative bradycardia contributes to the milieu for the development of atrial tachycardia, providing a regular atrial rhythm significantly decreases the incidence of problematic atrial tachycardia [155]. In a large series of Fontan patients, pacemakers have been implanted in 7–10% of patients owing to sinus bradycardia or atrioventricular block. At present, there are no data showing that prophylactic maintenance of a regular atrial rhythm following initial surgeries will prevent or reduce the incidence of late atrial tachycardia in high-risk patient populations. Nonetheless, due to the difficulty of implanting pacemakers late after Fontan repairs, it is our policy to implant epicardial atrial (and often ventricular) bipolar pacing leads at the time of initial Fontan repair (or at the time of ventricular septal defect closure in patients with congenitally corrected transposition of the great arteries) and implantation of a pacemaker generator if there is preexisting or operative evidence of sinus node dysfunction or chronotropic incompetence. Should bradycardia develop postoperatively, the atrial pacing lead simplifies pacemaker implantation in patients with limited venous access and prior thoracotomy.

Pacemaker and Device Therapy

Utilization of device therapy in children and patients with congenital heart disease is expected to increase substantially as survival to adolescence and adulthood increases, with attendant sequelae of heart failure. Device options have expanded with lead advancements, antitachycardia thera-

pies, cardiac resynchronization therapy, and the availability of epicardial or subcutaneous defibrillator leads. Technologic improvements have shifted attention from focusing on lead and generator longevity to issues of optimizing conduction characteristics, owing to the recognition of the development of myocardial dysfunction from chronic right ventricular apical pacing. Defibrillator therapy for primary and secondary prevention of sudden death includes populations with repaired congenital heart disease, dilated cardiomyopathies, and, with increasing frequency, electrical myopathies without structural heart disease. The psychologic impact of pacemaker or device implantation on children and particularly adolescents is frequently significant and requires a careful educational approach, and emotional support from all involved personnel. Restrictions from engaging in blunt contact sports after pacemaker implantation often involve a major change in lifestyle among adolescents.

Pacemakers

Antibradycardia Pacing

The most common indication for pacemaker implantation in the United States is sinus node dysfunction following surgical repair of congenital heart disease, followed by postoperative atrioventricular block, congenital atrioventricular block, and isolated sick sinus syndrome in the absence of structural heart disease [156]. Guidelines for implantation of cardiac pacemakers and antiarrhythmia devices have been published by the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [157], and the pediatric indications are summarized in Table 41.5 [53,157,158]. Symptomatic sinus bradycardia or tachycardia–bradycardia syndrome following atrial surgery, such as Senning, Mustard, and Fontan procedures [159], constitutes the most common indication for implantation. Indications for pacing in congenital complete atrioventricular block include a wide QRS escape rhythm, ventricular dysfunction, and a resting ventricular rate less than 50–55 bpm in the infant with a normal heart or less than 70 bpm in the infant with structural heart disease. In older children with congenital block, an average heart rate less than 50 bpm, or abrupt pauses two to three times the basic cycle length indicate a need for pacing. Per a multicenter long-term follow-up study, pacemaker implantation is recommended in older adolescents to avoid ventricular dysfunction, syncope, or sudden death in adulthood [160]. Surgical atrioventricular block (complete or advanced second-degree block) persisting beyond 7–10 days postoperatively is a class I indication for pacing. Without pacing, 53–65% of these patients will die suddenly [161,162]. Surgery involving ventricular septal defect closure, particularly in infants weighing less than 10 kg, or atrioventricular valve replacement accounts for most cases of surgically acquired heart block. In the setting of postoperative atrioventricular block, up to 65% of patients will recover normal conduction, with the majority resolving by the eighth postoperative day [163]; pacemaker implantation is generally delayed until this time in most patients.

There is a bimodal age curve for device implantation, with implantation in infancy for profound congenital or surgical atrioventricular block or sinus bradycardia, often associated with complex anatomy, with a second group receiving device implantation in childhood. The age at device implantation outside of infancy is typically 5-6 years of age [164,165]; this age has substantially decreased from earlier studies, where the median age ranged from 11–17 years [166]. Issues relative to pacing in infants include the optimal route, transvenous versus epicardial, and the mode of pacing. The availability of thin transvenous leads, 4 Fr or smaller, allows transvenous implantation in infancy, with improved pacing thresholds compared to epicardial leads [167,168], although utilization of steroid-eluting epicardial leads narrows the difference in lead longevity and function between the two approaches [93]. Disadvantages of transvenous lead placement in small children include acute complications of lead dislodgement and hemothorax, generator erosion, venous occlusion in patients with life-long need for pacing, tricuspid regurgitation exacerbated by the need to loop the lead within the atrium to accommodate patient growth, and the subsequent need for lead extraction with its attendant risks. Epicardial systems have the potential for generator migration or wound dehiscence, and an increased risk of lead fracture with activity. In most centers, current practice is to implant epicardial systems in infants and small children, and in children undergoing surgery for structural heart disease, maintaining this approach as long as the leads remain viable. The transvenous approach is used primarily at weights over approximately 35 kg, although many centers transition at lower weights. Using a subxiphoid incision, dual-chamber pacing can be accomplished in the majority of infants [169], although there are no data suggesting superiority of dual-chamber pacing versus rate responsive ventricular pacing in the small child without coexisting heart disease. Illustrations of our technique for epicardial pacing in a newborn are shown in Plates 41.8 and 41.9 (see plate section opposite p. 594), with the resultant chest radiograph in Figure 41.43 [169]. In patients with complex heart disease, the benefit of atrial contractility to cardiac output and arrhythmia avoidance provides a distinct rationale for dual-chamber pacing. Nonetheless, patients undergoing pacemaker implantation as neonates have a high mortality, reported as 30% within the first year [169,170]. An alternative approach in the very small newborn with atrioventricular block is pacing with temporary leads until the child has grown and matured enough for an implanted permanent pacemaker [171].

Technical issues related to transvenous lead access are present in patients with congenital heart disease, particularly single-ventricle patients following Fontan type repairs,

Table 41.5 Indications for permanent pacing in children and adolescents. (AV, atrioventricular.) (Adapted from Gregoratos *et al.* [157].)

Class	Indication
SINUS NODE DYSFUNCTION	
I	Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia Definition of bradycardia varies with patient's age and expected heart rate
IIa	Asymptomatic sinus bradycardia in child with complex congenital heart disease with resting heart rate <35 bpm or pauses in ventricular rate >3 seconds
IIa	Bradycardia-tachycardia syndrome with need for long-term antiarrhythmic treatment other than digitalis
IIb	Asymptomatic sinus bradycardia in adolescent with congenital heart disease with resting heart rate <35 bpm or pauses in ventricular rate >3 seconds
III	Asymptomatic sinus bradycardia in adolescent with longest RR interval <3 seconds and minimum heart rate >40 bpm
ATRIOVENTRICULAR CONDUCTION DISORDERS	
Congenital heart block	
I	Congenital third-degree AV block in infant with ventricular rate <50–55 bpm or with congenital heart disease and a ventricular rate <70 bpm
I	Congenital third-degree AV block with a wide QRS escape rhythm or ventricular dysfunction
IIa	Congenital third-degree AV block beyond the first year of life with an average heart rate <50 bpm or abrupt pauses in ventricular rate which are 2 or 3 times the basic cycle length
IIb	Congenital third-degree AV block in asymptomatic neonate, child, or adolescent with an acceptable rate, narrow QRS complex, and normal ventricular function
Postoperative AV block	
I	Postoperative advanced second-degree or third-degree AV block that is not expected to resolve or persists at least 7 days after cardiac surgery
IIb	Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block
III	Transient postoperative AV block with return of normal AV conduction within 7 days
III	Asymptomatic postoperative bifascicular block with or without first-degree AV block
Other conduction disorders	
I	Advanced second-degree or third-degree AV block associated with symptomatic bradycardia, congestive heart failure, or low cardiac output
III	Asymptomatic type I second-degree AV block
LONG QT OR VENTRICULAR TACHYCARDIA	
I	Sustained pause-dependent ventricular tachycardia, with or without prolonged QT, in which efficacy of pacing is documented thoroughly
IIa	Long QT syndrome with 2:1 AV or third-degree AV block

transposition of the great arteries following atrial repairs, and congenitally corrected transposition of the great arteries [172]. The presence of a right-to-left intracardiac shunt favors an epicardial approach, or chronic anticoagulation. Although transvenous pacing can be accomplished in patients with atriopulmonary Fontan repairs, sluggish flow predisposes to clot formation on the lead even in the presence of anticoagulation; we have removed a 4×6 cm dense thrombus from one such patient at the time of Fontan conversion; this patient had suffered a prior stroke. In patients with prior atrial baffle repairs for transposition, systemic venous baffle constriction may require stent placement to allow passage of a pacing lead. In congenitally corrected transposition, the incidence of developing atrioventricular block approaches 40%; the smooth trabeculations of the subpulmonary left ventricle may require active fixation leads [172]. Prior resection of atrial appendages may require alternate atrial pacing sites. Venous occlusions due to inter-

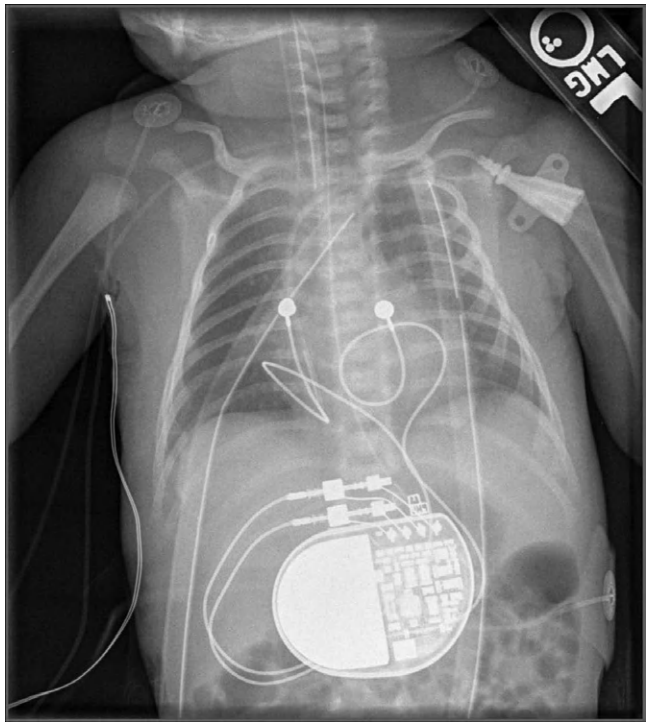

Figure 41.43 Babygram in a 2.2-kg infant shows the typical postoperative appearance after placement of a dual-chamber epicardial pacemaker. The left pleural space has been drained by a left chest tube. The right pleural space and mediastinum are drained by a chest tube passed through the right pleural space. The ventricular lead is on the high right ventricular outflow tract. Coils of the lead are placed within the pericardium to allow for growth. In a similar fashion, a coil is placed within the pacemaker pocket. The size of the dual-chamber pacemaker in comparison to the baby is quite evident, illustrating the need for implantation beneath both rectus muscles. (Reproduced with permission from Kelle *et al.* [169].)

ventional or surgical procedures are not uncommonly present. For most patients, venous angiograms to clarify anatomy and access are advisable, although cardiac magnetic resonance imaging or computerized tomography may be suitable.

Left ventricular dysfunction secondary to chronic right ventricular apex pacing has been reported in approximately 10% of patients with congenital atrioventricular block [164,173]. Ventricular remodeling based on the abnormal sequence of contractility is the presumed cause [174]. Several studies have attempted to identify the optimal location for right ventricular leads, without identification of a single optimal site [175,176]. The anterior right ventricular free-wall appears to result in the most desynchrony, and should be avoided; the left ventricular free-wall may be optimal. Alternate site pacing may produce a narrower QRS, although this finding does not predict improved contractility. For the individual patient, optimization of pacing site may require assessments intraoperatively of indices of cardiac contractility, ejection fraction, and blood pressure.

Antitachycardia Pacing

Newer generators and leads that can detect SVT and deliver antitachycardia pacing to terminate tachycardia are available, and are particularly suitable for patients with repaired congenital heart disease [177]. Limitations include an inability to terminate tachycardia with 1:1 atrioventricular conduction (without specialized software), and limitation of the peak programmable heart rate to 150 bpm (versus 210 bpm in other generators). Electrophysiologic testing to determine the accuracy of tachycardia detection, the efficacy and safety of termination protocols, and an assessment of the peak sinus rate in response to catecholamines is mandatory. A typical protocol recognizes atrial rates greater than 200 bpm, and the device delivers a train of six to eight atrial impulses at 80% of the tachycardia cycle length to terminate. The termination algorithm is programmed to continue pacing automatically at faster rates until termination is achieved or to a predetermined minimum paced cycle length. To avoid initiating inappropriate pacing therapy, tachycardia detection criteria need to account for sinus tachycardia at rates up to 200 bpm in pediatric patients. Beta-blocker therapy is frequently advisable to ensure that sinus rates do not exceed 160–180 bpm.

Lead Extraction

The increased usage of transvenous leads in small children, the incidence of lead failure and recall, and improved longevity of patients with repaired congenital heart disease, has resulted in the increasing need for lead extraction in children and patients with congenital heart disease. Laser lead extraction is presently performed, with success rates of 90%, and complications of 6% [178]. Complications may be life threatening, including vessel laceration and cardiac perforation with potential for exsanguination [179,180].

Cardiac Resynchronization Therapy

The efficacy of cardiac resynchronization therapy in improving symptoms of heart failure and longevity has been established in adult patients with dilated or ischemic cardiomyopathies, ventricular dilatation, and QRS prolongation. In these adult patients, guidelines for resynchronization include a left ventricular ejection fraction ≤35%, QRS duration ≥120 msec, and symptoms of heart failure despite optimal medical treatment with NYHA class III–IV [181,182]. The principle of therapy is to correct ventricular mechanical desynchrony, usually with biventricular pacing, although atrial pacing with optimization of atrioventricular delay and spontaneous ventricular activation is also used

[183,184]. Biventricular or multisite pacing requires electrical and spatial separation between pacing leads, with one lead placed in or on the subpulmonary ventricle and the other lead located over the systemic ventricular free-wall. Efforts to identify the appropriate pediatric or congenital heart disease population likely to benefit from this approach have been ongoing, and include patients with failing systemic right ventricles, right bundle branch block, and desynchrony without significant QRS prolongation [185]. Populations likely to benefit from this approach include patients with ventricular dysfunction, secondary chronic right ventricular pacing for congenital heart block, patients with dilated cardiomyopathy, and patients with systemic right ventricles or complex ventricular anatomy [186,187]. In some cases, improvement in ventricular dysfunction has been dramatic, allowing removal from listing for heart transplantation [187]. Sophisticated measures of ventricular synchrony are needed, including tissue Doppler imaging.

Automatic Implantable Defibrillators

Implantable defibrillators have demonstrated their efficacy in preventing sudden death in patients surviving cardiac arrest, and in adult patients with low ejection fractions [188]. Defibrillator implantations in children and patients with congenital heart disease account for fewer than 1% of all ICD recipients, with limited prospective data available. Improvements in lead technology, smaller implantable generators (weight <75 g), incorporation of antibradycardia and antitachycardia pacing capability, and device diagnostic memory, have led to dramatic expansion of defibrillator use in pediatric patients over the last decade [189–195].

The epicardial approach to pediatric cardioverter defibrillator placement has changed in the past several years. In the initial epicardial placements a large subcutaneous patch was placed along the upper left chest or along the left edge of the pericardium adjacent to the ventricle. The subcutaneous patch however is quite bulky and not easy to place. It is susceptible to crinkling and an increase in defibrillation thresholds. Recently we have been using the transvenous lead "coil" and placing the "coil" in either the transverse pericardial sinus or in the subcutaneous tissue of the left chest wall. The atrial and ventricular epicardial leads are placed in the usual fashion and connected to the defibrillator device. The cardioverter defibrillator is placed beneath the right rectus muscle. This provides an excellent vector across the myocardial mass for defibrillation. This can be performed with a subxiphoid incision without a full sternotomy. Obviously if the patient was having a simultaneous open cardiac procedure the sternotomy exposure is used.

Excellent results with the transverse sinus technique have been reported by Hsia and associates from the Medical University of South Carolina [193]. In that series of seven children all implantations were performed through a small subxiphoid incision without a full sternotomy. The coil lead was actively fixated in the transverse sinus under fluoroscopic guidance. We have used this technique in a 3-month-old, 6 kg child. Bove and associates have reported similar results with the subcutaneous coil placed along the left chest wall [196]. In pediatric and congenital heart disease patients, data from the registry of defibrillator implantation in the United States shows the majority of implants in the following three types of heart disease: 1) repaired congenital heart disease (>45%), most commonly tetralogy of Fallot and transposition of the great arteries following atrial repairs [197,198]; 2) primary electrical disease (long QT syndromes, Brugada syndrome, idiopathic ventricular fibrillation, >30%); and 3) cardiomyopathies (26%) [190]. The threshold for implanting defibrillators in pediatrics has decreased, and data are available on 443 pediatric and congenital heart disease patients with defibrillators implanted in the US between 1992 and 2004, at a median age of 16 years and median weight of 61 kg [190]. Acute implantation complications occur in 12% and chronic complications are reported in 29% of pediatric or congenital heart disease patients, almost all related to lead issues, including insulation breaches, lead fractures, and oversensing. Inappropriate shocks occur in at least 24% of pediatric patients, significantly higher than the 14% reported in adults [190]. Appropriate shocks are reported in 23% of pediatric patients and are more common in patients with defibrillators for secondary prevention (32%) versus primary prevention (18%) [190]. Mortality in the multicenter registry was 4%, mainly owing to progressive heart failure, with only 1% attributable to fatal arrhythmia [190].

Over time, the indications for implantation of defibrillators have become more commonly primary prevention (52%) versus secondary prevention (48%) [190]. Primary prevention refers to implantation in at-risk patients who have not yet experienced an episode of sustained ventricular tachycardia, venticular fibrillation, or resuscitated cardiac arrest. Secondary prevention refers to implantation following resuscitation from cardiac arrest or sustained ventricular arrhythmia. Secondary prevention indications also include patients with congenital heart disease and recurrent syncope of undetermined origin in the presence of ventricular dysfunction or inducible ventricular tachycardia, or associated with advanced ventricular dysfunction without identifiable etiology for syncope after thorough invasive and noninvasive evaluation [199]. Data establishing efficacy of defibrillators for primary prevention in patients with ejection fractions less than 35% is derived from adult populations with ischemic or nonischemic cardiomyopathy; comparable data are not available for the congenital heart disease populations. This is confounded by the difficulty in assessing ventricular function in the systemic right or univentricular heart, and the contribution to risk from multiple scars of prior surgeries, subendocardial ischemia, and coronary abnormalities. Appropriate candidates for primary prevention in congenital heart

disease may include patients with a failing systemic ventricle with an ejection fraction less than 30% in addition to other indicators of high risk, such as marked QRS prolongation, nonsustained ventricular tachycardia, and elevated end-diastolic pressure greater than 12 mmHg [200].

Defibrillator implantation may be used as a bridge to cardiac transplantation in patients with severe ventricular dysfunction and ventricular arrhythmias or syncope.

Management of Acute Perioperative Arrhythmias

Early postoperative arrhythmias in pediatric patients following repair of congenital heart disease occur in approximately 30–47% of patients [201,202]. Intraoperative procedural factors are directly associated with the development of arrhythmias, as well as the postoperative milieu characterized by excess catecholamines, elevated atrial pressures, intra-atrial monitor lines, pericardial inflammation, autonomic imbalance, and neurohormonal changes [203]. An excellent review of guidelines for postoperative arrhythmia management in adults has been published by van Mieghem [203], and that approach is summarized in Table 41.6 [53,203]. Appropriate therapy for postoperative SVT begins with establishing the mechanism of tachycardia as summarized in Table 41.7 [53]. The acute administration of adenosine has become the default acute treatment of choice due to ease of administrations and may be diagnostic even when not therapeutic. Caveats regarding the use of adenosine include recognition of the potential for provoking torsades des pointes or atrial fibrillation with rapid conduction requiring immediate defibrillation; patients following heart transplantation may experience profound asystole.

Determination of the mechanism of tachycardia may be facilitated by recording atrial electrograms, particularly when P waves are not readily apparent on the electrocardiogram (Figure 41.44A) [53]. Atrial activity should be clearly visible, allowing the atrial-to-ventricular relationship to be defined [204]. Administration of adenosine while recording electrograms may unmask rapid atrial activity with 2:1 or variable atrioventricular conduction (Figure 41.44B) [53] indicating a primary atrial tachycardia, such as atrial flutter. A 1:1 ventricular-to-atrial (VA) relationship (ventricular electrogram precedes atrial electrogram) indicates either junctional tachycardia with retrograde conduction or an atrioventricular re-entry tachycardia (utilizing an accessory connection). Measurement of the VA interval further defines the mechanism of tachycardia. A VA interval longer than 70 msec suggests orthodromic reciprocating tachycardia, while a VA interval shorter than 70 msec is consistent with either junctional tachycardia or AVNRT. Atrial overdrive pacing may then be performed to terminate tachycardia when appropriate. Atrial overdrive pacing is initiated at 120–150% of the atrial cycle length, or 20–30 bpm faster than the tachycardia rate, and continued for four beats or up to 30 seconds (Figure 41.44C,D) [53]. Pacing output of approximately 5 mA for temporary atrial wires, or 10–20 mA for esophageal leads, is required. Pacing will effectively terminate up to 95% of re-entry tachycardias.

Table 41.6 Guidelines for postoperative arrhythmia management. (Adapted from van Mieghem [203].)

1. Establish mechanism of tachycardia
2. Consider precipitating or aggravating causes
3. Evaluate hemodynamic consequences
4. Estimate natural course
5. Define therapeutic goal:
   a. Terminate arrhythmia
   b. Slow ventricular rate
   c. Correct precipitating mechanism

Table 41.7 Therapy for early postoperative supraventricular tachycardia. (ORT, orthodromic reciprocating tachycardia; AVNRT, atrioventricular nodal re-entry tachycardia; AV, atrioventricular.)

Mechanism	Adenosine	Atrial pacing	Other medications
ORT	•	•	Procainamide, esmolol or oral beta-blocker, digoxin
AVNRT	•	•	Digoxin, diltiazem
Atrial flutter		•	Ibutilide, amiodarone, procainamide, diltiazem for rate control
Atrial fibrillation			Ibutilide, direct current cardioversion, amiodarone, procainamide, esmolol or diltiazem for rate control
Sinus bradycardia		•	Isoproterenol, dobutamine
Junctional ectopic tachycardia		Overdrive for AV synchrony	Procainamide, amiodarone, diltiazem

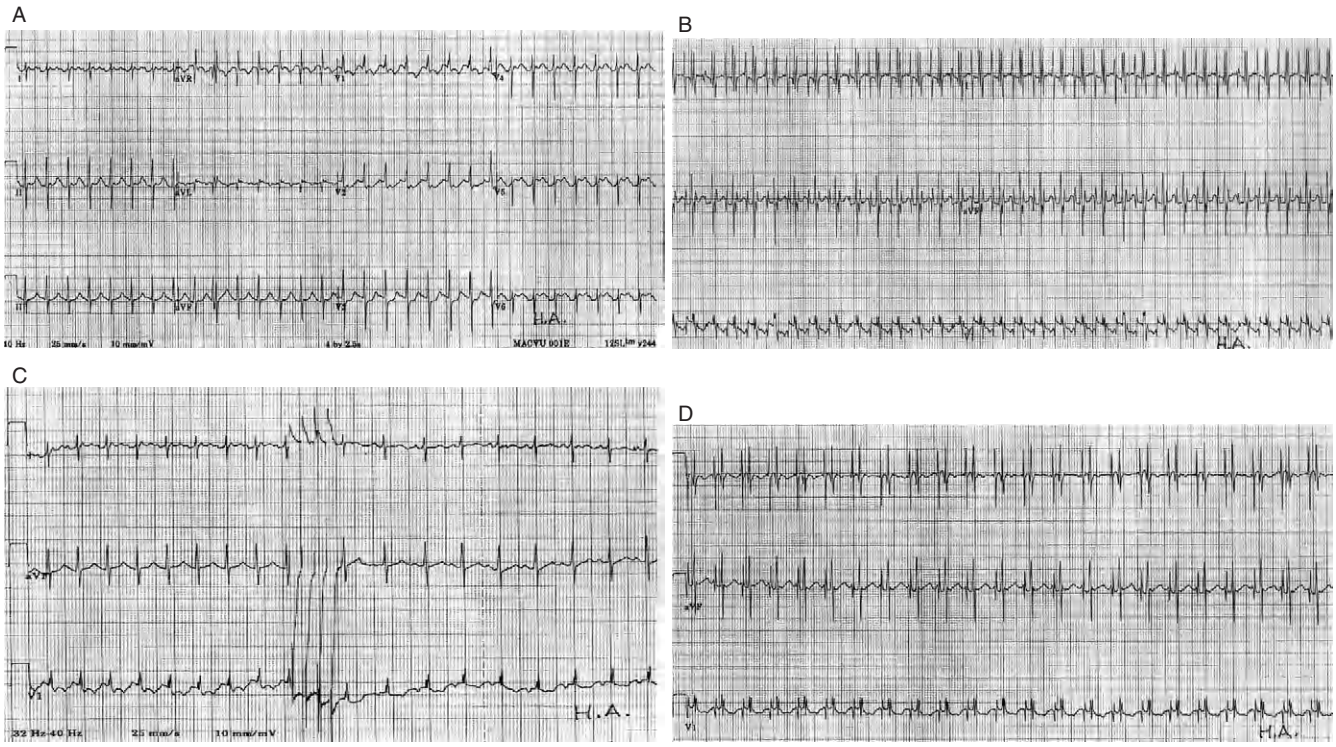

Figure 41.44 A, Postoperative atrial electrogram obtained in a 4-week-old infant after repair of anomalous left coronary artery arising from the pulmonary artery. Heart rate had been persistent at 180 bpm without variation for 12 hours. **B,** Esophageal electrogram in infant in **A** showing atrial tachycardia with 2:1 atrioventricular conduction. Atrial activity is indicated by the smaller spikes in the second lead, ventricular activity by the tall spikes. Atrial cycle length is 210 msec. **C,** Atrial overdrive pacing using esophageal lead. Four extrastimuli at 160 msec are delivered, resulting in conversion to sinus rhythm with 1:1 AV conduction. **D,** Atrial esophageal electrogram postconversion shows sinus rhythm with 1:1 AV conduction.

Junctional Ectopic Tachycardia

In childhood, the most frequent acute postoperative arrhythmia other than premature ventricular contraction is junctional ectopic tachycardia, present in 5–10% of pediatric patients, followed by atrioventricular block (2–4%), ventricular tachycardia (2%), and SVT [201,202,205]. Junctional ectopic tachycardia is defined as tachycardia originating from the His bundle, usually narrow complex, at rates greater than 170 bpm, often with atrioventricular dissociation [206]. The mechanism is presumed to be abnormal automaticity of the atrioventricular node, as the rhythm does not respond to cardioversion and may be due to either direct trauma or stretch of tissues near the atrioventricular junction. The median postoperative time for development of junctional ectopic tachycardia is in the first 24 hours, ranging up to 6 days with median rate of 195 bpm; duration ranges from 1–13 days postoperatively [207]. Anatomic lesions and younger age at repair are risk factors for the development of junctional ectopic tachycardia, which is associated with transient intraoperative or postoperative atrioventricular block [208], increased mortality, and prolonged length of stay [205,209]. Junctional ectopic tachycardia occurs most commonly in patients <24 months of age, particularly following repair of atrioventricular septal defect (47%), tetralogy of Fallot (35%), ventricular septal defects (30%), and arterial switch repair [201,202]. Prolonged bypass time and aortic cross-clamp time are risk factors for arrhythmia [201,202,210], as well as postoperative infusion of dopamine [210]. Magnesium supplementation during cardiopulmonary bypass may reduce the incidence of junctional ectopic tachycardia [211]. Treatment is necessary in 40–60% of patients with junctional ectopic tachycardia due to hemodynamic instability [205,210]; the goal of therapy is to achieve heart rates under 180 bpm. Current treatment strategies include cessation of dopamine infusion, normothermia, volume support, and intravenous amiodarone or procainamide infusion [208,212]. Atrial pacing using either temporary atrial pacing wires or an esophageal catheter at rates faster than the tachycardia may augment cardiac output, particularly when the junctional rate can be slowed by amiodarone infusion.

Atrial Fibrillation

Although atrial fibrillation occurs postoperatively in 20–40% of adult patients undergoing cardiac surgery [203,213], it occurs uncommonly in pediatric patients. However, as the number of older patients with congenital heart disease undergoing repeat surgeries increases, this arrhythmia will be encountered more frequently. Direct current cardioversion using high energy (1–2 J/kg) is used when prompt termination of hemodynamically significant atrial fibrillation is necessary. Conversion of atrial fibrillation to sinus rhythm may be achieved pharmacologically with ibutilide or amiodarone. Intravenous diltiazem or esmolol are effective for rapid rate control of atrioventricular conduction. In patients thought to be at high risk for developing atrial fibrillation, such as patients with enlarged left atria with mitral valve disease, a short prophylactic perioperative course of amiodarone may be useful [214–216].

Ventricular Arrhythmias

Early postoperative ventricular arrhythmias often are associated with ventricular dysfunction, severe hypertrophy, coronary insufficiency, electrolyte abnormalities, and excess catecholamines. Patients known to have episodes of sustained ventricular tachycardia preoperatively should be considered for operative mapping and ablation of the tachycardia focus intraoperatively. Certain patients at high risk for ventricular arrhythmias postoperatively, such as patients with hypertrophic cardiomyopathy or severe left ventricular outflow tract obstruction, may benefit from amiodarone infusion at the conclusion of cardiopulmonary bypass and during the early postoperative course. Postoperatively, correcting or minimizing the predisposing arrhythmogenic factors is essential. Maintaining the serum potassium greater than 3.5 mEq/L and magnesium greater than 2.0 g/dL, as well as decreasing the degree of inotropic support when possible, will decrease the potential for triggering sustained tachycardia. In patients thought to be at risk for developing sustained arrhythmias, a prophylactic lidocaine infusion is effective. Lidocaine is less efficacious than amiodarone or procainamide in terminating a sustained ventricular tachycardia [217,218]. For termination of sustained ventricular tachycardia, direct current cardioversion using 1 J/kg is indicated where acute hemodynamic compromise is present; otherwise amiodarone or procainamide infusions may be effective [217].

CHAPTER 42

Heart Transplantation

Joseph W. Rossano, David L.S. Morales, and Charles D. Fraser Jr

Texas Children's Hospital, Baylor College of Medicine, Houston, TX, USA

History of Heart Transplantation

The genesis of solid organ transplantation dates back to the beginning of the last century with the pioneering work of Alexis Carrel and Charles Guthrie [1]. Carrel and Guthrie improved techniques of suturing vascular structures that enabled them to perform successful experiments of solid organ transplantation in animals [2,3,4,5], earning Carrel the Nobel Prize in Medicine and Physiology in 1912. This work was advanced by others including Frank Mann and colleagues [6] at the Mayo Clinic and Vladimir Demikhov at Moscow State University [7]. Demikhov's work initially went unnoticed in the west, but he performed hundreds of experiments with heart transplantation in animals, initially placing the heart in the neck of the animal but eventually replacing the recipient's heart with that of the donor. The first orthotopic heart transplantation in an animal was performed by Demikhov on Christmas Day in 1951 [7]. Novel work continued around the world by pioneers such as Norman Shumway and Richard Lower *et al.* at Stanford University [8], which culminated in the first human orthotopic heart transplantation being performed on December 3, 1967, by Christiaan Barnard [9]. The first heart transplantation to be performed in a human actually occurred 3 years earlier in 1964 by James Hardy, who transplanted a chimpanzee heart into a 68-year-old man with end-stage heart failure [10]. The patient survived for less than 2 hours, and the operation drew substantial criticism [11].

Just days after Barnard's operation, heart transplantation expanded into the pediatric arena with the first pediatric transplant being performed by Adrian Kantrowitz in a neonate with severe Ebstein anomaly of the tricuspid valve. The infant, however, survived for only several hours. Extending pediatric heart transplantation to the youngest of patients was promoted by Denton Cooley and colleagues, who performed the first successful pediatric heart transplant in 1964 [12], and then by Leonard Bailey and coworkers, who performed the first successful neonatal heart transplant [13]. Today, approximately 450 pediatric heart transplantations are reported to the International Society for Heart and Lung Transplantation (ISHLT) each year [14].

Etiology and Indication for Heart Transplantation in Children

Heart failure is not rare in children; a recent nationwide study from the United States described more than 12 000 admissions for heart failure in children annually [15]. Even though most of these children will never require heart transplantation, a significant number will progress to end-stage heart failure where the only real option is heart transplantation. Other therapies, such as left ventricular assist devices (LVADs) for "destination therapy" (i.e., placing the ventricular assist device where there is no expectation of ventricular recovery or heart transplantation) can be used successfully in selected adults with improved survival and quality of life [16]; however, this has not yet been used in children. Thus, the only therapy that exists to improve survival and quality of life for children with end-stage heart failure is heart transplantation.

Unlike adults, where cardiomyopathy and coronary artery disease account for the majority of patients undergoing heart transplantation, congenital heart disease (CHD) and cardiomyopathy account for the majority of cases in children undergoing transplant [14,17,18]. Infants (<12 months old) make up the largest portion of heart transplantations performed in childhood, accounting for approximately 25% of cases, with the remaining distributed somewhat evenly throughout the remaining childhood years (Plate 42.1, see plate section opposite p. 594) [14].

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.
© 2013 Blackwell Publishing Ltd. Published 2013 by Blackwell Publishing Ltd.

Some form of CHD is the most common reason for infant heart transplants, accounting for >60% of cases, whereas cardiomyopathy accounts for approximately 30% [14]. In contrast, cardiomyopathy accounts for >60% of transplantations in older children. Retransplantation, an increasing indication for transplantation, now accounts for 5% of the total number of transplants performed.

Complex CHD remains an important indication for transplantation not only in infants but in older children as well. Although in the past heart transplantation was advocated by some centers as a primary management strategy only for some lesions, such as hypoplastic left heart syndrome, this strategy has fallen out of favor as surgical outcomes for complex lesions have improved [19]. In the current era, most children with repaired CHD are suitable for heart transplantation after not having fared well some time after surgical intervention [20].

Dilated cardiomyopathy is the most common cardiomyopathy in children and accounts for the largest percentage of transplants among the types of cardiomyopathies [21,22,23]. While many children with cardiomyopathy will experience improvement and normalization of ventricular size and function with the initiation of medical and occasionally surgical therapy, the overall survival is poor. The transplant-free survival for patients with dilated cardiomyopathy is approximately 50% at 5 years [24,25]. The etiology of dilated cardiomyopathy is important in the patient's overall outcome: for example, fulminant myocarditis has some of the highest reported rates of normalization of ventricular function [26,27], whereas dilated cardiomyopathy from neuromuscular disorders has the worst reported outcomes [24].

Hypertrophic cardiomyopathy is a common cardiomyopathy in children, accounting for 25–42% of cardiomyopathies in childhood [21,22]; however, <5% of these patients will progress to heart transplantation [28,29]. Restrictive cardiomyopathy is the least common type of cardiomyopathy experienced in children [22,30,31]; nevertheless, this condition has an extremely poor prognosis [32]. The transplant-free survival rate is less than 50% at 5 years after diagnosis, and the risk of sudden death and the development of irreversible pulmonary hypertension is high [33,34,35]. Because no known medical therapies effectively alter the natural history of restrictive cardiomyopathy, many centers, including our own, will consider patients for heart transplantation at the time of diagnosis for restrictive cardiomyopathy [36].

Left ventricular noncompaction (LVN) is an increasingly recognized cardiomyopathy in children with and without CHD [37]. While the features and phenotype of LVN are variable, many of these children will have features similar to dilated cardiomyopathy with a dilated and poorly functioning left ventricle [37,38,39,40]. Some of these patients will progress to end-stage heart failure and require transplantation. Arrhythmogenic right ventricular dysplasia/cardiomyopathy is a rare cardiomyopathy diagnosed in childhood. This cardiomyopathy is characterized by a loss of myocytes with fibrofatty infiltration of the right and often the left ventricle [41]. Arrhythmias are common with this condition.

Though overall survival has increased over time for children undergoing heart transplantation, this has been driven almost exclusively by the improvement in surviving the first posttransplant year [23,42]. Unfortunately, there has been little advancement in past two decades for survival after the first posttransplant year, with the current median survival after transplant being 11–18 years depending on the age at transplant [14]. Thus, many patients who have undergone heart transplantation in childhood will either die during childhood or require another heart transplant. The most common reason for late graft failure is transplant coronary artery disease, which will be discussed in a subsequent section. Because of the lack of long-term durability of the cardiac allograft, retransplantation has become an increasing reason for heart transplantation, now accounting for ~5% of the transplants performed annually. Several studies have found similar posttransplant survival in patients undergoing a retransplant compared with a primary heart transplant [43,44,45]. However, data from the United Network for Organ Sharing (UNOS) registry indicated that patients with early primary graft failure had a 1-year survival rate of only 53% [46].

Management of Chronic Heart Failure

Heart failure is generally a chronic, progressive disorder [47]. However, certain types of cardiomyopathies such as LVN can have an undulating phenotype with periods of improvement and/or deterioration in function [37]. Additionally, patients with acute myocarditis, especially the fulminant form, may have complete recovery of function. Guidelines exist for the management of chronic heart failure in adults and children and have been published by the ISHLT, the American College of Cardiology, and the American Heart Association [48,49]. The primary aims of therapy are to reduce symptoms, preserve long-term ventricular performance, and extend survival.

Pharmacologic Agents used for Treatment of Heart Failure

Diuretics

Treating symptoms of "congestion" is critical to the management of heart failure, both in the acute and chronic settings [49], and diuretics are recommended for patients with symptoms of heart failure and evidence of volume overload. However, the long-term use of diuretics may be

detrimental; in adults with heart failure, increasing loop diuretic dose has been identified as an independent predictor of mortality [50]. Thiazide diuretics and loop diuretics, such as furosemide, remain the most commonly used diuretics. In adults, aldosterone antagonists, such as spironolactone, have been shown to improve mortality when added to standard heart failure management [51], though there is an increase in hyperkalemia [52,53].

Angiotensin-Converting Enzyme Inhibitors/ Angiotensin Receptor Blockers

Angiotensin-converting enzyme (ACE) inhibitors were the first agents to demonstrate improved survival in adults with symptomatic heart failure. Prospective, randomized, controlled trails of various agents within this class have demonstrated improvement in symptoms with reduced progression of heart failure, decreased hospitalization, and improved survival [54,55,56,57,58,59]. Angiotensin receptor blockers, primarily used in adults who are not tolerant of ACE inhibitors, have also demonstrated an improvement in mortality that is comparable, and possibly superior, to ACE inhibitors [60,61,62]. While there have been no large, randomized, controlled trials of ACE inhibitors in the treatment of pediatric heart failure, several studies have demonstrated hemodynamic and echocardiographic improvements [63,64,65].

Beta Blockers

As with ACE inhibitors, there is an accumulation of evidence from multiple, randomized, controlled trials of beta blockers in adult heart failure patients demonstrating benefits in symptoms, heart function, frequency of hospitalization, and survival [66,67,68,69]. Data on beta blocker use in pediatric heart failure is limited, but most have been supportive. Retrospective studies of metoprolol and carvedilol have demonstrated improved cardiac function [70,71], and a small, randomized, placebo-controlled study found that patients given carvedilol had an improvement in ejection fraction and New York Heart Association (NYHA) class over a 3-month period [72]. However, a multicenter, randomized, placebo-controlled trial of carvedilol failed to demonstrate an improvement in the composite heart failure outcome, ventricular function, or natriuretic peptide levels compared with placebo [73].

Digoxin

Digoxin is one of the oldest medications used for the treatment of heart failure symptoms. While effective in alleviating symptoms of heart failure [74], digoxin has not been shown to improve mortality [75], and higher doses are associated with an increase in mortality [76]. Data on children have been extrapolated from adult studies, and the current recommendations of the ISHLT are to use digoxin for symptomatic patients with the aim of reducing symptoms [48].

Management of Acute Heart Failure

Most patients who present with acute decompensated heart failure (ADHF) have adequate tissue perfusion but require higher filling pressures to achieve it; however, some patients will present in cardiogenic shock. Assessment of cardiac output is an important aspect of the initial and ongoing assessment of patients in heart failure. Indirect measures of cardiac output include mental status, heart rate, temperature of extremities, capillary refill time, and urine output. Laboratory assessment of cardiac output includes measurements of acid-base status and lactic acid. In the absence of intracardiac shunting, superior vena cava (SVC) saturation correlates well to pulmonary artery (PA) saturation [77]. Thus, a central line placed into the SVC can be used to approximate a mixed venous saturation.

Patients with congestion but adequate perfusion are likely the largest group of patients with ADHF and the group that responds best to medical therapy. Diuresis is a critical component of the initial management of these patients and may be the only therapy needed to improve symptoms in patients with adequate perfusion. In studies of adult patients, diuretics were found to increase stroke volume, decrease pulmonary capillary wedge pressure, and decrease systemic vascular resistance [78]. Diuretics combined with vasodilators have also been shown to decrease mitral regurgitation and increase forward ejection fraction [79]. Careful monitoring is warranted with aggressive diuresis, as volume depletion and renal insufficiency may result.

Patients with poor perfusion represent a significant group of patients with ADHF admitted to the intensive care unit. The initial approach to these patients will depend on the degree of circulatory compromise. The cornerstone of therapy for these patients is afterload reduction. Avoiding inotropic agents when possible appears to be beneficial. A review of more than 15000 adults hospitalized for heart failure observed higher in-hospital mortality in patients treated with dobutamine or milrinone compared with patients treated with nitroglycerin or nesiritide [80]. However, inotropic agents may be required to improve perfusion in this group of patients. The decision to use inotropic agents should be based primarily on clinical assessment, not on echocardiography. The goal of acute therapy is to have the patient in a compensated state of heart failure, not to improve echocardiographic measures of systolic function. Many patients can become compensated without the use of inotropic agents.

In adult patients, milrinone use is associated with improved symptoms and decreased filling pressures [81,82]. However, it is not clear that milrinone has an

overall beneficial effect in patients with heart failure. In a study of almost 1000 patients evaluating the short-term use of milrinone versus placebo, there was no difference in mortality, hospital length of stay, or hospital readmission [83]. However, there was a significantly increased incidence of hypotension and arrhythmias in the milrinone-treated patients. In a retrospective analysis of this study, short-term milrinone in patients with ischemic cardiomyopathy was associated with increased in-hospital mortality and increased death or rehospitalization at 60 days [84]. Interestingly, patients with nonischemic cardiomyopathy had a decreased rate of death or rehospitalization at 60 days. Other studies have also supported the lack of overall benefit with milrinone. A prospective study of oral milrinone for chronic heart failure found that milrinone-treated patients had increased hospitalization, overall mortality, and cardiovascular mortality [85].

It is our practice to avoid catecholamines, especially at high doses, for the failing myocardium. Epinephrine has dose-dependent actions on alpha (α)- and beta (β)-adrenergic receptors. At low doses, β-adrenergic receptor response predominates, resulting in vasodilation, increased heart rate, and contractility. At higher doses there is α-adrenergic receptor stimulation resulting in vasoconstriction and increased systemic vascular resistance. The increased systemic vascular resistance and contractility may acutely improve perfusion, but will also increase myocardial oxygen consumption and myocardial work. Additionally, high-dose catecholamines for inotropic support will promote tachycardia and proarrhythmic effects, increase myocardial oxygen consumption, and depress the myocardial adrenergic response by downregulating β-adrenergic receptors. Furthermore, prolonged use of high-dose catecholamines may further amplify cardiomyocyte injury, thus aggravating diastolic and systolic ventricular dysfunction [86]. The failing myocardium will likely not tolerate long periods of epinephrine infusions.

In the setting of increased inotropic requirements for the failing myocardium, the situation is dire. Medical therapy is unlikely to return the patient to an asymptomatic state and continuation of therapy will increase the stress on an already stressed myocardium. At this point, mechanical support should be considered. A detailed description of mechanical circulatory support (MCS) is beyond the scope of this chapter, but a variety of options now exist. Total cardiopulmonary support from extracorporeal membrane oxygenation (ECMO), medium-term support with centrifugal pump devices (e.g., RotaFlow), and long-term support with LVADs (e.g., Thoratec, Berlin Heart, DeBakey VAD) are now available and are being used successfully.

The field of mechanical circulatory support for children is maturing; thus, ECMO should no longer be used for heart failure unless the patient is arresting or support is delayed (i.e., late presentation with compromised pulmonary function).

Transplantation Evaluation

All potential recipients of a heart transplant require a thorough pretransplant evaluation to assess the appropriateness of transplantation. The aim of this evaluation is to ensure as much as possible that long-term survival can be achieved. It is not only necessary to ensure the patient is an appropriate candidate from a medical standpoint, but also that there are no significant social or financial barriers that will limit the success of the transplantation.

Medical Evaluation

The medical evaluation is crucial so that transplantation is only offered to patients who are sick enough to benefit from the operation but not so sick with multiorgan system failure that they will not survive transplantation [87]. Table 42.1 includes generally accepted contraindications to heart transplantation [87]. Pediatric patients are quite sick once

Table 42.1 Contraindications. (Adapted with permission from Gajarski *et al.* [87].)

General contraindications
Presence of any noncardiac condition that significantly shortens life expectancy compared with that expected with cardiac transplantation or in conjunction with immunosuppressive requirements importantly reduces the expected survival after transplantation
Specific contraindications
Active infection
Active ulcer disease
Coexisting active neoplasm
Renal insufficiency[a]
Hepatic dysfunction with elevated transaminases[b]
Elevated, nonreactive pulmonary vascular resistance[c]
Recent pulmonary embolic event with infarction
History of or current recreational drug use
History of recurrent medical noncompliance

[a]Creatinine >2 times normal for age/body surface area (unless concomitant renal transplantation is planned).
[b]Aspartate aminotransferase/alanine aminotransferase (AST/ALT) out of proportion to that expected with passive congestion and may require liver biopsy for more complete assessment. May also include elevated total bilirubin. The presence of cirrhosis on liver biopsy generally contraindicates transplantation.
[c]Generally, pulmonary vascular resistance >6 Um^2 requires evaluation with vasodilators in the catheterization laboratory to test vascular bed reactivity with a target decrease in pulmonary vascular resistance to ≤4 Um^2.

listed for transplant, and the death rate while waiting for transplantation is high, especially for those with CHD requiring increased support such as mechanical ventilation, ECMO, or dialysis [88,89]. Our approach to recipient evaluation is detailed herein. However, certain portions of the evaluation may be delayed or deferred if the patient's status dictates urgency for listing.

A thorough evaluation of the underlying cardiac disease includes echocardiogram, electrocardiogram, usually cardiac catheterization, and occasionally other modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and exercise testing [90,91]. It is imperative to rule out any residual cardiac disease that, if treated appropriately, could avoid the need for transplantation. This would include conditions such as residual coarctation, anomalous left main coronary artery arising from the PA, ventricular outflow tract obstruction, or unrecognized arrhythmias. Additionally, anatomic details including any systemic and pulmonary venous anomalies must be clarified as they may have implications for surgical technique [92,93]. Cardiac catheterization can reveal anatomic and hemodynamic data. Importantly, pulmonary vascular resistance, which may be elevated in patients with long-standing left atrial hypertension from heart failure, can be determined. Patients with elevated pulmonary vascular resistance are at increased risk for right ventricular failure in the donor graft after transplantation [94,95,96]. While the use of pulmonary vasodilators such as inhaled nitric oxide has improved the course of patients with elevated pulmonary vascular resistance [97,98,99], a pulmonary vascular resistance indexed to body surface area of >6 Woods units with pulmonary vasodilators or a transpulmonary gradient >15 mmHg are generally considered a relative contraindication to heart transplantation [36]. However, these cut-offs are no longer considered absolute, as the chronic use of pulmonary vasodilators, inotropic medications, and/or MCS may decrease the pulmonary vascular resistance and allow heart transplantation in some of these patients [98,100,101,102].

Other components of the medical evaluation include an assessment of other organ systems including neurologic, immunologic, renal, and gastrointestinal. Table 42.2 describes the laboratory data that we obtain as part of our pretransplant evaluation at Texas Children's Hospital. Part of the immunologic evaluation includes an assessment of the presence of antibodies against human leukocyte antigens. Patients with prior blood product or allograft material exposure, which is common in pediatric patients with CHD or MCS, are at increased risk for the development of these antibodies [103]. The presence of these antibodies is typically assessed via panel reactive antibody (PRA) testing; 10% reactivity is generally considered significant [104,105]. Patients with elevated antibodies are at increased risk for acute rejection and early graft loss [105,106,107,108,109,110,111]. A detailed discussion of the treatment of patients sensitized to human leukocyte antigens is beyond the scope of this chapter. However, there are a number of strategies including avoidance of antigens from the potential donors [112], pretransplant medical therapy to decrease the number of antibodies [103], and posttransplant immunosuppressive strategies [40]. There is no clearly superior strategy or combination of strategies.

Our current strategy in sensitized patients is to avoid potential donor human leukocyte antigens that the recipient makes antibodies against. This is performed by a prospective crossmatch if the potential donor is local or a

virtual crossmatch if the donor is not local. If a virtual crossmatch is employed, we have generally performed a volume exchange blood transfusion when cardiopulmonary bypass is initiated for the transplant. If the crossmatch is subsequently positive, we follow a protocol of plasmapheresis, intravenous immunoglobulin (Ig), and anti-CD20 monoclonal antibody (e.g., Rituximab).

An evaluation of active or latent infectious diseases is also important given the lifelong immunosuppression required after transplantation. There is no general agreement about what noncardiac medical issues constitute an absolute contraindication to transplantation. For example, human immunodeficiency virus (HIV) infection has been considered an absolute contraindication; however, there are now reports of successful transplantation in HIV-positive patients [113]. Likewise, significant neurologic injury or neurodevelopmental delay is often considered a contraindication to heart transplantation, but there have been successful transplantations performed in patients with significant neurologic issues. Thus, it is important that each case is considered individually and that the pros and cons of transplantation are evaluated carefully.

Donor Evaluation

There are several factors including donor size and age, distance from the institution, infectious considerations, and cardiac performance, that need to be taken into consideration for proper donor selection. Most importantly, the adequacy of the donor must take into account the state of the recipient. One cannot always wait for an ideal donor if the recipient is a critically ill child or has a limited donor pool (i.e., size <4 kg, PRA >50%). There is some controversy regarding the optimal donor size for pediatric heart transplant patients. Data from the ISHLT registry suggest that there is increased risk with both significantly undersized or oversized donors [114]. The use of oversized donors has been advocated by some centers, especially in cases of pulmonary hypertension, with the thought that the larger graft may decrease postoperative right ventricular failure [115]. The group from Loma Linda University did not find a difference in cardiac performance or days of ventilator support based on donor-to-recipient size. There were, however, more instances of lung collapse when oversized grafts were used [116]. The group has also demonstrated similar long-term outcomes, though their experience is better with oversized grafts than undersized grafts [117]. A recent study from the UNOS registry did not find a difference on long-term survival based on donor-to-recipient weight ratios in children [118]. Other groups have found increased graft failure with undersized donors [119]. Our general policy has been to match the donor and recipient within 20% of weight; however, this guideline is not rigid and more liberal criteria are used depending on an individual patient's condition.

Donor age and size are generally closely correlated for younger patients, but older donors may be of acceptable size for adolescent patients. The issue of donor age in this group is important, as older patients are more likely to have significant cardiovascular disease, such as coronary artery disease, that may limit graft survival. There have been several studies that donor age is significant factor in long-term survival in pediatric heart transplant patients [14,120,121]. A recent study from UNOS found significantly worse survival when donors over 30 years of age were used for pediatric patients [121].

The distance of the donor from the transplant center is important, predominately for the ability to perform a prospective crossmatch for local donors and for donor heart ischemic times. A crossmatch is performed by testing the donor's tissue, usually lymphocytes, against the recipient's serum and assessing for an antibody-mediated reaction. This ideally is done before transplantation, as patients with a positive crossmatch are at significantly increased risk of acute graft failure. However, this approach limits the donor pool essentially to local donors. A virtual crossmatch may be performed in patients at increased risk for a positive crossmatch by performing tissue typing on the donor and assessing the antibody profile of the patient. A negative virtual crossmatch, however, does not guarantee a negative actual crossmatch. Thus, a crossmatch is still performed posttransplant. If the crossmatch is positive, generally the immunosuppression protocol is augmented. Donors at a long distance from the transplant center will have a longer ischemic time. However, with the advent of pediatric VAD explant and heart transplant, ischemic time is sometimes dictated by the explant procedure. Duration of donor ischemia has been associated with worse outcomes in many [94] but not all pediatric studies [14,122,123]. The group from Loma Linda University has been one of the largest proponents of not limiting potential donors on the basis of prolonged ischemic times. Their group has demonstrated functioning grafts with ischemic times as long as 10 hours [122].

Potential donors are screened for infectious diseases, including hepatitis B virus (HBV), hepatitis C virus (HCV), HIV, Epstein-Barr virus (EBV), and cytomegalovirus (CMV), that could be transmitted to the recipients. Current infection with HBV, HCV, or HIV would be considered a contraindication to transplantation. Cytomegalovirus and EBV may potentiate donor morbidity, such a posttransplant lymphoproliferative disorder and cardiac allograft vasculopathy; however, their presence does not preclude transplant. Most centers will administer prophylaxis against CMV infections posttransplant if either the donor or the recipient has a history of an infection.

Blood type compatibility is of interest in pediatric heart transplantation. Several studies from adult and pediatric patients have demonstrated superior outcomes when the donor and recipient are ABO identical (e.g., an O donor with an O recipient) as compared to ABO compatible (e.g., an O donor with a B recipient) [14,124,125,126]. However, even ABO-incompatible heart transplantation has been performed at times in infants, and reports have shown no decrease in survival [127,128]. While this strategy certainly has the potential to expand the donor pool for infants and thereby decrease waitlist mortality [127], a recent study from UNOS found that infants listed for ABO-incompatible hearts had similar waitlist mortality [129].

Ventricular function is frequently diminished in brain-dead donors and from donors who have undergone prolonged cardiopulmonary resuscitation [130]. Brain deaths are associated with increased catecholamines, altered thyroid hormone, and cortisol levels that can impair cardiac performance [130,131]. The use of inotropic medications is common in donors. It is difficult to quantitate the degree of ventricular dysfunction that precludes transplantation in children. While the use of high-dose inotropic support is considered a contraindication by many centers, a recent study from the Loma Linda University group found that when they accepted donors who had previously been turned down by other centers for donor quality, their long-term outcomes were not diminished [122]. The donor ejection fractions were as low as 37%, and 41% were on high-dose vasopressors [122]. There is a current interest in expanding the potential donor pool from brain-dead donors exclusively to donors after cardiac death. The limited experience with this strategy has demonstrated that transplantation can be successfully performed from donors after cardiac death [132].

Surgical Technique

Even though the right atrial technique developed by Lower and Shumway is still performed in some centers, the majority of programs (67% in the 2007 ISHLT registry) perform a bicaval-left atrial cuff technique. This was described by Sievers and associates in 1994 [133]. Through a standard median sternotomy, aortic and bicaval cannulation is established. High cannulation of the aorta and SVC will allow for adequate recipient cuffs. Also, dissection of the diaphragmatic reflection off the inferior vena cava (IVC) allows for low IVC cannulation and an adequate IVC recipient cuff. Once cardiopulmonary bypass has been established, the patient is cooled to 32 °C. The aorta is cross-clamped and antegrade cardioplegia is given until the heart stops. Caval snares are applied, the SVC is transected, and a large right atrial-IVC cuff is created. The aorta is transected followed by the main PA. Once completed, the dome of the left atrium is opened just posterior to the great vessels. The left atrial cuff is created being careful to include all four pulmonary veins but not the left atrial appendage. It is important to ensure hemostasis of the left atrial cuff.

Once the recipient field is prepared, the donor heart is removed from the transport cooler and prepared for implantation. The aorta and main PA are separated. The left atrium is prepared by opening the pulmonary veins and then making a uniform circular cuff. The atrial septum is then probed from the left atrial side and the right atrial side via the IVC to identify a patent foramen ovale. If present, it can be closed primarily. If lungs were procured, the left atrial appendage was most likely incised for decompression during the procurement procedure; this must be repaired.

Implantation consists of five anastomoses completed with a running Prolene polypropylene suture in the following order: left atrial cuff, aorta, IVC, SVC, and main PA (Figure 42.1) [134,135]. The three right-sided connections are done with the heart beating on cardiopulmonary bypass. The left atrial anastomosis is preformed first, starting at the base of the left atrial appendage and sewing to the IVC, ensuring that the cuff edges are everted out of the left atrium so that only endocardium is exposed to the blood stream. We believe this to be less thrombogenic. The left atrial anastomosis is not completely finished because a left heart vent is left in place. The aorta is prepared with the idea that it should be the shortest vessel among the SVC and PA so that the donor heart that often is small compared with the pericardial space will "hang" off the aorta. This will ensure that the SVC and PA are not under tension. As the aortic anastomosis is being completed, the left heart vent is turned off and the heart is de-aired. This anastomosis is completed and an anterior aortic vent is placed. The cross-clamp is removed and, once normal sinus rhythm has been established, the IVC anastomosis is completed followed by the SVC anastomosis. It is important, especially with infants, to make the SVC anastomosis tension free, aligned, and free of a purse-string effect. When connecting the main PA, it is important to remember that making it too long is a well described technical error that results in either main PA or branch PA stenosis secondary to buckling of the PA. Therefore, the donor and recipient PAs should be aggressively trimmed, making certain to keep the pulmonary valve and the branch PAs properly aligned. The patient should be completely rewarmed while the PA is anastomosed. We place a transthoracic left atrial line as well as temporary atrial and ventricular pacemaker wires. Before, separating from cardiopulmonary bypass, the heart should be lifted to ensure hemostasis of the left atrial suture line. Separation from bypass is performed under transesophageal echocardiography guidance to ensure excellent

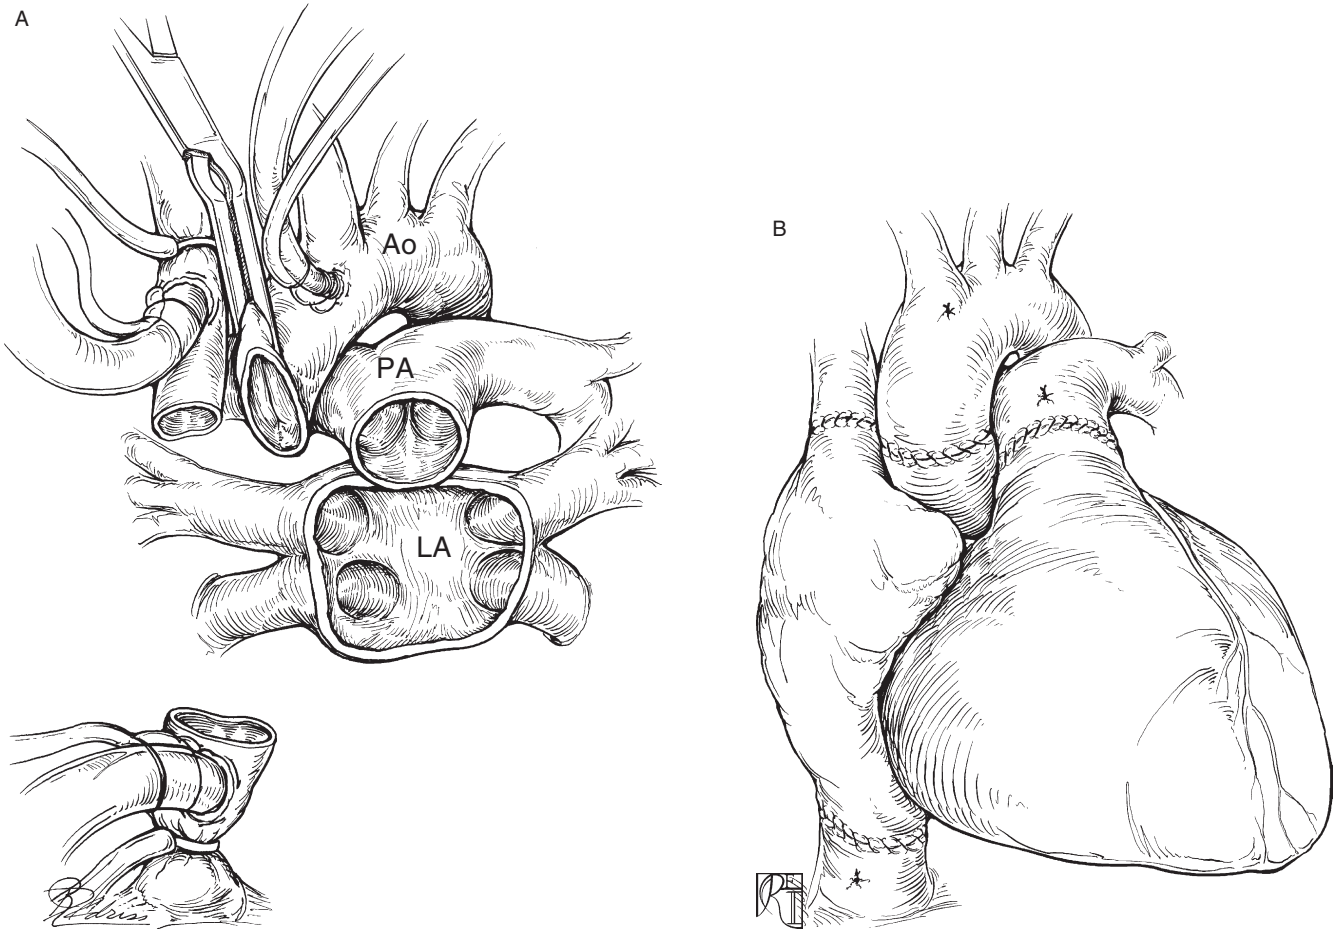

Figure 42.1 "Bicaval" cardiac transplantation. **A,** The recipient cardiectomy has been completed. Note the entire recipient right atrium has been removed. **B,** The completed implant. The sequence of anastomoses is (1) left atrial (LA), (2) aortic (Ao) (cross-clamp removed and heart perfused), (3) inferior vena cava, (4) pulmonary artery (PA), and (5) superior vena cava. de-airing and to assess post-bypass ventricular and valvar function.

Many anatomic variants require special consideration; however, the vast majority are not a contraindication to heart transplant and can usually be resolved by procuring an adequate amount of tissue from the donor. A left SVC can be anastomosed to a donor innominate vein. Patients who have hypoplastic left heart syndrome can have their arch reconstructed with the donor aorta and the recipient arch vessels taken as a patch and sewn into the donor arch. An anatomic variant that can make transplant difficult occurs when all the pulmonary veins drain far to the right of the vertebral column. When anastomosed to the left atrium, these tend to become draped over the vertebral column causing obstruction. Left VAD explant and heart transplant is becoming a more frequent procedure in children and can prove challenging with regard to adhesions and aortic cannulation. Cannulae often are substernal. Techniques to avoid unwanted cavitary entry should be employed in consideration of future resternotomy. Also, enough ascending aorta may not be available to cannulate and cross-clamp at the time of transplant, especially in the smaller child with a VAD. Therefore, we often cannulate a shunt anastomosed to the innominate artery, which allows for a cross-clamp, an adequate aortic cuff, and the avoidance of circulatory arrest.

Postoperative Recovery

One of the clear distinctions between children recovering after heart transplantation compared with children with other forms of CHD is the need for immunosuppression. The cornerstone of immunosuppression at many centers has been triple drug immunosuppression with corticosteroids, a calcineurin inhibitor (e.g., cyclosporine or tacrolimus), and an antiproliferative agent (e.g., azathioprine or mycophenolate mofetil). This has been modified by many centers with steroid weaning or avoidance, and occa-

sionally calcineurin inhibitor monotherapy. Other agents such as proliferation signal inhibitors (e.g., sirolimus or everolimus) may have a role in the prevention of coronary allograft vasculopathy; however, there is an increased risk of wound healing problems with these agents if used in the first few weeks after transplant [136]. Many centers will use additional agents at the time of transplant that are not part of the chronic immunosuppressive regimen, so-called induction therapy. Medications such as antithymocyte globulin and interleukin-2 receptor antagonists have been used for induction therapy. Some believe that with induction therapy the incidence of acute rejection can be diminished and that the initiation of calcineurin inhibitors, and their associated toxicities, can be delayed. While more than half of pediatric centers report the use of induction therapy, the use of therapy has not clearly been associated with decreased episodes of rejection or survival in the ISHLT registry [14]. As discussed previously, the presence of antibodies against donor antigens places the patient at increased risk for acute or hyperacute rejection and primary graft failure. This can have devastating effects in the early postoperative period. Treatment may include intensive immunosuppression and MCS, which has been used successfully for primary graft failure [137].

Patients with longstanding heart failure or certain CHD often have elevation in pulmonary vascular resistance (PVR). This can lead to donor right ventricular dysfunction and failure in the immediate postoperative period as the donor heart may respond poorly to the increased afterload. Medical therapy with pulmonary vasodilators such as inhaled nitric oxygen, isoproterenol, milrinone, and prostacyclin can be helpful in this clinical scenario [138,139]. These new therapies have clouded the limits of pretransplant PVR that would exclude transplant. Most patients with elevated PVR before heart transplantation will improve over time after transplantation [140].

It is important to note that the transplanted heart does not have the normal sympathetic innervation and thus may not respond in the usual manner to sympathetic stimulation. It has been our practice to use isoproterenol or cardiac pacing to avoid significant bradycardia in the immediate postoperative period. Partial reinnervation may occur over time [141,142]. Patients are also at risk for tachyarrhythmias, including ventricular tachycardia, likely occurring secondary to myocardial ischemia.

Long-Term Outcomes and Follow-Up

After heart transplantation, children require a lifetime of immunosuppression and are at risk for serious complications including graft rejection, cardiac allograft vasculopathy, infections, and malignancy. While there has been significant improvement in overall survival, this has been mostly from improved early survival. Patients who survive the first year posttransplant have good overall survival with >70% alive at 7 years after transplantation (Plate 42.2, see plate section opposite p. 594) [14].

The largest contributor to decreased graft longevity is the development of cardiac allograft vasculopathy; however, acute rejection remains an important cause of death even late after transplantation [14,143]. Cardiac allograft vasculopathy is a form of atherosclerosis distinct from the typical coronary artery disease in adults and consists initially of intimal proliferation and eventual luminal obstruction. Multiple immunologic and nonimmunologic factors likely contribute to the development of cardiac allograft vasculopathy including viral infection (e.g., CMV), rejection episodes, hypertension, hyperlipidemia, and diabetes [144].

Heart transplant patients are at an increased risk of multiple chronic comorbidities including hypertension, renal insufficiency, hyperlipidemia, cognitive difficulties, and psychological problems [14,145,146]. Fortunately, however, most are without major functional limitations. Data from the ISHLT indicates that more than 90% of patients have no limitations in physical activities [14].

Heart transplant for children remains the safest and most efficient therapy for children with end-stage heart failure.

CHAPTER 43

Pediatric Lung and Heart-Lung Transplantation

Dewei Ren, George B. Mallory Jr, David L.S. Morales, and Jeffrey S. Heinle
Texas Children's Hospital, Houston, TX, USA

Introduction

Lung and heart-lung transplantation have become accepted therapeutic modalities for end-stage pulmonary and pulmonary vascular diseases. In the past two decades more than 25 000 adult and 1200 pediatric lung transplantations were performed worldwide [1,2]. This life-saving procedure has been applied to a small but significant number of infants, children, and adolescents in a relatively small number of centers around the world. Over the last 10 years the number of lung transplants per year worldwide has ranged from 59 to 93 in recipients less than 18 years of age with the majority of these performed in adolescent patients (12–17 years) (Figure 43.1) [1]. This is in comparison to approximately 1000–2000 transplants performed annually in adults [2]. The number of infant transplants has continued to remain low, with less than 10 procedures performed each year since 1997 [1].

The number of centers performing pediatric lung transplants has been rising, with 32 centers reporting pediatric transplants in 2006, and 36 centers reporting transplants in 2007 [1]. A majority of these 36 centers are adult programs performing occasional lung transplants in adolescents. However, over the past 5 years, less than 10 pediatric centers report performing more then five transplants per year and no single pediatric center is consistently performing more than 20 transplants per year, while 38 adult centers are performing greater than 20 transplants per year [1,2]. Of these pediatric centers, only two centers have averaged more than 10 transplants per year from 2002 to 2009 [1,2].

To date, more than 549 pediatric heart-lung transplants (HLTs) have been performed [1]. The volume of pediatric HLT procedures has decreased since a peak in 1989 to recent years with only eight pediatric HLTs performed in 2007. This finding is probably because single-/double-lung transplantation offers potential advantages over HLT, including shorter waiting time and improved efficiency of organ utilization. High death rates on the waiting list [3] and poor long-term survival posttransplant may also be a limiting factor for HLT candidates.

Historical Background

The first human lung transplantation was performed by Hardy and his team in 1963 [4]. The patient was a 58-year-old male with severe emphysema and left lung carcinoma. Single-lung transplant was successfully performed, but the recipient died from renal failure and malnutrition on the 18th postoperative day. In 1967, Denton Cooley and associates performed HLT in a 2½-year-old girl with an atrioventricular canal defect and pulmonary hypertension [5]. The patient died 14 hours after the procedure. In 1969, Lillehei and colleagues transplanted a heart-lung block to a 43-year-old man, who expired 8 days later [6].

Between 1963 and 1980, multiple attempts at lung transplants were performed around the world with no real success. Most of these transplants were performed on debilitated patients as "rescue" attempts after the development of acute respiratory failure. Challenges presumably related to immunosuppression and healing of the airway anastomoses prevented successful application of lung and HLT until the early 1980s. The advent of cyclosporine and vascular anastomotic techniques led to the first successful HLT [7]. In 1981, Reitz performed the first successful HLT in a 45-year-old woman with idiopathic pulmonary hypertension [8]. She did well for more then 5 years after the transplantation. This was soon followed by the first successful single-lung transplant in 1983 and the first successful double-lung transplant in 1986, both performed by

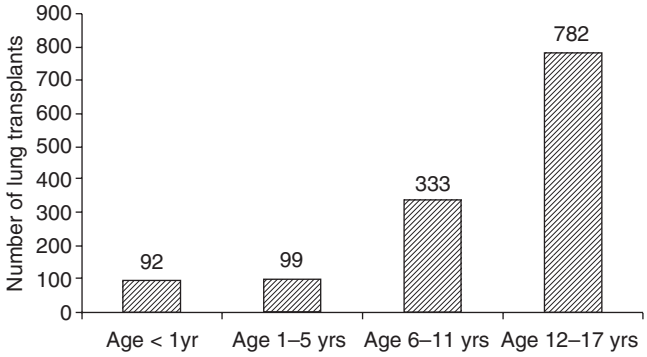

Figure 43.1 Pediatric lung transplantation age distribution and number, from January 1990 to June 2008. (Data from Aurora *et al.* [1].)

Table 43.1 Indication for pediatric lung transplantation by age group, January through June 2008. (Data from Aurora *et al.* [1].)

Diagnosis	<1 year	1–5 years	6–11 years	12–17 years
Cystic fibrosis (%)	2.4	5.1	53.0	69.2
Idiopathic pulmonary arterial hypertension (%)	13.4	22.2	10.7	7.6
Retransplant (%)	3.7	8.1	6.4	5.5
Congenital heart disease (%)	25.6	8.1	1.7	1.3
Pulmonary vascular disease (%)	9.8	5.1	3.0	0.2
Surfactant protein B deficiency (%)	13.4	4.0		
Other (%)	31.6	47.4	25.2	16.2

Cooper and his team at University of Toronto [9]. The first reported pediatric lung transplantation was performed in Toronto in 1987 in a 16-year-old boy with familial pulmonary fibrosis [10]. These practices have since been successfully employed to provide selected children with end-stage lung disease with years of improved quality of life.

In 1966 Shinoi and colleagues at Tokyo Medical College performed the world's first human lobar transplant [11]. However, the transplanted lobe was removed on postoperative day 18 because of graft failure. This attempt by Shinoi and team advanced knowledge and interest in lobar transplantation and foreshadowed the development of living donor lobar transplantation. The disparity between available donors and potential recipients of lung transplants remains a significant limitation to pediatric lung transplantation. Living donor lobar transplant has been tried as a partial solution to the problem of donor graft availability. Starnes and colleagues first introduced living donor lobar transplantation in 1993 [12]. Since most children are best treated with bilateral lung transplantation, living-donor lobar transplantation involves two suitable adult donors each donating a single lower lobe. Despite over 300 procedures having been performed worldwide, application of this technique has generally fallen out of favor, the number dramatically falling from a peak of 14 in both 1998 and 1999 to only three total procedures from 2005 to 2007 in the United States [1]. Recently, Date and colleagues have demonstrated impressive success with this technique with reported survival of 94% at 54 months in 31 patients [13].

Indications for Transplantation

The indication for lung transplantation is end-stage pulmonary parenchymal or vascular disease that is not amenable to any further medical or surgical therapy. Patients being considered for transplantation are generally those who are expected to die of their primary disease within 1–2 years. Diseases leading to pediatric lung transplantation are distinct from those seen in adults. The primary indications for adult lung transplant are chronic obstructive pulmonary disease/emphysema, idiopathic pulmonary fibrosis, and cystic fibrosis (CF), while the indications in children depend on the age of the recipients. According to the Registry of the International Society for Heart and Lung Transplantation (ISHLT): Twelfth Official Pediatric Lung and Heart/Lung Transplantation Report – 2009 [1], the great majority of lung transplants in children greater than 5 years of age are performed for CF, whereas, in infants and preschool children, the most common indications are idiopathic pulmonary arterial hypertension, congenital heart disease, and surfactant dysfunction syndromes. A breakdown of these diagnoses by age group is listed in Table 43.1 [1]. Lung retransplant for severe graft dysfunction was the indication for 6% of lung transplants in children [1]. The total number of transplants reported to the Registry has remained relatively constant with approximately 50–60 pediatric lung transplants performed per year; this number was slightly higher in recent years with 87 transplants performed in 2006 and 93 transplants performed in 2007. The majority were performed in adolescent patients (Figure 43.1) [1] owing to CF or pulmonary hypertension.

For CF patients, bilateral lung transplantation, or occasionally, HLT, is indicated. Because end-stage pulmonary insufficiency in this disease has a significant infectious component, single-lung transplant has no practical role. Heart-lung transplantation is rarely performed for CF anymore, especially in North America, unless left ventricular function is significantly decreased. Patients with CF are considered for lung transplantation secondary to poor pulmonary function as indicated by a combination of the following: a forced expiratory volume in 1 second (FEV_1) below 30% of predicted normal value, hypercarbia, hypoxemia with requirement for supplemental oxygen, decreased 6-minute walk, or need for noninvasive ventilation. The level of pulmonary insufficiency warranting a lung trans-

plantation consult usually results in a poor quality of life with a life expectancy of 1 year or less. More recently, unremitting infection requiring repeated hospitalizations and/or continuous intravenous antibiotics causing a poor quality of life has also become an indication for transplant in some patients. Patients with CF may benefit more from transplantation than other transplant groups [14].

The child with end-stage pulmonary hypertension is hemodynamically fragile and tends to follow an aggressive course with high pretransplant mortality [15,16]. Idiopathic pulmonary hypertension can be approached with single-lung, double-lung, or heart-lung transplantation depending on left ventricular function. Double-lung transplantation is now performed more often than single-lung or heart-lung transplantation for this indication without an increase in mortality or morbidity [17]. However, idiopathic pulmonary artery hypertension and congenital heart disease resulting in pulmonary vascular disease represent the most frequent indication for pediatric HLT over the past 8 years in North America [1].

Living donor lobar lung transplantation (LDLT) developed in 1993 [12] and became an accepted alternative to deceased donor lung transplantation in a few transplant centers in select patients with end-stage lung disease. One-year survival rate for LDLT recipients has been reported at 81% [18], which compared favorably with ISHLT average of 75% for pediatric transplant. Living donor lobar lung transplantation has also been reported to reduce the incidence of bronchiolitis obliterans in pediatric patients [19]. Complication rates in living donors have been reported to be as high as 20% [20], and prospective donors need to be informed of the potential morbidity and mortality associated with lobectomy. In retransplant patients, Kozower and colleagues have demonstrated that LDLT offers potential advantages over deceased donor donation and may be the preferred method of retransplantation for this high-risk group [21].

In properly selected patients, HLT provides a viable therapeutic option in those children with uncorrectable congenital heart disease and pulmonary vascular disease who are unresponsive to conventional management. Patients with surgically irreparable complex congenital heart disease with a systemic ventricular ejection fraction less than 35% and end-stage pulmonary disease or Eisenmenger's syndrome are candidates for HLT [22]. Gorler and associates reported 16 pediatric HLTs performed at Hannover Medical School, Germany [23]. Among them, nine patients had congenital heart disease with Eisenmenger syndrome, four patients had underlying pulmonary hypertension, and three with other diseases [23]. Another German group has performed 51 HLTs since 1983 with eleven patients younger than 14 years old [24]. Among these pediatric patients, idiopathic pulmonary hypertension was the indication for transplant in 55% of patients, pulmonary atresia with severe pulmonary artery hypoplasia in 27%, and CF and cardiomyopathy with fixed pulmonary hypertension in 9% [24].

Contraindications to Transplantation

Medical and surgical contraindications to lung transplantation in children are listed in Table 43.2. In the current era, many of the contraindications can be viewed as relative and not necessarily absolute. Over time, the surgical contraindications to transplantation have narrowed at many centers. For example, several centers, including our own institution, have successfully performed thoracic organ transplantation in select children with significant scoliosis. A tracheostomy alone generally would not be considered a contraindication because early posttransplant decannulation could obviate the problem of a long-term portal of entry for microorganisms into the lower airway. In previously operated patients with pulmonary atresia and nonconfluent pulmonary arteries, transplantation is generally

Table 43.2 Medical and surgical contraindications to pediatric lung transplantation. (BID, twice daily; CF, cystic fibrosis.)

Absolute

1. Pan-resistant Gram-negative or mycobacterial lung and/or sinus infection in CF
2. Uncontrolled seizure disorder
3. Severe mental retardation
4. Current/history of substance or alcohol abuse
5. Positive serum pregnancy test at the time of evaluation
6. HIV infection
7. Chronic hepatitis B and C
8. Acute active viral infection
9. Multiorgan failure*
10. *Burkholderia cenocepacia* (genomovar 3) lower respiratory infection in patient with CF
11. Severe scoliosis or thoracic cage deformity
12. Poorly controlled diabetes mellitus
13. Active neoplasm
14. Serious and untreatable psychiatric disorder on the part of patient or primary caretaker
15. Severe tracheomalacia

Relative

1. Symptomatic osteoporosis or osteopenia
2. Pneumonectomy (unless volume-occupying device in place)
3. Panresistant microorganisms within the respiratory tract
4. Other *Burkholderia cenocepacia* complex lower respiratory infection
5. Daily systemic corticosteroids (>60 mg/day BID)
6. Severe malnutrition
7. Talc pleurodesis

*Multi-organ transplantation such as liver-lung, renal-lung or heart-lung transplantation might be an appropriate option.

contraindicated [25]. Pulmonary blood flow depends exclusively on collateral arterial supply, and in the context of previous thoracotomy, there may also be diffuse arterial connections across the pleura. In the early experience at St. Louis Children's Hospital, this particular clinical scenario predisposed to diffuse small arterial bleeding, which led to the early demise of several patients [25].

Issues of active infection are generally straightforward. It appears that outcome after lung transplantation in CF patients infected with the most virulent and transmissible form of *Burkholderia cepacia* infection is poor with an early mortality from infection approaching 50% [26,27]. Recently, *Burkholderia cepacia* complex has been differentiated into distinct species, of which *B. cenocepacia* [genomovar 3] appears to be the most virulent species post transplantation; we consider this organism to be an absolute contraindication to transplant.

Nonmedical contraindications include financial and psychosocial factors. Inability to attend follow-up visits or recalcitrant medical nonadherence are contraindications to transplant. It would seem obvious that serious mental health disorders or disability that would obviate cooperation with the administration of medication and/or follow-up testing are strong contraindications to transplantation. A thorough evaluation of the child and family by a child psychologist, pediatric social worker, and the team of transplant caregivers should be required before accepting or rejecting any individual candidate.

Timing of Referral

The timing of the referral and listing of patients for lung transplantation remains a difficult decision. The careful consideration of the natural history and prognosis of the underlying primary disease needs to be weighed against the projected survival time post transplant. Quality of life with and without a transplant and the waiting time for the patient while on the transplant list also need to be factored into the timing of the listing. The ultimate goals remain obtaining "maximal mileage" from the patient's native lung, conferring a greater chance of survival with a new lung, and avoiding death while waiting on the transplant list [28]. It is generally recommended to consider transplantation when the patient is symptomatic during activities of daily living (New York Heart Association class III or IV) and survival is expected to be limited to 1–2 years. Ultimately, life expectancy and quality of life issues are commonly used by referring physicians as determinants of when to refer [29]. Table 43.3 [29] outlines the general recommendation for timing of referral.

Allocation of Organs

Like their adult counterparts in the United States, pediatric candidates for lung transplantation used to be listed by ABO blood group, height range, and the date of initial listing. Waiting period was and remains highly variable

Table 43.3 Recommendations regarding timing of referral. (FEV, forced expiratory volume in 1 second; NYHA, New York Heart Association.) (Reproduced with permission from Sweet [29].)

	Timing of referral
Surfactant dysfunction disorders	Patients with SP-B deficiency and ABCA3 deficiency with refractory respiratory failure should be referred immediately
	Patients with SP-C deficiency and less severe forms of ABCA3 deficiency may respond to medical therapy and should be referred when unrelenting progression of disease develops
Idiopathic pulmonary hypertension	Patients who present in NYHA class III or IV or have evidence of right heart failure should be referred immediately
	Patients who fail to respond adequately to vasodilator therapy should also be referred
Eisenmenger syndrome	Refer when the trajectory of pulmonary hypertension appears to be worsening with impaired exercise tolerance and worsening quality of life
Other pulmonary vascular disorders (pulmonary vein stenosis, alveolar capillary dysplasia)	These patients should be referred immediately since they typically do not respond to medical management and are at risk for sudden death
Cystic fibrosis	Patients with percent predicted FEV_1 values less than 30%, frequent hospitalizations, refractory hypoxemia or hypercapnia should be referred for transplant
Bronchopulmonary dysplasia	Refer patients with recurrent or severe episodes of respiratory failure or evidence for progressive pulmonary hypertension and absence of significant comorbidities
Diffuse parenchymal lung disease	Patients without evidence for systemic disease that could affect outcome should be referred early

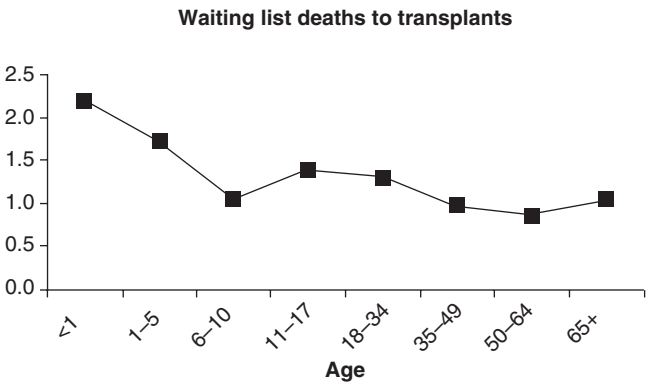

Figure 43.2 Ratio of the number of waiting list deaths to the number of transplants for each age group. (Reproduced with permission from Sweet [30].)

Table 43.4 Standard lung donor selection criteria.

Age <55 years
ABO blood group compatibility
Clear chest radiograph
Normal bronchoscopic examination
No history of pulmonary disease
Adequate gas exchange (PaO_2 >300 mmHg on FiO_2 1.0 and PEEP 5 cmH_2O or PaO_2 120 mmHg on FiO_2 0.4 and PEEP 5 cmH_2O)
Absence of pulmonary contusion
Size matching
Negative serologic screening for hepatitis B, C and HIV
<20-pack-year smoking history

from region to region and center to center owing to a variety of factors. According to the data from Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients (SRTR), the incidence of waiting list deaths to transplants was higher in pediatric candidates than in most adults (Figure 43.2) [30], and post-transplant survival of adolescent lungs in adolescent recipients may be better than the survival of adolescent lungs transplanted into adults [30]. Therefore, allocation policies for potential recipients 12 years of age and older changed in May 2005 [30]. The new lung allocation scoring system (LAS) is based on waiting list urgency and measure of predicted transplant benefit. The score is calculated by multiple clinical measures, some of which are forced vital capacity (FVC), age, body mass index, 6-minute walk distance, diagnosis, and current use of mechanical ventilation. The LAS is currently being used only in patients 12 years of age and older because there were not enough data to generate a reliable LAS in younger candidates. Candidates 11 years of age and younger are still listed by date of listing and a simplified two-level status designation. Finally, OPTN recently prioritized lungs from pediatric donors to be preferentially offered to pediatric recipients in the local area before being offered to adults. With over 3 years since implementation, the LAS system has resulted in smaller waiting lists, shorter waiting times, and a shift in the predominant diagnosis group receiving transplantation [31]. While preliminary results on the effects of the new system on waiting list mortality and long-term survival have recently been published and showed no significant effects, more time is needed to assess its impact on organ allocation [32].

Donor Selection

Organ shortage is particularly significant for lung transplantation because less than 20% of suitable organ donors have lungs that meet the standard donor lung criteria [31]. Donor and recipient ABO compatibility is essential. Donor and recipient human leukocyte antigen (HLA) matching is not routinely required. Size considerations are important for pediatric recipients and donors because of the wide variability in size of the thorax and lungs during the span of childhood. Undersizing of the donor lung is to be avoided. Although some authors have expressed preference for donors less than 35 years old [33], there is no objective data to support this practice and recent data suggest that lungs from donors over 55 years of age have acceptable short- and intermediate-term success [34]. Satisfactory gas exchange of the donor lungs is confirmed by a PaO_2 to FiO_2 ratio of 300 or greater. A recent chest radiograph should show clear lung fields without evidence of infiltrates or contusion. Bronchoscopic assessment is performed to confirm normal airway anatomy and to identify and characterize any secretions and confirm the ease of clearance with suction. If mucopurulent secretions are present, easily cleared with suction and do not reaccumulate, the lungs may function acceptably after implantation. However, evidence of aspiration or persistent purulent secretions would be a contraindication to transplantation of that lung [35]. Standard donor lung criteria are outlined in Table 43.4.

Anesthetic and Operative Considerations

The pediatric anesthesiologist must be aware of the individual characteristics of each transplant recipient and their important comorbidities. Pediatric patients, especially infants, are more likely to be in the intensive care unit (ICU) at the time that organs become available than adult candidates. The transition from the ICU to the operating room should be managed with careful attention to timing of donor organ recovery and the condition and therapy of the child. Close coordination with the procurement team is

critical to minimize donor lung ischemic time. As a rule, the recipient is moved to the operating suite 2 hours before the donor operation, allowing time for induction of anesthesia, line placement, and positioning without increasing ischemic time. Once the donor lungs are visualized and felt to be of acceptable quality, the recipient operation is begun. Furthermore, in our institution, a thoracic epidural catheter is inserted in most patients before surgery for intraoperative and postoperative infusion of local anesthetic.

Although single-lung transplantation is still a relatively common option in adult lung transplantation, most pediatric lung transplants involve bilateral lung transplantation and are performed with the use of cardiopulmonary bypass (CPB). Bilateral lung transplantation is preferred in most centers in children because of growth considerations, for CF patients because of irreversible bacterial infection in both lungs, and because there are usually two lungs available for most pediatric patients. Cardiopulmonary bypass provides adequate perfusion and oxygenation during the recipient pneumonectomy and donor implantation, aids in exposure and dissection of the hilar structures, allows both native lungs to be removed thereby minimizing contamination of the donor organ, provides the ability to cleanse (with instillation of antibiotic irrigation) the proximal tracheobronchial airway, and potentially minimizes ischemic time. The use of CPB also allows for gradual and controlled reperfusion of the implanted donor lungs to limit reperfusion injury and early graft dysfunction. The potential disadvantages of CPB include the associated coagulopathy owing to anticoagulation and hemodilution and the potential inflammatory effects of bypass.

Operative Technique

Organ Procurement

Following arrival at the donor hospital, the procurement team confirms appropriate brain-death notification, donor consents, and ABO compatibility. Serial arterial blood gas and chest radiograph results are reviewed. Flexible bronchoscopy via the endotracheal tube is performed to confirm normal anatomy and clear the airway of secretions. A final assessment is made by gross inspection of the lungs. The donor is ventilated throughout the recovery at an FiO_2 of 0.5 and a tidal volume 10 mL/kg. The administration of large fluid boluses is avoided. Airway heaters and heating blankets are discontinued.

Most commonly, the lung procurement is performed in conjunction with heart and abdominal organ procurement. The mediastinal organs are exposed via a median sternotomy which is continuous with a midline laparotomy for the abdominal organ procurement. Both pleural spaces are opened widely with care being taken to avoid injuring the lungs and creating an air leak. The lungs are visually inspected and palpated. Areas of atelectasis are recruited by manual ventilation by the anesthesiologist under the surgeon's direct view. Throughout the procedure, overinflation of the lungs must be avoided because distention is strongly associated with reperfusion injury. If the lungs are found to be acceptable, the implant team is notified of suitability and the anticipated donor cross-clamp time.

A pericardial well is created and the heart is inspected by the heart procurement team. The ascending aorta is mobilized to allow for placement of the aortic cross-clamp. The aorta and superior vena cava (SVC) are mobilized from the right pulmonary artery. The innominate vein and artery are mobilized to expose the trachea superior to the aortic arch. The trachea is circumferentially dissected to allow for later stapling with care being taken to avoid injury to the membranous portion during posterior dissection. Once thoracic and abdominal dissection is completed, the donor is systemically heparinized with 300 units/kg of heparin. A cardioplegia cannula is placed in the ascending aorta and a large bore cannula is placed in the distal main pulmonary artery (MPA) at the level of the bifurcation. A prostaglandin E1 bolus (500 μg mixed in 9 mL sterile water) is instilled into the MPA. The SVC is clamped, the left atrial appendage is amputated/incised to vent the left heart, the inferior vena cava (IVC) is transected, and the aortic cross-clamp is applied. The lungs are flushed antegrade with 50–60 mL/kg of cold (4 °C) flush solution given over approximately 5 minutes at low pressure. Our preferred lung preservation solution is an extracellular low potassium dextran (LPD) solution (Perfadex; Vitrolife, Goteborg, Sweden) shown clinically and experimentally to enhance graft preservation [36–38]. It is buffered with THAM and modified to include calcium chloride and sodium nitroprusside. Prostaglandin E1 (500 μg) is added to the first perfusate bag. The lungs are topically cooled with iced saline slush solution placed in the mediastinum and pleural spaces. Gentle ventilation is continued until the time of tracheal stapling. Care is taken to avoid effluent from the abdominal organs draining into the right pleural space and warming the lung. A suction catheter is placed in the incised IVC (or alternatively, the abdominal team may place a drainage catheter through the abdominal IVC) to capture the effluent. Clear Perfadex solution should be seen draining from the left atrial appendage. Complete decompression of the left heart should be confirmed during the administration of the flush solution.

After the cardioplegia and pulmonary flush are completed, the cannulae are removed and the heart is separated from the lungs. The IVC is divided and posterior pericardial attachments are divided to the level of the inferior pulmonary vein. The SVC is divided and separated from the right pulmonary artery. The MPA is divided at the level of the bifurcation. The distal ascending aorta is transected. The left atrium is divided with the heart and lung teams working together to insure adequate cuffs for both teams. The left atrium is incised inferiorly midway between the coronary sinus and pulmonary veins. The right and left

Table 43.5 Pediatric lung preservation protocol. (Adapted with permission from de Perrot *et al.* [39].)

Preservation solution: Perfadex®
Volume of antegrade flush solution: 50–60 mL/kg
Volume of retrograde flush solution: 250 mL per pulmonary vein, or 5 mL/kg for donor <40 kg
Pulmonary artery pressure during flush delivery: 10–15 mm Hg
Temperature of flush solution: 4 °C
Ventilator settings: FiO_2 0.5, V_T 10 cc/kg, PEEP 5 cmH_2O, airway pressure 15–20 cm H_2O
Storage temperature: 4 °C

pulmonary veins are visualized and the atrium divided leaving a cuff of left atrial tissue around the pulmonary vein orifices. The heart is removed from the field. Retrograde pulmonary flush is then delivered through the individual pulmonary veins (250 mL/vein for donors >40 kg or 5 mL/kg for donors <40 kg) to flush out thrombi or other material that may have embolized to the pulmonary arteries and to provide uniform flush of the capillary beds. The inferior pulmonary ligament is divided and the posterior mediastinal pleura are incised bilaterally. The endotracheal tube is withdrawn slightly and the trachea is stapled well above the bifurcation with the lungs expanded at approximately end-tidal volume. Care is taken to avoid over-inflation of the lungs during the final stages of recovery and transport. The trachea is divided and posterior dissection anterior to the esophagus is performed. The pericardium is excised anterior to the hilum. The pericardium at the diaphragm is incised to the level of the spine and the dissection is carried superiorly to the level of tracheal dissection. The lungs are removed to the back table and prepared for transport. They are immersed in lung preservation solution, triple bagged, and transported in ice. Donor lungs safely sustain an ischemic time up to 8 hours under these conditions. A summary of the authors' current protocol for lung preservation is outlined in Table 43.5 [39].

Deceased Donor Lung Transplantation

As noted, the vast majority of lung transplantations performed in children and adolescents use two donor lungs and CPB support. At the authors' institution, all pediatric transplants, with the exception of HLT, have been performed in this manner. The patients are intubated with a large single-lumen endotracheal tube and arterial and central venous accesses are obtained. A thoracic epidural catheter is placed preoperatively for perioperative pain management. The patient is positioned supine and padded appropriately. Although access to the lungs can be obtained

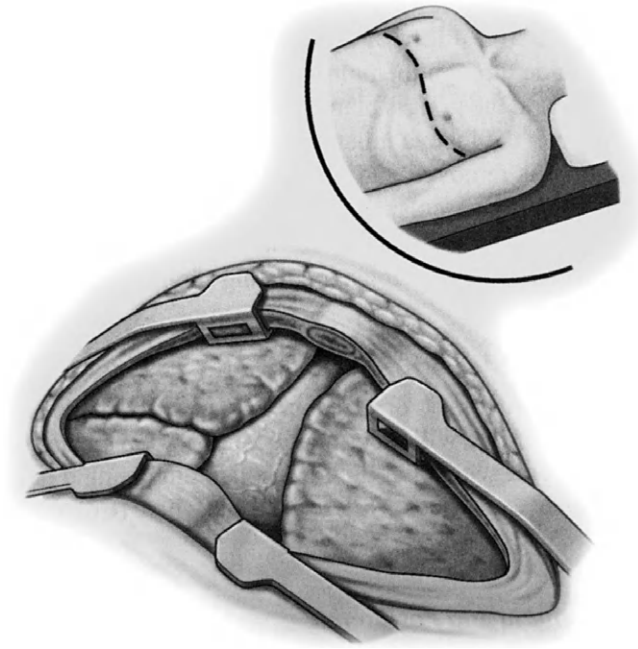

Figure 43.3 Transverse sternotomy with bilateral thoracotomy (clamshell incision). (Reproduced with permission from Nigro *et al.* [40].)

via sternotomy, bilateral anterior thoracotomies, or a bilateral thoracosternotomy incision (the so-called "clamshell" incision), we most commonly use the bilateral thoracosternotomy incision (Figure 43.3) [40] because of the excellent exposure of the mediastinal and hilar structures and both pleural spaces.

Once the donor lungs are confirmed to be of good quality, the recipient operation begins. The bilateral thoracosternotomy is performed in the fourth or fifth intercostal space. Initial chest wall dissection is carried out, dividing pleural adhesions with electrocautery. We perform the majority of the dissection on CPB. A pericardial well is created, the patient is heparinized, and the patient is cannulated for bypass using a single venous cannula via the right atrial appendage. If an intracardiac procedure is planned, direct bicaval venous cannulation is used. Bypass is established and the patient is cooled to 32–34 °C. An active vent is placed into the MPA. Ventilation is discontinued. For patients undergoing transplant for septic lung disease, tracheal secretions are aspirated and tobramycin irrigation is instilled into the airway. The remaining pleural adhesions are divided with electrocautery.

Bilateral recipient pneumonectomies are carried out. The inferior pulmonary ligament is divided. The hilar structures are mobilized with care being taken to identify and avoid injuring the phrenic and vagus nerves. The pulmonary veins are mobilized into the lung. The pulmonary arteries are dissected distal to the upper lobe takeoff and

are controlled proximally with atraumatic snares. The pulmonary veins are divided individually between staple lines preserving a length of vein for the eventual atrial cuff. Dividing the veins first aids in exposure to the pulmonary artery. The pulmonary artery is ligated distally and divided. On the right side, the upper lobe artery is ligated and divided and the pulmonary artery is divided distal to the upper lobe branch. Tracheal secretions and the tobramycin irrigation are aspirated and a suction catheter is left in the airway. The bronchus is transected with care being taken to avoid contaminating the pleural space with residual tracheobronchial secretions. Large bronchial collateral arteries, common in recipients with CF, are controlled with hemoclips. The lungs are removed, and the pleural spaces irrigated with an appropriate antibiotic solution based on preoperative respiratory cultures with antibiotic susceptibility testing. Traction is placed on the pulmonary vein stumps and the pericardium is circumferentially incised around the veins exposing the left atrium. Meticulous hemostasis is obtained at this point as visualization of the posterior mediastinum and chest wall is difficult following implantation of the graft.

Bilateral sequential lung transplantation is then carried out. The donor lungs are brought onto the field and prepared. They are kept cold with iced saline sponges during the preparation. Bilateral atrial (pulmonary venous) cuffs are prepared. The pulmonary artery is transected. The left bronchus is stapled proximally and divided. Donor secretions are sent for culture. The right lung is returned to the cold preservative solution, still inflated while the left lung is implanted. The donor bronchus is trimmed to within several millimeters of the upper lobe bronchus. The lung is placed into the pleural space and kept cold with iced saline sponges. The bronchial anastomosis is performed first followed by the pulmonary venous anastomosis and finally the pulmonary artery anastomosis. An end-to-end bronchial anastomosis is performed using a running absorbable monofilament suture (polydioxanone) for the membranous portion and simple interrupted polydioxanone sutures on the cartilaginous portion (Figure 43.4) [40]. This technique allows for any size discrepancy and permits for future growth. The suction catheter is advanced into the left bronchus and left to low continuous suction. The pulmonary veins are retracted and a large vascular clamp is placed across the left atrium at the base of the veins. The staple lines are excised and a common pulmonary venous cuff created. An end-to-end pulmonary venous anastomosis is performed with running polypropylene suture (Figure 43.5). [40]. Before completing the anterior suture line, the pulmonary artery is flushed with iced preservative solution to de-air the pulmonary veins. The suture line is completed, the pulmonary veins controlled with an atraumatic snare, and the venous clamp removed. The donor pulmonary artery is trimmed to prevent kinking of the artery owing to excessive length and end-to-end anastomosis performed with running fine polypropylene suture (Figure 43.6) [40]. Care is taken to avoid purse-stringing of the anastomosis. The lung is packed in iced saline and in a similar fashion the right lung is implanted. Occasionally, the right pulmonary artery anastomosis is

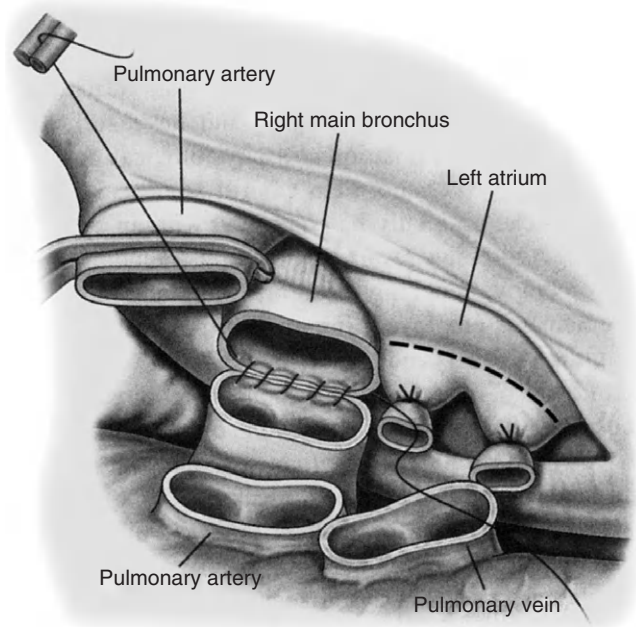

Figure 43.4 End-to-end right bronchial anastomosis. (Reproduced with permission from Nigro *et al.* [40].)

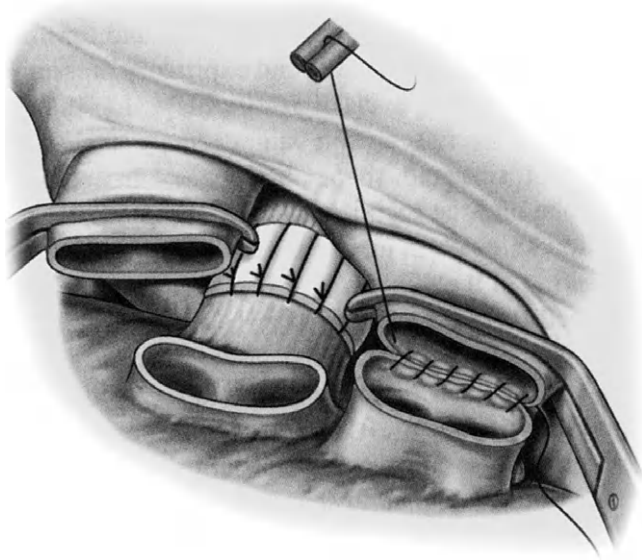

Figure 43.5 End-to-end right pulmonary vein anastomosis. (Reproduced with permission from Nigro *et al.* [40].)

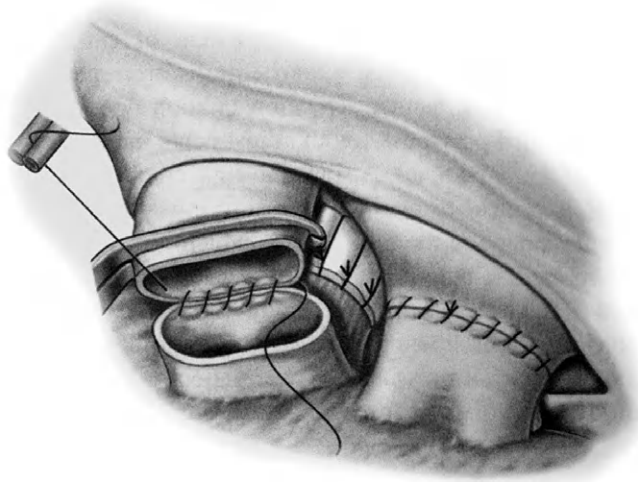

Figure 43.6 End-to-end right pulmonary artery anastomosis. (Reproduced with permission from Nigro *et al.* [40].)

performed distal to the recipient upper lobe branch based on relative diameter of the bronchi.

During the final anastomosis, the patient is rewarmed and bronchoscopy is performed by the anesthesiologist to clear the airway of secretions and blood and to confirm patency of the airway. An active vent is placed in the ascending aorta, the pulmonary artery vent is removed, and the pulmonary vein and artery snares removed. The lungs are ventilated with an FiO_2 of 0.5 and recruitment maneuvers performed keeping peak airway pressures less than 30 cm H_2O. Donor appropriate tidal volumes are used with a positive end-expiration pressure of 5 cm H_2O and peak inspiratory pressures less than 25 cm H_2O. Prostaglandin (0.025 μg/kg/min), dopamine and vasopressin infusions are begun as indicated by blood pressure, and the patient is slowly weaned from bypass over a 10–15-minute period to minimize reperfusion injury. Inhaled nitric oxide is frequently used to improve ventilation-perfusion mismatch during this phase of surgery and generally continued in the ICU. When graft function and hemodynamics are satisfactory, the patient is decannulated, heparin is reversed, and hemostasis is achieved. The mediastinum and pleural spaces are irrigated with antibiotic saline irrigation. Bilateral anterior and posterior chest tubes are inserted and placed to suction drainage. The sternum is reapproximated with stainless steel wires and the rib edges are reapproximated with interrupted, absorbable pericostal sutures. The soft tissues are closed in layers and the skin edges reapproximated with a running absorbable suture.

Living Donor Lobar Lung Transplantation

In 1990, Starnes introduced living donor lung transplantation (LDLT) [12]. In the most common form of LDLT, the recipient undergoes bilateral pneumonectomy and then receives implantation of lower lobes from each of two healthy adult donors. Given the size of even the shortest adults, LDLT is not a realistic option for children younger than 6 years of age [41]. Ideally, the donors should be taller than the recipient so that the donor lobe can readily fill the recipient hemithorax. There are important differences in performing a lobectomy for lobar transplantation in comparison with that for cancer or infection. The lobe must be removed with an adequate cuff of bronchus and pulmonary artery and vein to allow for successful implantation into the recipient [42]. Despite concerns of potential donor morbidity and mortality, Barr and Starnes and colleagues reported no perioperative or long-term mortality and a low morbidity rate following lobectomy for living lobar lung transplantation [43]. At the time of LDLT, three simultaneous thoracic operations are carried out – a requirement of resources that may be more than most transplant centers can mobilize. Although the most recent results achieved by Starnes in adults and children were acceptable, technical considerations and survival rates have been a problem in other institutions. We have not performed LDLT in our institution and readers are referred to Barr *et al*. [42] for a more detailed description of the operative technique.

Heart-Lung Transplantation

Sternotomy is frequently used in performing HLT. However, a bilateral thoracosternotomy (clamshell) is a useful alternative especially if significant adhesions are expected or if major bronchopulmonary or aortopulmonary collaterals are expected. However, bicaval cannulation can prove challenging via a clamshell incision as can the IVC anastomosis, both of which are easily achieved via sternotomy. The clamshell incision can be associated with more postoperative pain and prolonged respiratory insufficiency than the sternotomy. However, the use of an epidural catheter in these patients can greatly help with these issues and improve postoperative mobility. The clamshell incision is performed through the fourth or fifth intercostal spaces. When choosing where to transverse the sternum, we feel that it can be helpful to look at the preoperative computed tomography (CT) scan and chest X-ray to determine the level of the hilum, whether it is high or low in the thoracic cage.

The heart is cannulated for CPB using bicaval venous drainage. However, if the patient has significant aortopulmonary collaterals, which if excessive may be a contraindication to HLT, then they must be controlled so that adequate perfusion can be achieved with bypass. Once stable on bypass, the patient is cooled to nasopharyngeal temperature of 30 °C. The phrenic nerves are identified, and incisions in the mediastinal pleural reflection posterior to the phrenic nerves are created bilaterally. It is important that

these pericardial windows are large enough to place the new lungs without having to put undue stress on the phrenic nerves. The ascending aorta is cross-clamped, and cardiac arrest is achieved with cardioplegia. The caval tourniquets are secured, and superior and inferior venae cavae are transected. The ascending aorta is transected as proximally as possible. The heart is excised leaving the pulmonary vein cuff behind and transecting the MPA. The hilum of the left lung is dissected out and the left pulmonary artery is transected, leaving a small button of the pulmonary artery at the insertion of the ligamentum arteriosum. This is done to protect the left recurrent laryngeal nerve. Once the phrenic nerve and vagus nerves have been clearly dissected off the hilum, the left atrial cuff is divided, followed by the left bronchus, allowing the left lung to be removed. The hilum of the right lung is dissected out, the right bronchus is transected, and the right lung removed. If there is an infectious component to the recipient's clinical history, one may choose to transect the airways after applying a thoracoabdominal stapler. The trachea is dissected to right above the carina and transected. One should minimize tracheal dissection especially laterally. The best opportunity to establish meticulous hemostasis of the posterior mediastinum is following completion of the recipient explantation as this area will be inaccessible after graft implantation.

The heart-lung donor block is brought onto the field and inspected. Once the block is placed in the chest with both pulmonary hila being posterior to the phrenic nerves, the trachea is cut one ring above the carina. An end-to-end tracheal anastomosis is accomplished using a running polydioxanone suture circumferentially or alternatively, running polydioxanone posteriorly with interrupted simple polydioxanone sutures anteriorly. The latter is a preferred technique when there is a significant size discrepancy between the airways. The donor and recipient aorta are tailored appropriately and an end-to-end aortic anastomosis is accomplished using a running polypropylene suture. After ensuring the absence of a donor patent foramen ovale, rewarming begins, the heart is de-aired, and the aortic cross-clamp is removed. After establishing a normal sinus rhythm, both caval anastomoses are created using a running polypropylene suture. Weaning off CPB is similar to that after bilateral lung transplantation.

Postoperative Management

Important immediate postoperative issues are graft function, bleeding, and stabilization of a critically ill patient after a major operation. Patients are initially managed in an ICU setting. A thorough physical examination, initial chest radiograph, continuous monitoring of blood pressure, central venous pressures, and gas exchange, and assessment of urine output are critical in assessing graft function and organ perfusion on arrival in the intensive care unit. Fluid administration including the administration of blood products (always treated to eliminate all white blood cells) and inotropic agents are administered according to cardiac status and renal function. Judicious use of fluids is essential to avoid volume overload and pulmonary dysfunction in the early postoperative period. Inotropic agents and vasopressin are begun in the operating room to maintain adequate cardiac output and blood pressure in an effort to limit the use of volume bolus infusions to treat hypotension. A prostaglandin (alprostadil) infusion is begun before weaning from bypass and is continued for 48–72 hours postoperatively to promote pulmonary vasodilation and perfusion of pulmonary capillary beds. Inhaled nitric oxide is frequently employed in the early postoperative period to improve ventilation-perfusion mismatch. Flexible bronchoscopy is performed in the first 6–24 hours to inspect the bronchial anastomosis and the vascular supply of the bronchial mucosa just distal to the anastomosis and to perform bronchoalveolar lavage (BAL) to clear the airways and for the diagnosis of infection. Once hemostasis is assured and hemodynamics are satisfactory, weaning from ventilatory support should proceed as quickly as graft function permits. More than half of our pediatric patients are able to be weaned from ventilatory support within the first 24 hours postoperatively. We have used thoracic epidural anesthesia for postoperative pain control in our older patients to minimize the dosing of opiate therapy and to assist in mucus clearance and early mobilization of these patients.

For HLT, the postoperative management of these patients is almost identical to patients undergoing double-lung transplant at our institution. Their postoperative management is coordinated between the heart and lung transplant teams. However, immunosuppression and antimicrobial prophylaxis and therapy are managed by the lung transplant team. The postoperative course and complications are usually driven by the lungs. The surveillance for graft dysfunction, graft rejection, and infection is coordinated between the heart and lung transplant teams. In our institution, transbronchial biopsies and endomyocardial biopsies are routinely performed during the same anesthetic procedure at 2 weeks, 6 weeks, and 3, 6, 9, and 12 months after surgery.

Immunosuppression

With the introduction of cyclosporine into routine clinic practice nearly 30 years ago, early success in lung and heart-lung transplantation was achieved in pioneering centers, especially Toronto, Stanford, and Harefield in the United Kingdom. By 1990, these procedures became established treatment for adult and pediatric patients with advanced heart and lung disease. Most lung and heart-lung transplant programs rely on a triple-drug immunosuppression regimen consisting of a calcineurin inhibitor,

an antimetabolite, and corticosteroids (cyclosporine/tacrolimus, azathioprine/mycophenolate mofetil, and prednisone/prednisolone). The number of patients currently receiving tacrolimus is approximately double the number of those reported receiving cyclosporine and the majority of patients receive mycophenolate rather than azathioprine [1]. More than 95% of recipients remain on maintenance corticosteroids at 1 year and 5 years after transplantation [1].

In 2007, the International Pediatric Lung Transplant Collaborative (IPTLC), a consortium of pediatric lung transplant centers in the United States, Europe, Australia, and Canada, adopted an immunosuppression regimen consisting of tacrolimus, mycophenolate, and steroids for all pediatric lung transplants performed after January 1, 2007. Our immunosuppression protocol is based on the IPTLC consensus and is outlined in Table 43.6.

Induction Immunosuppression

Although induction therapy has been used to decrease the incidence and severity of acute rejection in solid organ transplantation, there are conflicting results from multiple studies regarding the effectiveness of induction therapy [44–49]. The most recent ISHLT registry [1] reports approximately 45% of pediatric lung transplants are recipients receiving induction immunosuppression. Interleukin-2 receptor (IL-2) antagonists (e.g., basiliximab and daclizumab) were used in approximately 30% of recipients while polyclonal antilymphocyte globulin (e.g., thymoglobulin or ATGAM®) was used in 10%. The IPTLC has concluded that no definitive long-term survival benefit or reduced incidence of bronchiolitis obliterans syndrome (BOS) has yet been demonstrated and no consensus regarding the use of induction therapy has been reached. We continue to use basiliximab as an induction agent in our practice (Table 43.6).

Perioperative Antimicrobial Prophylaxis

Antibiotic treatment before and after transplantation is not, in the strictest sense, prophylaxis. Most donor lungs, if cultured, grow one or more potential pathogens [35]. Cystic fibrosis patients have intrathoracic airways, including the proximal trachea and bronchi, which probably remain colonized and *in situ* after transplantation. Therefore, it is universal practice to choose an antibiotic regimen before, during, and immediately after lung transplantation tailored to the most recently cultured respiratory pathogens.

Table 43.6 Pediatric lung transplant immunosuppression protocol.

Preoperative
Tacrolimus: 0.05–0.1 mg/kg orally 2 hours before surgery
Basiliximab: 10 mg if less than 35 kg, 20 mg if greater than 35 kg intravenous (IV) before surgery
Mycophenolate mofetil (MMF): 600 mg/m^2 or 800 mg/m^2
Intraoperative
Methylprednisolone: 10 mg/kg IV at skin incision
Postoperative (within the first two hours)
Tacrolimus: 0.05–0.15 mg/kg by nasogastric tube or gastrostomy tube and continue every 12 hours
MMF: IV infusion 30 mg/kg every 12 hours (maximum dose 1500 mg twice daily)
Methylprednisolone: 5 mg/kg IV every12 hours for 4 doses, then 1 mg/kg every 12 hours
Postoperative (beyond 2 hours)
Methylprednisolone: transition to oral prednisone when able to take medication orally
MMF: convert to oral when oral intake established (check MMF blood trough level weekly for first 6 weeks with target trough level 1.0–5.0 μg/mL)
Tacrolimus: convert to oral when oral intake established; daily morning blood trough assays (target trough level 12–15 ng/mL) are mandatory in the first days after transplantation when oral absorption, renal and hepatic drug metabolism, and clearance are dynamic
Basiliximab: same IV dose as preoperative on day 4
Maintenance
Prednisone: wean slowly to 1 mg/kg once daily by 2 weeks posttransplant, 0.5 mg/kg daily by 3 months, 0.25 mg/kg by 6 months, and 0.1–0.15 mg daily by 1 year posttransplant
Tacrolimus: target trough will be 12–15 ng/mL through the first 6 months, then if doing well without significant rejection, 10 ng/mL until 1 year, then 6–10 ng/mL depending on record of allograft rejection and renal function
MMF: titrated to blood trough levels (range as noted above) and white blood cell on serial determinations

Initial antibiotic choice in non-CF patients is usually limited to vancomycin and ceftazidime. In CF patients, at least two intravenous antipseudomonal antibiotics are chosen based on the most recent respiratory microbiological specimen. Other agents are chosen if *Pseudomonas aeruginosa* is either not present or not the exclusive pathogen. Two agents are chosen to obtain synergism between antibiotics and to lessen the chance of emergence of antibiotic-resistant organisms. Because of the severe morbidity of inapparent early graft fungal infection, antifungal therapy with inhaled amphotericin B and enteral voriconazole has become our practice in all transplant recipients. Depending on the clinical course and the results of respiratory cultures at transplant and the first bronchoalveolar lavage culture, amphotericin B is usually discontinued after 1–2 weeks. Virtually all patients remain on oral voriconazole titrated to therapeutic drug level for weeks to months after transplantation.

Lung transplant recipients who have circulating antibody for cytomegalovirus (CMV) before transplantation or who receive an organ from a donor with positive CMV serology are treated with intravenous ganciclovir for the first days posttransplant. As soon as the oral route has been established, oral valganciclovir is begun and continued for 5 months posttransplantation.

Trimethoprim-sulfamethoxazole is commenced the first week after transplantation as prophylaxis for *Pneumocystis jiroveci* pneumonia (PCP). Some programs continue PCP prophylaxis long-term; others discontinue after 3 months of therapy. Oral nystatin is commonly prescribed to reduce the likelihood of clinically significant oral candidiasis. Oral acyclovir is used in some programs routinely as prophylactic treatment for herpes simplex infection although this has not been a routine part of our perioperative protocol.

Outcome

Survival

One and 5-year survival rates for recipients transplanted in the most recent era (2002–2007) are 83% and 50%, respectively, compared with 67% and 43% for recipients transplanted between 1988 and 1994 [1]. The majority of this survival advantage is owing to improvement in early posttransplant survival likely owing to advances in donor and recipient selection, surgical technique, and postoperative management. Expected operative survival is now greater than 95%; however, conditional long-term survival is relatively unchanged over the different eras [1]. The most recent data from the ISHLT reveals an average survival for pediatric lung transplant similar to that for adult lung transplant: half-life of 4.5 years and 5.2 years, respectively

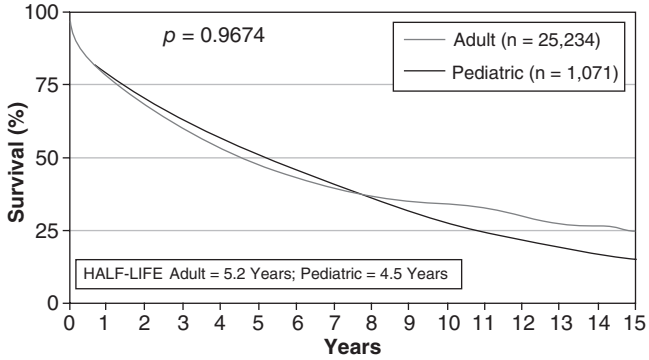

Figure 43.7 Kaplan-Meier survival by age group (pediatric vs. adult) for lung transplant performed from January 1990 through June 2007. (Reproduced with permission from Aurora *et al.* [1].)

(Figure 43.7) [1]. Among pediatric age groups, children under 1 year of age have survival half-life of 6.4 years compared with 5.7 years in children ages 1–11 years, and 4.2 years in adolescents. Children aged 1–11 years have a trend toward better survival than children aged 12–17 years at time of transplant. Outcomes for infants may be limited by a relatively higher incidence of early death. When early deaths are excluded (Figure 43.8) [1], infants have a trend toward better survival than adolescents, although there is no statistically significant difference between the two groups [1].

The causes of recipient death at different time points posttransplant are presented in Figure 43.9 [1]. Graft failure, technical issues, and infection are the most common cause of death in the early posttransplant period. Chronic rejection (bronchiolitis obliterans) is the most common cause of later death. Bronchiolitis obliterans syndrome has been reported in more than 40% of deaths at long-term follow-up posttransplant and is the most significant factor limiting long-term survival.

Pediatric HLT in the modern era, 1999 through June of 2007 [n = 122], has a graft half-life of 3.8 years. It appears that patients receiving HLT for idiopathic pulmonary artery hypertension (half-life 4.0 years) do significantly better than for other diagnoses like congenital heart disease (half-life 1.8 years). Infant HLT have been rare over the past two decades (n = 20) and have had disappointing outcomes (half-life 0.2 years). Early and late graft loss mimic those seen in lung transplantation with graft failure and infection dominating early graft loss and infection but predominately bronchiolitis obliterans being responsible for late graft loss. Overall survival analysis of pediatric heart-lung transplant recipients reveals at 5-year survival of 45% in the most recent era [1].

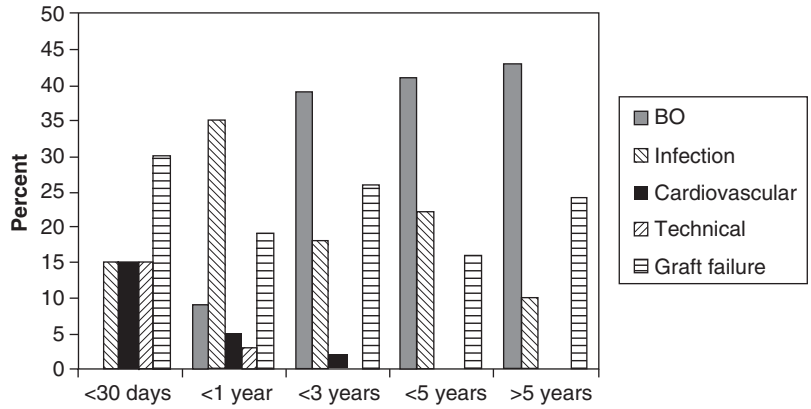

Figure 43.9 Cause of death after pediatric lung transplantation from January 1992 to June 2008. (BO, bronchiolitis obliterans.) (Data from Aurora *et al.* [1].)

Quality of Life After Lung Transplantation

Increasing attention has been given to assessments of the quality of survival following lung transplantation. Health-related quality of life (HRQL) has been defined on the basis of physical, psychological, and social function. Health-related quality of life has been reported by several authors to improve significantly in the physical and psychological components after lung transplantation [50–53]. Patients have reported better overall HRQL, higher level of energy and mobility, and decreased feelings of anxiety and depression compared with before transplantation. Furthermore, the functional status of long-term survivors of pediatric lung transplantation is good with 84% of children surviving 5 years after lung transplantation reporting no limitations in their activity [1]. However, BOS has a strong negative impact on quality of life, particularly on the physical component [53].

Acute and Chronic Rejection

Despite the introduction of improved immunosuppressive agents for use in transplantation, acute rejection affects up to 55% of lung transplant recipients within the first year after transplant [54]. Timely surveillance and accurate diagnosis of allograft rejection is central to the post-transplant care of children. Clinical presentation of acute rejection is usually without symptoms but may include fever, dyspnea, hypoxemia, leukocytosis, perihilar interstitial infiltrate on chest radiograph, and decline in FEV_1. Most frequently acute rejection is diagnosed in the absence of clinical signs in patients undergoing surveillance biopsy. Routine surveillance bronchoscopy with bronchoalveolar lavage and transbronchial biopsy is performed in lung and heart-lung transplant patients at 2 weeks, 6 weeks, and then every 3 months during the first year following transplantation in our program. Bronchoscopic biopsy allows acute rejection to be distinguished from other potential etiologies of allograft dysfunction such as airway stenosis or infection, and routinely is accompanied by bronchoalveolar lavage with viral, fungal, and quantitative bacterial cultures. The diagnosis of acute rejection is based on the histopathologic evaluation of the transbronchial biopsy specimen. The characteristic histologic appearance of rejection is the perivascular and interstitial mononuclear infiltrate with airway inflammation. Recent evidence

Table 43.7 Histologic grading of pulmonary allograft rejection. (Reproduced with permission from Stewart *et al.* [56].)

A: Acute rejection
Grade A0 (none)
Grade A1 (minimal)
Grade A2 (mild)
Grade A3 (moderate)
Grade A4 (severe)
B: Small airways inflammation: lymphocytic bronchiolitis
Grade B0 (none)
Grade B1R (low grade)
Grade B2R (high grade)
BX (ungradeable)
C: Chronic rejection: obliterative bronchiolitis
Present (C1)
Absent (C0)
D: Chronic vascular rejection: Accelerated graft vascular sclerosis

Table 43.8 Refractory acute allograft rejection immunosuppression protocol from Texas Children's Hospital. (IV, intravenous; MMF, mycophenolate mofetil.)

Methylprednisolone 10 mg/kg IV for 3 consecutive days plus 10 days of IV Atgam or Thymoglobulin
or
Methotrexate 0.15–0.25 mg/kg orally 6-week course of once weekly
or
Sirolimus 3 mg/m^2 orally as single loading dose followed by 1 mg/m^2 orally once daily, follow serum trough levels aiming for 5-20 ng/mL
or
Push MMF dosing higher by up to 50% and follow blood trough levels
or
Total lymphoid irradiation

demonstrates that peribronchiolar mononuclear inflammation (also known as lymphocytic bronchiolitis) or even a single episode of minimal perivascular inflammation significantly increases the risk for bronchiolitis obliterans syndrome [55]. The internationally accepted classification for pulmonary rejection was revised in 2006 (Table 43.7) [56].

The first episode of grade A2 or greater acute rejection is treated with three consecutive days intravenous methylprednisolone at a dose of 10 mg/kg. Uncertainty remains whether to treat grade A1 and isolated B-grade airway inflammation. In light of recent evidence that grade A1 rejection and lymphocytic bronchiolitis are risk factors for BOS, treatment seems prudent. Most patients respond promptly to corticosteroids. For recurrent and/or persistent acute rejection of grade A2 or greater, the majority of programs will alter the immunosuppressant program in addition to intravenous methylprednisolone. Alternatives commonly considered include a course of cytolytic therapy, an intermediate course of weekly oral methotrexate, or substituting sirolimus for mycophenolate (Table 43.8).

Despite a shift toward more potent immunosuppressive regimens that incorporate tacrolimus and mycophenolate, the development of chronic allograft rejection, as manifested by BOS, continues to have a negative impact on the long-term survival of lung and heart-lung transplant recipients. Bronchiolitis obliterans is the major factor limiting prolonged survival in lung and heart-lung transplant recipients, and affects more than half of pediatric patients who survive transplantation for 5 years [1]. Bronchiolitis obliterans is a fibroproliferative process of the small airways that results in multifocal bronchiolar obliteration. Although the diagnosis of BOS is based on histologic findings, a tissue diagnosis via transbronchial or open lung biopsy may not always be possible. The ISHLT has proposed the use of a spirometric definition for the clinical diagnosis

Table 43.9 Bronchiolitis obliterans syndrome scoring system. (BOS, bronchiolitis obliterans syndrome; FEV, forced expiratory volume in 1 second.) (Reproduced with permission from Cooper *et al.* [57].)

0. No significant abnormality: FEV_1 >80% of the best postoperative value
1. Mild BOS: FEV_1 66–80% of the best postoperative value
2. Moderate BOS: FEV_1 50–65% of the best postoperative value
3. Severe BOS: FEV_1 <50% of the best postoperative value

of chronic allograft dysfunction based on serial lung function testing [57]. The term of BOS was established by the ISHLT [58] for patients with an unexplained and sustained decline in FEV_1 by a greater than 20% decrease from baseline and/or a greater than 25% decline in FEV 25 to 75 (FEV_{25-75}) without acute rejection or infection [58,59]. The severity of BOS is graded based on the recommendations of the ISHLT (Table 43.9) [57]. The prevalence of bronchiolitis obliterans increases steadily with time post-transplant (Figure 43.10) [1]. Clinical symptoms at onset (dyspnea, wheezing, exercise intolerance) are nonspecific or even absent. The diagnosis of BOS is based on serial lung function testing. Bronchoscopy with transbronchial and endobronchial biopsies is performed when a diagnosis of BOS is being considered to rule out airway stenosis or active, treatable infection and to assess via transbronchial biopsy the presence or absence of active lymphocytic inflammation within the airways suggesting active immune response, which might respond to augmentation of immunosuppression.

Once the diagnosis of BOS is established, first-line therapy is short-course corticosteroids and intravenous

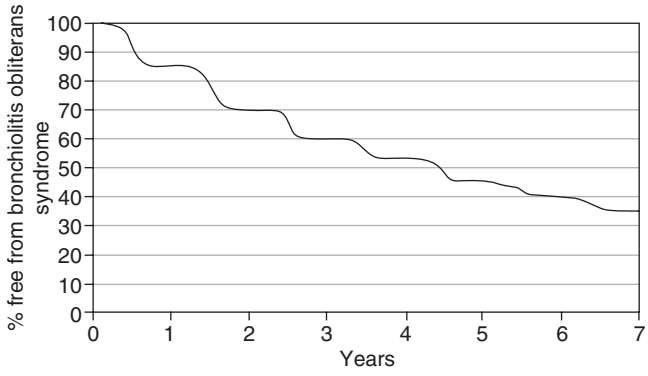

Figure 43.10 Freedom from bronchiolitis obliteran syndrome for pediatric lung recipients followed from April 1994 through June 2008. (Reproduced with permission from Aurora *et al.* [1].)

ATGAM or thymoglobulin or oral sirolimus. On occasion, alemtuzumab may be used. Because of the progressive nature of the disease, the average survival following onset of BOS is only 50% at 3 years [60]. For progressive BOS not responding to the above measures, retransplantation may be considered in select patients.

Only a minority of HLT recipients die as the result of cardiac disease or cardiac rejection [61]. Therefore, posttransplant surveillance and immunosuppression are based on the surveillance for pulmonary rejection.

Infection

Pediatric recipients are immunologically vulnerable to infections. Respiratory infections result in significant morbidity and mortality in lung and heart-lung transplant recipients in children. Infection has been reported for approximately 60–90% of recipients [62,63]. Infection is the leading cause of death among children who died between 1 month and 1 year posttransplant, accounting for almost 28% of deaths [1].

Bacterial infection is a serious infectious complication in lung and heart-lung transplant patients. Among all diagnosed infections, 35–66% are bacterial and 50–85% of patients present with at least one infectious episode [64]. Cystic fibrosis patients after lung or heart-lung transplant are particularly challenging. Their airway and sinuses are colonized with large numbers of virulent organisms, often multiresistant and pan-resistant Gram-negative organisms especially *Pseudomonas* species. As discussed previously, CF patients infected with *Burkholderia cenocepacia* have worse outcomes [65].

Cytomegalovirus has historically been the second most frequent cause of infectious complications following lung or heart-lung transplantation. Despite the use of various preventive strategies, the risk of developing CMV disease in lung transplant recipients is over 30% during the first year [66]. Donor or recipient CMV seropositivity is associated with increased risk of CMV episodes. One recent study suggests that extended prophylactic regimens may be more efficacious in reducing CMV-related events [67].

Fungal pathogens most often responsible for infections in lung or heart-lung transplant recipients are *Candida* species, *Aspergillus* species, and *Cryptococcus neoformans*, although other fungi may also cause infection in these patients. Overall, *Aspergillus* species are the most common cause of fungal infection in lung or heart-lung transplant population [68], and the associated mortality rate is high [68,69]. It has been estimated that 9.3% of deaths after lung transplantation result from fungal pathogens [70,71]. The threat of serious fungal infection after lung transplantation has led many institutions to utilize some form of prophylactic or preemptive antifungal management. A variety of prophylactic protocols have been used for the prevention of aspergillosis under these circumstances. Most commonly oral itraconazole has been used. Recently, aerosolized amphotericin B, followed by an indefinite maintenance period on oral itraconazole [72] has been used with some success. We prefer oral voriconazole because of its extended antifungal spectrum and better bioavailability compared with itraconazole. We use therapeutic drug monitoring to titrate the dose of voriconazole.

Posttransplant Lymphoproliferative Disorders

The incidence of posttransplant lymphoproliferative disease (PTLD) are higher in children than in adults [73], and there are additional data suggesting that primary Epstein-Barr virus infection after transplantation is a related risk factor [74]. Posttransplant lymphoproliferative disease encompasses a wide spectrum of disease manifestations, ranging from a benign plasmacytic hyperplasia and infectious mononucleosis-like PTLD to an aggressive monoclonal lymphoma that leads to high morbidity and significant mortality. Most cases are Epstein-Barr virus–related B-cell tumors resulting from impaired immunity owing to immunosuppressive therapy. Approximately 15% of children will develop a lymphoproliferative malignancy by 5 years posttransplantation [1]. The most common treatment of PTLD has included decreasing immunosuppression and the use of rituximab often in combination with chemotherapy; radiation and antiviral agents are less commonly used [75–77]. A higher risk of graft rejection is associated with PTLD [75–78].

Morbidity

Other long-term complications related to immunosuppressive agents such as hypertension, renal dysfunction,

Table 43.10 Morbidity at 1, 5, and 7 years of follow-up from April 1994 to June 2008. (Data from Aurora *et al.* [1].)

Outcome	% within 1 year	% within 5 years	% within 7 years
Hypertension	43	69	71
Renal dysfunction	11	22	35
Hyperlipidemia	5	11	5
Diabetes	27	33	34
Bronchiolitis obliterans	14	37	36

hyperlipidemia, and diabetes mellitus are common in survivors (Table 43.10) [1]. Hypertension is highly prevalent in lung transplantation and increases steadily with time posttransplant. With the introduction of calcineurin inhibitors as immunosuppressive drugs, acute allograft rejection episodes have been significantly reduced. However, cardiovascular complications have become an important cause of morbidity and mortality. Treating cardiovascular risk factors such as diabetes, dyslipidemia, and hypertension is important in the routine posttransplant management of lung transplant recipients.

Summary

Experience has shown definitively that lung transplantation can be successfully performed in infants, children, and adolescents. With improvements in selection and management, survival continues to improve. However, this survival is driven by an improvement in short-term (1 year) survival. Long-term survival for pediatric lung transplantation has not changed in over two decades. The basic indication for lung transplantation is end-stage lung disease not amenable to other forms of therapy, but the specific disease entities vary by age group. There is a strong preference for bilateral lung transplantation using CPB in pediatric patients. Donor organ availability and waiting list mortality remain serious issues. At present, the paucity of pediatric lung transplant centers severely limits the options for infants, children, and adolescents with end-stage lung and pulmonary vascular disease. Postoperative management requires attention to early graft function, acute and chronic rejection, and infection. Bronchiolitis obliterans continues to be a significant obstacle limiting long-term survival. Despite the recognized complications of transplantation, quality of life improves significantly posttransplant and the functional status of the great majority of long-term survivors is very good.

Definition

Infective endocarditis (IE) is the infection of the endothelial lining of the heart. In addition, the term is very commonly used to include infection of the patent ductus arteriosus and the proximal great arteries and veins, though histologically there is no endocardium present in these structures. The condition commonly involves the cardiac valves leading to valvar dysfunction. The process starts with damage to the endothelium. Fibrin and platelet deposition ensues along with bacterial growth of the deposits to form clumps of exudative and proliferative material termed "vegetations." Further deposition of fibrin and platelets allows vegetation growth, isolating the microorganisms from leukocytes and antibiotics in a zone of "agranulocytosis" [1]. Vegetations are responsible for the remote effects from micro and macro emboli. Diagnosis of IE focuses mainly on the epidemiologic risk, culture results, and imaging. Most cases are successfully treated with prolonged antimicrobial management; however, surgical intervention may be necessary for complex or unresponsive cases.

Epidemiology

Infective endocarditis is less common in children than adults, accounting for ~1 in 1300 to ~1 in 3000 pediatric hospital admissions [2–4]. However, the incidence of IE appears to be increasing [3,5,6]. Previously, complications of rheumatic heart disease accounted for a significant proportion of endocarditis episodes in children, but recent studies estimate the contribution of rheumatic heart disease to IE at <10% in the developed world [2,7]. The surgical advances in the treatment of congenital heart disease (CHD) increase the risk for IE for several reasons. First, surgical repair creates physiology within the heart that may predispose to endocarditis. Second, surgical techniques frequently require implantation of prosthetic materials including conduits, shunts, and patches [8]. The use of nonsurgical repair with intracardiac devices, including coils, also continues to rise and poses a potential risk. Finally, with improved survival, lifetime cumulative risk of IE increases despite the potential decrease in risk related to surgical intervention.

In 2007, the American Heart Association (AHA) revised guidelines for the prevention of IE [9] including the risk stratification based on underlying CHD. The new guidelines focus on providing prophylaxis based on the risk of adverse outcome with IE rather than lifetime risk of IE acquisition. Conditions considered to be high risk for adverse outcomes related to IE include unrepaired or palliated cyanotic CHD, repaired CHD with residual defects adjacent to prosthetic material, and completely repaired CHD with implanted device or prosthetic material for the first 6 months after repair. Heart transplant recipients with cardiac valvulopathy and patients with prosthetic valves are also categorized as high risk. Many common CHDs (e.g., patent ductus arteriosus, ventricular septal defect [VSD]) have increased risk of IE, yet prophylaxis is no longer recommended owing to the lack of efficacy data. Patients who are more than 6 months after their repair with no residual defects are considered to have the same risk as the general population.

The incidence of IE in patients without CHD has also increased. Immunosuppression secondary to malignancy and transplantation with or without the use of long-term indwelling catheters are risk factors for IE. The incidence of IE in neonates is also rising. Advances in the care of premature and other critically ill neonates, who have substantially improved neonatal survival, rely on the prolonged use of arterial and venous indwelling catheters,

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

which has been associated with an increased risk of IE even in the absence of CHD [10–12].

Pathophysiology

The primary event leading to the development of IE is damage to the epithelial lining of the heart followed by bacteremia with organisms capable of adhering to the damaged endothelial tissue. Several dynamics create the potential for endothelial damage. Turbulent blood flow from high- to low-pressure areas creates trauma to the endothelium. Injury may also be mediated by intracardiac catheters and intracardiac surgical or transcatheter repair. The damage to endothelial lining of the heart allows formation of nonbacterial thrombotic endocarditis (NBTE), which results from the deposition of fibrin and platelets on the damaged endothelium. Prosthetic materials including shunts, patches, valve, conduits, and intracardiac catheters provide additional sites for the deposition of fibrin and platelets. Once vegetations form, transiently circulating bacteria adhere to the fibrin-platelet aggregate to propagate the infection. Transient bacteremia occurs frequently with daily activities including brushing teeth or chewing food that cause local trauma to mucosal surfaces. Additional episodes of bacteremia can occur with dental or select surgical procedures [9]. The ability of the bacteria to adhere to the sterile vegetation influences the risk of IE after transient bacteremia. Gram-positive bacteria have specific factors that promote their ability to adhere to NBTE. Staphylococcal species have adhesin proteins and some viridans streptococci have FimA protein, which promotes adherence [13–15]. Once the bacteria attach to the platelet-fibrin aggregate they multiply. Although the adherence factors are immunogenic in animal studies [16], once the bacteria embed in the vegetation they become sequestered from the circulating host immune defenses avoiding clearance of the infection. Additional layers of platelet and fibrin deposit over the bacteria. Therefore, prolonged antibiotic therapy is recommended to penetrate the vegetation and kill the bacteria.

Microbiology

The span of organisms identified as causative agents in IE continues to grow, especially with the availability of molecular diagnostic techniques. However, Gram-positive cocci, with their identified adherence factors, remain the dominant causative organisms of IE in children [2,3,5]. Streptococci have previously been reported as the most common organisms in pediatric IE with viridans streptococci reported most frequently. However, in the most recent reports, *Staphylococcus aureus* has emerged as the most common overall cause of IE in children [2,8]. Although it is less common than *Staphylococcus aureus*, coagulase-negative *Staphylococcus* is also a significant contributor. Other organisms including Gram-negative bacteria, *Candida* species, and fungi are rare but may pose increased risk to children without underlying structural heart defects, including neonates and immunocompromised hosts.

Endocarditis related to prosthetic valves or other implanted foreign material requires special consideration. For children with CHD, more than 50% with IE have had previous corrective or palliative surgery. Both early and late postsurgical infections have been reported. Early infections, within a few months of surgery, may be related to surgical contamination or invasive postsurgical monitoring [1]. *Staphylococcus aureus* and coagulase-negative *Staphylococcus* are commonly recovered early after interventions [2]. In addition, less commonly reported organisms include *Klebsiella*, *Pseudomonas aeruginosa*, diphtheroids, and *Candida*. Reports of IE from anaerobic bacteria in pediatrics are rare [17]. The organisms recovered more than one year after surgical intervention reflect the organisms recovered before or without surgery. In a significant proportion of cases, an organism is not identified despite aggressive evaluation. Culture-negative endocarditis occurs in 5–20% of cases of IE [5,7,18].

Diagnosis

Combined information from clinical, laboratory, and imaging areas assist in the diagnosis of IE.

Clinical Manifestations

The clinical manifestations of IE are variable but include systemic symptoms relating to persistent bacteremia. The presentation for persistent bacteremia ranges from simple fever with malaise to fulminant sepsis with multiorgan system failure. Fever is the most common symptom in patients outside of the neonatal age. Fever and other symptoms may be subtle, delaying the diagnosis [4,7]. In the absence of fever, IE should be considered in patients with signs and symptoms of a systemic illness especially for neonates who may not mount an appropriate fever response. Additional nonspecific systemic symptoms include malaise, anorexia, weight loss, and arthralgia.

Cardiac manifestations of IE also vary and are dependent on the site of infection within the heart. Valvar lesions may lead to regurgitation or the perforation of the valve leaflet. Subvalvar lesions can cause rupture of the cordae tendineae or papillary muscles with subsequent severe valvar dysfunction. Lesions near the valve annulus may invade the myocardium resulting in cardiac conduction disturbances. Additionally, annular abscess and valve rupture occur with infection at the annulus. Large vegetations may produce mechanical obstruction mimicking

valvar stenosis. Clinical manifestations of cardiac dysfunction include congestive heart failure (CHF), tachycardia, and arrhythmia. Functional changes in murmur quality occur in the patient with underlying CHD. Fever without a source in the presence of underlying valvar disease or CHD should prompt investigation for IE.

Embolic phenomena depend greatly on the site of infection as well. Areas of embolization primarily include the lung and brain. However, embolization to kidney, spleen, liver, skin, and coronary arteries has been reported [4,7,19]. Pulmonary embolization principally occurs with right-sided vegetations that enter the pulmonary circulation resulting in infarction and lung abscess. Early in its presentation, IE may masquerade as pneumonia after unrealized pulmonary embolization.

Neurologic manifestations complicate a significant number of cases. Involvement likely results from embolic events and can include isolated papilledema, altered sensorium, paresis, seizures, cranial nerve palsies, stroke, and coma [7,20]. Mycotic aneurysms may develop after septic embolization from a vegetation leading to rupture and death in rare cases. Infections with *Staphylococcus aureus* are associated with increased risk of neurologic complications with IE [21].

Renal manifestations, including glomerulonephritis, are also fairly common with IE. The etiology for renal involvement is multifactorial, including the deposition of immune complexes within the kidney, hypoperfusion secondary to CHF and sepsis, or deposition of septic emboli. Clinical evaluation for gross and microscopic hematuria should be considered.

Skin manifestations can be either from emboli or deposition of immune complexes and are relatively rare in children. Janeway lesions, which present as flat painless lesions on the palms and soles, result from hemorrhage around microabscesses from septic emboli. Alternatively, Osler nodes, which present as painful, red lesions, develop after immune-mediated infiltration around the dermal vessels. Roth spots found on the retina and subungual splinter hemorrhages on the digits may also occur.

Laboratory Investigations

Diagnosis of IE relies primarily on recovery of a pathogen with a positive blood culture. A positive blood culture with a causative pathogen, in the absence of a pathologic diagnosis from positive histology or culture from vegetation, is one of the major conditions in the modified Duke criteria for IE diagnosis. Increased numbers and volumes of blood culture improve the yield of organisms in the diagnosis of IE. Generally, three or more individual cultures are sent in a 24-hour period aiming to meet the Duke criteria for IE. Blood volumes for pediatric patients may not meet volumes recommended for adults (10–20 mL of blood per culture) owing to restrictions in specimen collection, but volumes of at least 3 mL per sample are generally acceptable in small children, although smaller volumes may be collected in neonates. To avoid confusion with skin flora contamination, sterile preparation at the time of sample collection is essential. Administration of antibiotics before specimen collection decreases the yield of positive blood cultures by up to 40% [22]. Several additional techniques to improve pathogen recovery exist. Antimicrobial absorbent resins improve bacterial recovery in patients exposed to antibiotics before cultures are obtained [23]. Prolonged incubation of blood cultures for up to 2 weeks is also recommended to evaluate for fastidious organisms. These organisms include the HACEK organisms (*Haemophilus*, *Actinobacillus*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*) and nutritionally deficient *Streptococcus*. Emerging molecular technologies have the potential to further improve organism identification, potentially limiting the diagnosis of culture-negative endocarditis, both in patients who received antibiotics before cultures were obtained and also in patients with endocarditis attributed to organisms that are extremely difficult to grow in conventional culture. These techniques have improved recovery of organisms in adult and pediatric patients but require further standardization and are not considered a major criterion in the Duke classification [24–26]. Availability of molecular diagnostics and other techniques to improve recovery of pathogens should be discussed with specialists in infectious diseases and microbiologists in complicated cases.

Additional laboratory findings support the diagnosis of IE and may include elevated erythrocyte sedimentation rate and C-reactive protein and positive rheumatoid factor. Decreased serum complement and hematuria from glomerulonephritis are immunologic phenomena that may be present; glomerulonephritis is one of the minor criteria for IE. Leukocytosis may be present; however, severe sepsis from IE may present with leukopenia. Additionally, anemia from chronic illness can be masked by relative polycythemia secondary to cyanotic CHD.

Imaging Studies

Imaging is the mainstay of defining intracardiac disease in IE, and it is key in guiding therapy and prognosis. Findings of vegetations, intracardiac abscess, new partial dehiscence of a prosthetic valve, or new valvar regurgitation are included as major criteria for the diagnosis of IE [27]. Furthermore, progression of disease and valvar dysfunction can also be followed echocardiographically. Transthoracic echocardiography (TTE) has a poor sensitivity but is usually the first test performed [28]. Transesophageal echocardiography (TEE) typically provides more detailed information [29,30], especially when small vegetations and intramyocardial abscesses are suspected. Reynolds *et al.*

[30] found the sensitivity of TTE in detecting vegetations to be only 55% when compared with TEE. Li *et al.* [27] found TEE to be positive in 19% of cases where the TTE was negative. Limitations of echocardiographic imaging include the difficulty in distinguishing old healed vegetations from active infection. Also, it is difficult to differentiate small vegetations from uninfected clots related to suture material and pledgets. Interference from prosthetic materials such as valves and patches makes it difficult to look for vegetations around these structures with echocardiography. Repeat studies are very helpful to evaluate progression of disease.

Other imaging modalities may be used to assess IE. Magnetic resonance imaging (MRI) can occasionally be helpful in assessing ventricular and valvar function. Its value along with contrast-enhanced computed tomography (CT) scanning is more for detection of remote emboli and distinguishing between infarction, hemorrhage, and abscess. Interestingly, a recent study showed that CT scan was more accurate than TEE in detecting perivalvar extent of endocarditis, but all cases of leaflet perforations were missed [31]. Fluoroscopy may play a role in detecting valvar dysfunction in prosthetic valves by demonstrating impaired disc excursion. Angiography is rarely needed except in detection of aneurysms in the affected area, especially intracranial mycotic aneurysms. Coronary angiography is occasionally performed in children with unexplained ventricular dysfunction.

Antimicrobial Therapy

Treatment of IE depends on prolonged antimicrobial therapy with or without surgical intervention. The prolonged duration of antibiotics recommended is a function of the relatively slow metabolism of the organisms in the vegetation as well as the structure of the vegetation with the pathogenic organisms deeply embedded in the fibrin-platelet aggregate. Duration of antimicrobial therapy depends on the organism recovered, and counting should begin from the date of the first negative culture. Antibiotics should ideally be tailored to the organism, but empiric therapy after multiple cultures are obtained can be directed at the most likely causative organisms pending results, especially in the case of a critically ill patient. Generally, treatment recommendations for duration range from 4–6 weeks or longer depending on the clinical scenario, with longer durations for patients with implanted prosthetic materials. Empiric therapy for presumed viridans *Streptococcus* relies on penicillin G or ceftriaxone, while penicillinase-resistant penicillin (nafcillin, oxacillin) should be used for possible staphylococcal endocarditis. For penicillin-allergic patients and in areas with a high prevalence of methicillin-resistance *S. aureus*, vancomycin is recommended. The use of an aminoglycoside for synergy is considered optional in most recent recommendations from the AHA, secondary to reports of renal toxicity without increased benefit with aminoglycoside use, although some experts recommend its use in fulminant cases [32–34]. Aminoglycosides are recommended for 2 weeks along with rifampin for the duration of therapy in addition to the primary antimicrobial in patients with staphylococcal infections who have prosthetic materials. Empiric therapy for culture-negative endocarditis depends on the clinical course and epidemiologic aspects including pretreatment with antimicrobial agents and the presence of and time since placement of prosthetic materials. Current recommendations include ampicillin-sulbactam plus an aminoglycoside for 6 weeks for native valve IE. For patients with prosthetic material, vancomycin is recommended with the addition of a broad-spectrum cephalosporin if IE occurs within 2 months of valve placement [32]. Early surgical intervention should be considered if the patient is unresponsive to empiric therapy.

Fungal endocarditis is primarily caused by *Candida* species, with *Aspergillus* species occurring less frequently [35]. Morbidity and mortality related to fungal endocarditis is high. Early surgical intervention is suggested by many experts, and medical therapy with an amphotericin B-containing product is suggested for at least 6 weeks.

Indications for Surgery

Traditionally, surgery was reserved as a means of last resort. However, early surgery is recommended with increasing frequency [36,37]. The goal of surgery is removing the infected material, improving valvar function, repairing anatomic complications, and decreasing mortality [18,37,38]. Data and recommendations specific for children are not available separately, but AHA guidelines [39] recommend surgical intervention in native valve endocarditis in the presence of:

1. heart failure (especially related to valvar dysfunction);
2. worsening valvar function;
3. recurrent emboli;
4. evidence of intramyocardial infection (such as abscess formation, heart block, and intracardiac fistula formation);
5. infections from resistant organisms.

The decision to proceed to surgery is frequently subject to much discussion. In the absence of specific recommendations for children, it is important to take all factors into consideration, including the clinical status of the patient, chances of recovery from a neurologic event, the microorganism involved, prospects of valve repair or replacement, and the AHA guidelines [39]. Also, it is recommended that these factors be assessed as a continuum rather than only at a single point in the clinical course of a patient (Table 44.1).

Table 44.1 Indications for consideration of surgery in infective endocarditis. (IE, infective endocarditis.)

Congestive heart failure despite medical therapy
Deterioration of valve function (regurgitation from leaflet perforation or dehiscence, stenosis from vegetation)
Mechanical intracardiac complications (ventricular septal defect, fistula, pseudoaneurysm, mycotic aneurysm formation, etc.)
Evidence of myocardial infection (annular or myocardial abscess, heart block)
Recurrent embolization or single episode while on adequate therapy
Large vegetation or growth of vegetations while on adequate medical therapy
Failure of medical therapy (as evidence by persistent bacteremia, fever, growth of vegetations)
Endocarditis owing to resistant or difficult to treat organisms (fungal IE, Gram-negative bacilli)
Early prosthetic valve endocarditis
Late prosthetic valve endocarditis with prosthetic dysfunction

Congestive Heart Failure

This is perhaps the most important consideration in surgical therapy as it is the most common predictor of mortality [40]. Congestive heart failure in IE is frequently related to the added burden of sepsis on the underlying valvar lesion. For example, a patient with preexisting aortic stenosis without heart failure may decompensate into CHF because of associated fever, anemia, and sepsis. Under such circumstances, correction of these associated factors may improve CHF. Heart failure from acute valvar dysfunction, destructive intracardiac lesions, and uncorrected shunting lesions is more likely to need surgical intervention. Early surgery for endocarditis is associated with reduced mortality in patients with CHF when compared with medical treatment alone [37].

Valvar Dysfunction

Stable patients with valvar dysfunction and no other complications can frequently be treated with antibiotics alone until the acute infection has cleared. Subsequently, patients can be assessed for intervention if the usual surgical indications exist for valvar dysfunction. However, acute valvar dysfunction from leaflet perforation or valve stenosis owing to vegetations is frequently associated with CHF and is unlikely to improve with antibiotics alone. Renal and other organ dysfunction is commonly present. Surgery in this group of patients can frequently improve cardiac function by treating valvar dysfunction. In mitral valve endocarditis, early surgery makes repair more likely than valve replacement [39].

Mechanical Intracardiac Complications

Intracardiac complications of fistula and abscess formation are frequently associated with CHF and have a high mortality with medical treatment alone. Periannular or myocardial abscess may be a precursor of mechanical complication. New-onset atrioventricular (AV) block is indicative of myocardial infection. These are indications to proceed with surgery even without significant CHF [39]. The size of vegetations alone is difficult to interpret in small children. While, a 5-mm vegetation on the tricuspid valve in a teenager may not be significant, a similar-sized vegetation on the mitral valve of a newborn may be quite significant. Furthermore, a small embolus in a child may result in ischemia of a large territory. In adults with IE, vegetation >10 mm is felt to be a risk factor for remote emboli, especially stroke [41]. Similarly, patients with mobile vegetations or those that increase in size while on adequate therapy, are at risk of remote emboli. Such factors should be taken into consideration during decision making for surgery.

Remote Embolic Complications

Embolic stroke frequently leads to cerebral abscess formation or intracranial mycotic aneurysm formation. Occurrence of two or more episodes of major embolism during adequate medical treatment is commonly considered an indication for surgery. However, the presence of large vegetations with a single episode or new stroke, especially during adequate therapy, are reasonable indications for surgical intervention. Mortality of IE with a cerebral embolus is higher [37,41]. Some studies report *S aureus* and *Candida* endocarditis to be more commonly associated with embolic stroke [41–43]. At least half the strokes in adults are not apparent clinically and are discovered by MRI [42]. Because of the possibility of intracranial hemorrhage, the presence of a recent stroke is frequently of concern when using cardiopulmonary bypass. As a result, many surgeons prefer to wait for a few days, or up to 3 weeks if possible, before proceeding to surgery [44]. However, a low incidence of postoperative stroke has been reported in adults in the absence of hemorrhagic infarction [42,45].

Failure of Adequate Medical Therapy

Persistent fever or bacteremia, failure of the indices of infection to resolve, and progression of echocardiographic evidence of disease are considerations leading to a decision about failed medical therapy. Evidence of organisms that are frequently resistant to antibiotics or failure to clear with

antibiotics alone, such as methicillin-resistant *S. aureus*, fungal endocarditis, and Gram-negative endocarditis, especially with a prosthetic valve, fall into this category [39,43].

Culture-Negative Endocarditis

In cases of culture-negative endocarditis, a detailed examination of all parameters of the disease must be considered, as organisms resistant to commonly used therapy may be the causative agents. Progression of anatomic disease on echocardiography, such as large or growing vegetations, evidence of emboli, and persistent indices of inflammation all point to failure of medical therapy. Culture-negative endocarditis has a higher chance of complications and need for surgery [46].

Prosthetic Valve/Device Endocarditis

Intracardiac prosthetic materials are not well endothelialized within the first 2 months. Bacteremia early after surgery may be more likely to cause infection of the prosthesis, necessitating its removal. Furthermore, endocarditis on a recently placed prosthetic valve is more likely to lead to annular abscess. Hence, presence of even mild heart failure and early staphylococcal endocarditis of a prosthetic valve is sufficient to warrant surgery [39]. Indications for surgery in late prosthetic valve endocarditis are similar to the ones discussed previously.

Timing of Surgery

Timing of surgery in IE should not be based on duration of preoperative antibiotics alone, but rather on clinical status of the patient. In stable patients, without progressive valve destruction or other complications, a complete course of antibiotics followed by re-evaluation for possible need for surgical therapy is appropriate. Very unstable patients will frequently require a period of resuscitation in the intensive care unit (ICU) before surgery. However, in the presence of severe sepsis, or severe CHF, prolonged delay before surgery for controlling sepsis is unnecessary. Patients with cerebral infarction are not necessarily at a higher risk of postoperative stroke [36,45]. However, if possible, it is prudent to wait 2–3 weeks after the stroke before proceeding to cardiac surgery [45]. Hemorrhagic stroke presents with a more difficult situation. Cardiopulmonary bypass in face of a hemorrhagic stroke from a ruptured mycotic aneurysm is associated with a significant chance of extending the stroke. A multidisciplinary approach with involvement of the neurosurgery service is recommended. Though postoperative hemorrhage from a previously unruptured mycotic aneurysm has been reported [47], it is generally felt that cardiopulmonary bypass does not increase the immediate risk of rupture [48]. Furthermore, mycotic aneurysms related to IE may have a lower propensity to rupture as opposed to atherosclerotic aneurysms [49]. Ruptured mycotic aneurysm with subarachnoid hemorrhage presents a prohibitive risk to cardiopulmonary bypass. Many of these patients require craniotomy. Based on their experience, Gillinov *et al.* [44] recommended waiting 2–3 weeks after craniotomy before proceeding with open heart surgery.

Surgical Procedures

The procedure of choice for treatment of IE varies with the underlying pathology. The primary surgical principles include:

1. Complete debridement and removal of infected material. This includes vegetations, myocardial abscess, and infected prosthesis. The infected area is commonly irrigated with povidone-iodine solution, though the efficacy of this technique has not been studied.

2. Restoration of hemodynamic abnormality. Intracardiac defects are repaired and the underlying malformation can also be addressed. An exception may be made in case of infected Blalock-Taussig (BT) shunts. The underlying pathology may not be ready to be repaired. In such a situation, a new shunt, preferably in a new location, removal of the old shunt, and repair of the underlying vessels can be carried out. If a new site is not available or preferred, the old shunt needs to be completely debrided. Vegetations are commonly adherent to the suture lines. As a result the native blood vessels may need debridement and reconstruction and then a new shunt is reconstructed.

3. Repair using autologous tissues such as pericardium.

4. Use of biologic tissues. There is lack of evidence to show that biologic tissues have a lower incidence of reinfection [50]. However, we find that homograft material is easier to handle in the face of extensive debridement and possibly reduces the chance of postoperative hemorrhage [51].

Technique of Cardiopulmonary Bypass

Our preferred technique of cardiopulmonary bypass includes aortic and bicaval cannulation, systemic hypothermia, use of cold blood antegrade/retrograde cardioplegia, and modified ultrafiltration on completion of surgical repair. If cardiac perforation is suspected, carotid or femoral cannulation in small children and axillary or femoral cannulation in teenagers should be considered, as catastrophic fatal hemorrhage may ensue when opening the chest. Remote arterial cannulation can be aided by sewing in a tube graft in end-to-side fashion to the carotid, axillary, or femoral artery. This allows the use of larger cannula in a smaller artery with reduced risk of arterial damage. Furthermore, with this technique the distal vessel does not have to be clamped, thus avoiding distal ischemia. Bicaval cannulation allows inspection of all intracardiac structures, as the extent of pathology is frequently underestimated

during preoperative assessment. Smaller catheters for retrograde cardioplegia allow its use even in small babies. Patients with IE frequently have overt renal dysfunction; in these cases modified ultrafiltration is recommended.

Aortic Valve Endocarditis

Aortic valve endocarditis occurs with similar incidence as mitral valve endocarditis, though some series have reported it being more common [30,40]. Vegetations on the leaflets should be debrided and leaflets can frequently be preserved. Perforation of a leaflet can frequently be repaired using fresh or glutaraldehyde-treated autologous pericardium. Infection extending to the common annulus with the mitral valve can similarly be debrided and the aortic and mitral continuity reconstructed without valve replacement. However, infection into the myocardium or a frank annular abscess necessitates complete debridement of the aortic root and subsequent reconstruction. Though such reconstruction is facilitated with the use of an aortic homograft in teenagers and adults [52], this prosthesis has dismal durability in smaller children. We prefer the Ross procedure in younger children [53–55]. However, a mechanical valved conduit can also be used for aortic root replacement. There does not appear to be a difference in recurrence rates between biologic and mechanical prostheses [50]. As the durability of biologic prosthesis in small children is quite disappointing, we prefer to use a mechanical prosthesis if the Ross procedure is not feasible. In females, the use of mechanical prosthesis must be weighed against the issues of potential subsequent pregnancy. Root reconstruction may be facilitated by using fresh autologous pericardium to buttress or reconstruct the debrided areas. More complex techniques using coronary bypass grafts are rarely applicable to children.

Mitral Valve Endocarditis

Mitral valve endocarditis was previously felt to be more frequently associated with systemic emboli, though recent studies show equal incidence of emboli from aortic and mitral valve endocarditis [41]. Earlier surgery may allow a higher likelihood of repair and also, possibly decrease the risk of recurrent systemic emboli. A variety of repair techniques have been used [18,56]. Debridement of the vegetation may be all that is needed [18]. Defects in the mitral leaflets can be repaired using a pericardial patch or by performing a primary repair. Homograft material can be used as an alternative to pericardium. Chordal reattachment or chordal transfer can be performed for ruptured chords. Ring annuloplasty is typically not required and is certainly contraindicated in growing children, but localized annuloplasty can be performed, especially in the posterior annulus, if a portion of posterior mitral leaflet is excised. Presence of annular or ring abscess does not preclude repair if the leaflets and chordae are intact. In this situation, leaflets can be detached and annular abscess can be completely debrided. The annulus is then reconstructed using fresh autologous pericardium or a pulmonary homograft, and the leaflet can be reattached. If the mitral valve is not amenable to repair, then a mechanical valve is our prosthesis of choice in young children. This is because of diminished durability of biologic valves in this position in children [57]. Homograft mitral valves have been used. However, they are difficult to place, with unpredictable function. In a sick patient with endocarditis, an expedient operation with a competent valve is more likely to be successful.

Tricuspid Valve

Isolated tricuspid endocarditis is frequently associated with indwelling catheters. It is also more commonly involved in fungal infection especially in premature babies and newborn who require long-term venous catheters [35,43]. Mortality from surgery for fungal endocarditis is high. However, in the presence of usual indications, surgery should not be delayed. Surgical treatment should include removal of the associated catheter and atrial mass if present. Vegetations on the tricuspid valve should be excised and tricuspid valve should be repaired in the usual fashion. Residual VSD or primary VSD should be repaired using preferably a pericardial patch, especially in cases of active endocarditis. Excision of the tricuspid valve is not well tolerated in young children and infants; however, it may be considered in a teenager. If the tricuspid valve is not amenable to repair, a bioprosthesis is our preference.

Pulmonary Valve

Native pulmonary valve endocarditis is rare in children. In almost all cases in children, insertion of a pulmonary valve can be avoided. The infection is debrided, even if this means removal of all leaflets [58]. In patients with poor cardiac function, tricuspid regurgitation or high pulmonary vascular resistance, where a competent valve may be desired, insertion of pulmonary homograft or bioprosthesis is safe.

Ventricular Septal Defect

Many infections associated with VSD can be treated with antibiotics, and surgery can be performed at a time when infection is cleared. This is also true for infections occurring in residual VSDs late (>2 months) after surgery. Early postoperative infections in the presence of the usual surgical indications are approached with the goal of removing the VSD patch and all associated pledgets. The VSD is subsequently repaired with glutaraldehyde-treated or fresh pericardium. Aortic homograft material is another option

to use for VSD closure. It is important to avoid even small residual VSDs in this situation.

Patent Ductus Arteriosus

Infections associated with patent ductus arteriosus (PDA) are rare. The vegetation is typically on the pulmonary artery opposite the opening of the PDA, though involvement of the aortic valve has been reported [58,59]. Urgent surgery is rarely needed. At the time of surgery, debridement of the vegetation should be strongly considered unless it can be demonstrated that it is sterile and not mechanically obstructive. In the absence of active infection, the PDA can simply be closed in the usual fashion without the use of cardiopulmonary bypass.

Systemic-to-Pulmonary Artery Shunts

Infections in the BT shunts are rare. In some cases the infection can be cleared with antibiotics alone. It is difficult to clear documented infections of BT shunts with vegetations or pseudoaneurysm with medical treatment alone. Infection of the shunt can result in increased cyanosis by decreasing pulmonary blood flow. Surgery typically involves complete removal of the shunt and either repair of the underlying cardiac defect or insertion of a new shunt from a different source vessel to a new site on the pulmonary artery. As there is insertion of new prosthetic material there is the potential for reinfection. Thus, it is important to have adequate serum levels of appropriate antimicrobials. If a new source blood vessel is not possible, complete removal of the old shunt with removal of any visible disease followed by insertion of a new shunt may be acceptable.

Infections in Prosthetic Valves

Early (<2 months) infection in a prosthetic valve is commonly treated surgically with removal of the prosthesis and replacement with a new prosthetic valve [51]. Diagnosing prosthetic valve endocarditis may be quite challenging. Presence of alternative sources of bacteremia (e.g., central venous catheters), difficulty of echocardiogram to confirm vegetations owing to presence of pledgets, and shadowing from the mechanical valve, possibility of thrombi at intracardiac suture lines causing remote emboli, are some of the challenges that are frequently encountered. Serial echocardiograms and TEE may help resolve some controversial issues. In the absence of the usual indications for surgery, especially if no vegetations are confirmed and if there is no prosthetic valvar dysfunction, it is acceptable to treat with a course of antibiotics. Rapid clearance of bacteremia, stable heart function, and good prosthetic valve function, indicate successful treatment and possibly error in the initial diagnosis. Otherwise, reoperation with removal and debridement of the prosthetic valve is warranted. It is important to remove the old sewing ring and pledgets used at the original surgery. The valve is replaced with a new prosthesis. Surprisingly the incidence of recurrent infection is low. Indications for surgery in late prosthetic valve infection are similar to those for native valve endocarditis, but the surgical technique remains the same.

Results

Infective Endocarditis in Children

Very few series of surgical treatment of endocarditis are reported in children in the recent era. Surgical mortality has been reported from 8–25%. Mavroudis *et al.* [18] reported a series of 16 patients with endocarditis undergoing surgery. Surgical mortality was 25%. In half of the patients, excision of vegetations was the only procedure needed. More recently, Niwa *et al.* from Japan [60] reported 119 patients with CHD who were diagnosed with endocarditis; 43.1% of the patients underwent surgery. Total mortality in the series was 8.8%. Mortality was 11.1% in patients who underwent surgery in the acute phase, but there were no deaths in the group who could undergo surgery after the infection was cleared with antibiotics. The mortality in patients undergoing medical treatment alone was 8%. Another pediatric series from the United Kingdom by Alexiou *et al.* [61] reported a 6.25% surgical mortality, and only one patient had late recurrence of endocarditis. Interestingly, 68% of patients underwent valve replacement, and the median time to surgery was 21 days.

Early Surgery

A number of studies demonstrate the advantage of early surgical treatment within the first month of starting antibiotics [36,37]. Chu *et al.* [62] reported a mortality of 14% in patients undergoing surgery versus 20% in patients undergoing medical treatment alone. Tleyjeh *et al.* [63] performed a systematic review of observational studies, which included propensity score analysis. They found surgical advantage on mortality from two observational studies only. Other studies yielded inconclusive results. Interestingly, despite having advanced disease in patients undergoing surgery, none of the studies showed a survival disadvantage of surgery. Thuny *et al.* [36] reported on 291 patients undergoing surgery within 1 week of starting antibiotics. Surgical mortality was 15%. Interestingly only one of the 10 patients with a preoperative stroke had worsening of the neurologic status, whereas two patients had a new postoperative stroke, and 12% of the patients had recurrence of endocarditis within 1 year of surgery. Prosthetic valve endocarditis was a risk factor for mortality. A number of studies in adults show a survival benefit [36,37].

Table 44.2 Risk factors for mortality.

Authors	Year	Adults vs. children	Risk factors for mortality
Mavroudis *et al.* [18]	1992	Children	Age <2 years
Chen *et al.* [64]	1994	Children	Age <2 Native valve endocarditis
Hill *et al.* [41]	2008	Adults	Vegetation >10 mm *Staphylococcus aureus* Multiple emboli
Nadji *et al.* [37]	2008	Adults	Heart failure *Staphylococcus aureus* Major neurologic event Prosthetic valve endocarditis
Thuny *et al.* [36]	2008	Adults	Periannular extension
Chu *et al.* [62]	2008	Adults	*Staphylococcus aureus* Embolic event APACHE II score

However, there is lack of randomized data. In a review by Tleyjeh *et al.* [63], two studies showed benefit of surgical therapy and two revealed conflicting results.

Risk Factors for Death

A number of risk factors have been related to mortality and morbidity (Table 44.2) [18,36,37,41,62,64]. Both Rhodes and Mavroudis found age <2 years to be a risk factor for death after surgery in children [18,65]. Fungal endocarditis [35,66] and culture-negative endocarditis [46] have been implicated in higher mortality in children. A large series from adult patients with endocarditis report *S. aureus* endocarditis, large vegetation size (>10 mm), and multiple emboli to be associated with death [41]. Similarly, prosthetic valve endocarditis, uncontrolled sepsis, CHF, and periannular extension of infection have all been associated with mortality [36,37].

Summary

Infectious endocarditis is rare in children. The risk is increased in those with untreated CHD or those with residual lesions post repair. Cyanotic children are particularly at risk. Routine antibiotic prophylaxis is no longer recommended by new AHA guidelines except in high-risk cases. Gram-positive organisms are the most common cause of infection, but fungal infections occur with increasing incidence, especially in premature babies and immunocompromised children. A prolonged course of antibiotic treatment is needed. We advocate early consideration of surgery in patients with appropriate indications to avoid valve replacement and reduce mortality and morbidity.

CHAPTER 45

Pediatric Mechanical Circulatory Support

Brian W. Duncan[1,2]

[1]BioEnterprise, Cleveland, OH, USA
[2]Arboretum Ventures, Cleveland, OH, USA

Introduction

Mechanical circulatory support has become standard therapy for adults with medically refractory heart failure. Several device options are available for adults for most clinically relevant indications including bridge to transplantation, bridge to myocardial recovery, or destination therapy. Historically, these same options have been unavailable for children. The main cause for limited device availability for pediatric circulatory support is clear—the small number of affected children makes it difficult for manufacturers to justify the expense and other resources required for the limited pediatric market. In addition, anatomic limitations imposed by patient size and physiologic limitations imposed by the nature of pediatric cardiovascular disease make many devices used for adult circulatory support unsuitable for children. During the past several decades, extracorporeal membrane oxygenation (ECMO) has been the therapeutic mainstay for pediatric mechanical circulatory support; at many centers in the United States, it remains the only available option. However, ECMO is suitable only for short-term support, significantly limiting its effectiveness as a bridge to transplantation or recovery for children. These limitations are particularly significant for the youngest patients; infants with unrecoverable cardiac failure who require mechanical circulatory support often die if a donor heart does not become available within a few weeks. Lack of availability of ventricular assist devices (VADs) and other circulatory support technologies designed to meet the specific requirements of children remains a major therapeutic gap in the management of pediatric heart failure [1–24].

Over the last few years, significant advances have been made suggesting that the outlook for the field of pediatric mechanical circulatory support is brighter. These advances, over a variety of subdisciplines, include educational activities (medical conferences with dedicated content), increased pediatric experience with a number of new devices, and research funding for the development of innovative circulatory support systems aimed specifically at the pediatric population (Table 45.1) [25]. This broad range of activities is important in that the therapeutic approach has been substantially broadened to address current clinical needs, and development and educational activities ensure that a pipeline of innovative technologies will continue to have a positive effect in the future.

As the experience with pediatric circulatory support has increased, the greater number of devices available for children has required increased understanding of which device is most suitable in a given clinical setting. Currently available devices for which there is significant clinical experience include ECMO, the Bio-Pump (Medtronic Corp., Minneapolis, Minnesota), a number of adult devices that have been successfully used in children, the DeBakey VAD *Child* (MicroMed Cardiovascular, Inc., Houston, Texas), and the Berlin Heart VAD (Berlin Heart Inc, The Woodlands, Texas) (Figure 45.1) [7,26]. Based on the clinical circumstances, each device possesses certain advantages and limitations; therefore, thorough understanding of the unique characteristics of each device is critical to appropriate device selection for a given clinical case.

Available Devices for Pediatric Mechanical Circulatory Support

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation remains the most commonly used form of pediatric mechanical circulatory support in the United States; well over 3500 cases of pediatric cardiac ECMO have been recorded in the registry of the Extracorporeal Life Support Organization [1,3,6,23,27–37]. Extracorporeal membrane oxygenation is flexible in its ability to provide support for even the smallest patients and

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.
© 2013 Blackwell Publishing Ltd. Published 2013 by Blackwell Publishing Ltd.

its ability to be instituted via peripheral cannulation. This flexibility and the extensive experience in pediatric hospitals using ECMO in the management of newborn respiratory failure has led to its widespread use in the treatment of children with heart failure. In fact, until recently, ECMO was the only available form of mechanical circulatory support capable of treating newborns and infants at many pediatric hospitals in the United States. Because of the presence of an oxygenator, ECMO remains the only option for support when significant hypoxemia and respiratory failure contribute to the underlying pathophysiology. Ease of cannulation via sternotomy or via peripheral sites makes it particularly useful as an acute resuscitative tool [38–40].

However, ECMO also has a number of limitations; its use is restricted to short-term applications making it a poor choice for long-term bridge to transplantation. Perhaps most important is that its large size as usually configured and its extracorporeal design limit attempts at ambulation and effective physical rehabilitation during support. In addition, the presence of an oxygenator and long tubing lengths that are usually employed damage blood elements and activate the inflammatory cascade. Historically, survival to discharge for pediatric cardiac patients supported with ECMO has been in the range of 40–50% [35]. If successfully supported in the short term, long-term survival of pediatric cardiac patients who require ECMO has been reported to exceed 90% after discharge; however, some degree of neurologic impairment in most patients has also been reported [13].

Extracorporeal membrane oxygenation retains an important role in pediatric mechanical circulatory support and has saved thousands of lives of pediatric cardiac patients who otherwise would have died without the availability of this modality; however, the shortcomings cited above are significant and have been well documented (Table 45.2) [26]. In the current era, ECMO continues to play a particularly important role when respiratory failure is present, in addition to cardiac failure and for the rescue of children who suffer cardiorespiratory arrest. As an extension of its role as a resuscitation tool, it is anticipated that ECMO will increasingly be used as a bridge to bridge, similar to its use in adult patients where it has been very useful in providing a period of support after acute resuscitation during which time decision making and evaluation can occur [41]. If cardiac dysfunction is quickly reversible, these patients can be weaned, and patients without prompt cardiac recovery can be transitioned to a device capable of providing long-term support if other end-organ function appears to be recoverable.

LVAD, RVAD, BVAD	Bleeding
	Thromboembolic
	Extracorporeal
	No ambulation/rehabilitation potential during support

The Bio-Pump

Historically, centrifugal pump-based systems have been the most commonly used form of VAD support for children. The Bio-Pump (Medtronic Bio-Medicus, Minneapolis, Minnesota) employs a constrained vortex design that provides nonpulsatile flow, which is both preload and afterload sensitive. The VAD circuit based on this pump employs short tubing lengths to connect the pump to the venous and aortic cannulas, which results in smaller priming volumes compared with ECMO and makes the system easy to maintain (Table 45.3) [8,14,26,40,42–47]. Similar to ECMO, the Bio-Pump can be used to support patients of all ages and can be used as a right, left, or biventricular assist device (RVAD, LVAD, or BVAD). Despite its simplicity and proven track record, the Bio-Pump is limited to short term support, usually ranging from days to at most a few weeks. As is the case for ECMO, the relatively large size and extracorporeal configuration of the Bio-Pump limits ambulation and rehabilitation potential during support (Table 45.3) [26]. With the availability of newer VADs designed specifically for children, the role of the Bio-Pump for pediatric applications is likely to decline in the future.

Adult Systems Used for Pediatric Support

A number of devices designed for adults have been used successfully to support older children and adolescents with results that are at least as good as those reported for adults [48]. These devices include the Thoratec and Heartmate VADs (Thoratec Corp; Pleasanton, California), the BVS 5000 (ABIOMED, Inc; Danvers, Maine), and the NovaCor LVAS (WorldHeart Inc; Oakland, California). The Thoratec VAD has had the greatest use in children, with a worldwide experience that exceeds 200 pediatric implants [48–50]. As

Excellent performance	
LVAD, RVAD, BVAD	

in adults, these devices are capable of providing long-term circulatory support in children, making them suitable for use as a bridge to transplantation. In addition, the Thoratec VAD and similar paracorporeal systems allow children to ambulate and facilitate rehabilitation during support with the same salutary effects as seen in the adult population. The chief limitation for these systems is their large size, which restricts their use to large children and adolescent patients (Table 45.4) [26]. The relatively large stroke volumes of these pulsatile systems require their operation at nonphysiologic, low pump rates for all but the largest children, limiting pump wash-out, which leads to increased thromboembolic risk [42,51].

Recently, Blume and colleagues summarized a 10-year, multicenter experience with VADs as a bridge to heart transplantation in children [48]. Most of the patients in this report were older than 10 years of age, which is reflective of VAD use patterns in North America during that period when the majority of the pediatric bridge to transplant

experience was limited to older children who could be supported with devices designed for adults. Seventy-seven percent of these patients were successfully bridged to transplantation, with 86% successfully bridged in the most recent cohort. Hill and Reinhartz reported the worldwide pediatric experience from the Thoratec registry in 2006 that included 209 pediatric patients with a mean age of 14.5 years (range, 5–18 years) and a mean body surface area (BSA) of 1.6 m^2 (range, 0.73–2.3 m^2) [50]. Fifty-three percent of these patients were supported with BVAD, and 42% were supported with LVAD. The mean support period was 44 days, with the longest duration of support greater than 430 days. More than 68% of the patients survived to heart transplantation or native heart recovery.

The MicroMed DeBakey VAD Child

In the spring of 2004, the DeBakey VAD Child (MicroMed Cardiovascular, Inc; Houston, Texas) was granted Humanitarian Device Exemption (HDE) status by the FDA for use in children [52]. The pediatric version employs the same axial-flow pump used in the adult system, with design modifications aimed at reducing the lateral space requirements to make implantation easier in small children. These modifications include a shortened, more acutely angled inflow cannula, a shortened plastic outflow graft protector, and reduced size of the flow probe on the outflow graft (Plate 45.1, see plate section opposite p. 594). Under the current HDE, the VAD Child is limited to use as a bridge to cardiac transplantation for children from 5–16 years of age with a BSA greater than 0.7 m^2 and less than 1.5 m^2 and is designed to be fully implantable in this size range, which allows ambulation and rehabilitation during support (Table 45.5) [26]. Fraser and colleagues summarized a six-patient experience with the VAD Child with an average age of 11.3 years (range, 6–15 years) and a BSA of 0.8–1.7 m^2 [53]. The average duration of support was 39 days, with 84 days being the longest duration of support. Three of these patients were successfully transplanted, and three died during support, before transplantation.

Table 45.5 DeBakey VAD *Child* characteristics. (LVAD, left ventricular assist device.) (Reproduced with permission from Duncan [26].)

Advantages	Disadvantages
Implantable	Limited age range (5–16 years)
Allows ambulation/rehabilitation during support	Implantation difficult in smallest patients
Long-term support	LVAD only
	Limited indications

The DeBakey VAD Child was the first VAD designed specifically for children available in the United States, and its development represented a true breakthrough in the field of pediatric mechanical circulatory support. However, the restricted patient size range for which the device is suitable has contributed to its relatively limited pediatric experience to date [53].

The Berlin Heart VAD

The Berlin Heart VAD (Berlin Heart Inc, The Woodlands, Texas) is a pulsatile, paracorporeal VAD that is suitable for the entire size range of pediatric patients, including neonates [2,12,17,18,21,49,54–63]. The Berlin Heart VAD employs pneumatically driven, thin membrane pumps to provide pulsatile flow and is available in a variety of pump sizes (10–80 mL), with the smallest pump sizes suitable for infant support (Plate 45.2, see plate section opposite p. 594). The Berlin Heart VAD has been an important tool in the management of heart failure in children for more than a decade in European centers, and a number of reports exist detailing these results [57,64,65]. Of particular benefit, this pulsatile paracorporeal system allows extubation and ambulation, providing an opportunity for rehabilitation during support. Improvement in a patient's physiologic status during support is commonly seen in adults but has only recently been attainable for small children; the Berlin Heart is almost singularly responsible for this revolutionary improvement in pediatric patient management. The Berlin Heart VAD is superior to ECMO in providing moderate- to long-term support, while preserving the options of bridging to transplantation or recovery (Table 45.6) [26,66].

The chief impediment to more widespread use of the Berlin Heart VAD in the United States was its limited availability, which until recently was limited to emergency compassionate use. In 2007, the Berlin Heart was approved for a US multicenter trial in pediatric patients. Early US experience with the Berlin Heart includes a report by Rockett and

colleagues, with a survival rate during support to transplant or recovery in excess of 80% [62]. Malaisrie and colleagues reported a small experience, with more than 60% successful bridge to transplantation [59]. Both of these studies reported a significant number of neurologic complications because of thromboembolic phenomena during support. A previous report has suggested that the Berlin Heart VAD may have fewer bleeding complications compared with ECMO, with decreased blood product use during support [64]. One recent report notes improving results for infants in the latest cohort of patients, with survival rates now approaching those achieved in adults [65].

Other Devices

There is increasing but still limited pediatric experience with a number of other devices. The MEDOS HIA-VAD (MEDOS Medizintechnik AG; Stollberg, Germany) is a pulsatile, paracorporeal system that is available in a variety of pump sizes capable of providing support for pediatric patients of all sizes from newborns to adolescents [49,67–72]. The Levitronix CentriMag LVAS (Levitronix LLC; Waltham, Maine) employs a magnetically suspended rotor without bearings and has been used in children; and a version intended specifically for pediatrics, the PediVAS, is in development [67,73]. In addition, TandemHeart (CardiacAssist, Inc; Pittsburgh, Pennsylvania) and the VentrAssist LVAD (VentraCor Ltd; Sydney, Australia) have had limited pediatric use [74,75].

Despite their widespread use in the management of heart failure and ischemic heart disease in adults, there has been relatively limited clinical experience with intra-aortic balloon pumps (IABP) in children [76–79]. The general view in pediatrics has been that effective circulatory support with IABP is limited because of greater elasticity of the aorta and the inability of the device to track high heart rates seen in pediatric practice. Complications from insertion in significantly smaller femoral vessels have been a particular limitation to more widespread adoption. Despite these limitations, a number of centers have developed reasonably large experiences with pediatric IABP, and technologic developments aimed at addressing specific needs in children may lead to greater use in the future.

Decision Matrix to Guide Device Selection for Pediatric Circulatory Support

The increased number of available devices for mechanical circulatory support may lead to uncertainty in pediatric practice regarding which device is most suitable for a given case of medically refractory heart failure. As described above, each of the available devices has unique characteristics that affect their use; on the other side of the equation are the unique needs presented by the specific clinical situation. A decision support tool has been developed that provides a graphical representation of the key clinical components, namely patient size and the intended duration of support on a 2×2 matrix to guide selection from among the available devices currently available for pediatric use [26].

Graphical Depiction of the Clinical Setting on the Decision Matrix

Patient size is obviously an important issue in device selection; in pediatrics, the need for devices that are suitable over a wide range of patient sizes from newborns to adolescents is the single greatest difference compared with the practice of mechanical circulatory support in adults. The anticipated duration of support is also a critical determinant of the overall clinical setting. Perioperative cardiac arrest after congenital heart surgery may be rescued with rapid resuscitation devices and may require only brief periods of support for conditions that are quickly reversible (electrolyte imbalance, transient pulmonary hypertension) [38–40]. At the other end of the spectrum, medically refractory heart failure occurring in end-stage dilated cardiomyopathy may require months of support waiting for a suitable donor organ as a bridge to cardiac transplantation.

Figure 45.2 depicts a 2×2 graph that defines the clinical setting in which heart failure occurs in terms of patient size and anticipated duration of support [26]. On this graph, patient age is a surrogate for patient size and is plotted on the vertical axis while the anticipated duration of support is plotted on the horizontal axis. The clinical setting may

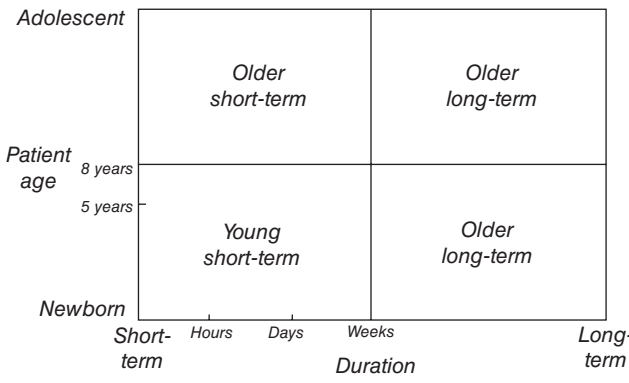

Figure 45.2 Graphical representation of the clinical setting in which pediatric heart failure occurs, determined by patient age (vertical axis) and the anticipated duration of support (horizontal axis). The four clinically relevant clinical settings are depicted as belonging to one of four quadrants: (1) young patients requiring short-term support, (2) young patients requiring long-term support, (3) older children/adolescents requiring short-term support and (4) older children/adolescents requiring long-term support. (Reproduced with permission from Duncan [26].)

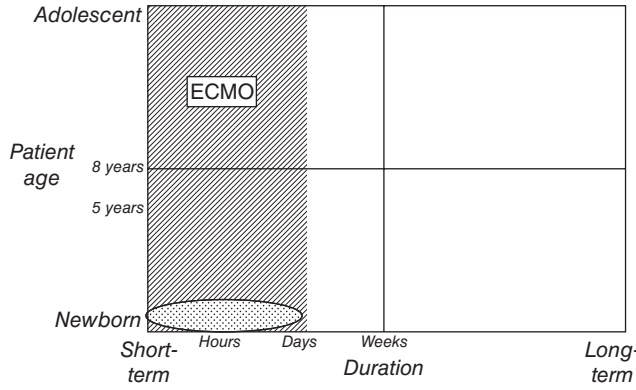

Figure 45.3 Graphical representation of postoperative cardiorespiratory failure in an infant. This patient may recover after relatively short periods of support demonstrated by the stippled oval in the young patient/short term support quadrant. Extracorporeal membrane oxygenation (EMCO) works well in this setting being capable of providing support for newborns and being limited to short term support only (cross-hatched area). In addition, it is the only device capable of providing respiratory support. (Reproduced with permission from Duncan [26].)

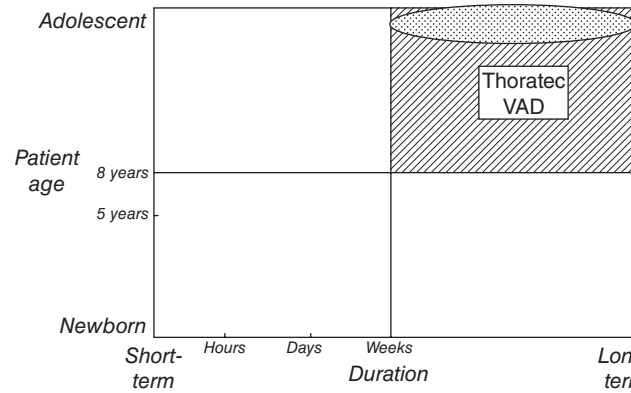

Figure 45.4 Graphical representation of advanced heart failure in an adolescent with cardiomyopathy. This patient will most likely require extended support as a bridge to transplantation (stippled oval in the older patient/long-term support quadrant). Devices primarily designed for adults such as the Thoratec ventricular assist device (VAD) have demonstrated good results for this indication (cross-hatched area). (Reproduced with permission from Duncan [26].)

then be considered to belong to one of four quadrants: (1) young patients requiring short-term support, (2) young patients requiring long-term support, (3) older children and adolescents requiring short-term support, and (4) older children and adolescents requiring long term support.

All of the available devices can then be placed on this graph that defines the clinical setting based on suitability for patient size and intended duration of support. Colocation of the patient characteristics and the device on the matrix then identifies the appropriate device for that patient in the relevant clinical setting. Figure 45.3 demonstrates this matching process for a device and patient for a hypothetical case of postoperative cardiorespiratory failure in an infant [26]. Extracorporeal membrane oxygenation is suitable for patients of all sizes and therefore spans the entire vertical axis; however, ECMO is limited to short-term use, which accounts for spanning the horizontal axis from days to weeks. The graphical representation of an infant who suffers cardiorespiratory failure is appropriately placed on the vertical axis close to the origin. Regarding the anticipated duration of support, lung disease in this setting may not respond as promptly as other causes of pediatric cardiorespiratory failure [8]; therefore, the anticipated duration of support may range from days to weeks, as demonstrated by the span of the patient marker on the horizontal axis. The colocation of the device and the patient graphically demonstrates that ECMO is the best choice for support in this case. This example also demonstrates how underlying anatomy and physiology can override all other considerations; for patients suffering from respiratory and cardiac failure, ECMO is the only appropriate choice.

Figure 45.4 [26] provides another example: devices that are designed primarily for adults but which may be used in older children and adolescents, such as the Thoratec VAD, occupy the older child/long-term support quadrant on the graph. These patients would colocate with devices such as the Thoratec, Berlin Heart or Heartmate VADs, which would all be reasonable choices for support.

The National Heart, Lung, and Blood Institute Pediatric Circulatory Support Program

The National Heart, Lung and Blood Institute (NHLBI) Pediatric Circulatory Support Program is another recent landmark development in this field. This program was established to fund stage development of novel pediatric circulatory support devices. Included in the technical requirements of the original solicitation were the following objectives for applicant devices [80]:

1. capable of being instituted in less than 1 hour after the decision to initiate support;
2. minimal priming volumes;
3. cannulation strategies that accommodate potential variations in patient anatomy commonly encountered in pediatric practice;
4. minimized blood product exposure;
5. minimized risks of infection, bleeding, hemolysis, and thrombosis;

Table 45.7 Devices supported by the National Heart, Lung, and Blood Institute Pediatric Circulatory Support program. (pCAS, pediatric cardiopulmonary assist system; PVAD, pediatric ventricular assist device; VAD, ventricular assist device.)

Device	Institution	Characteristics
PediaFlow VAD	University of Pittsburgh	Implantable mixed-flow VAD
PediPump	Cleveland Clinic	Implantable mixed-flow VAD
pCAS	Ension, Inc.	Integrated cardiopulmonary assist system
Pediatric Jarvik 2000	Jarvik Heart, Inc.	Implantable axial-flow VAD
PVAD	Penn State University	Pulsatile VAD

6. capable of providing support for up to 6 months, depending on the intended application.

In the spring of 2004, five contracts were awarded by the NHLBI to support preclinical development of a range of pediatric VADs and similar circulatory support systems (Table 45.7). The pediatric circulatory support devices funded by the NHLBI Pediatric Circulatory Support Program are described below.

The PediaFlow Ventricular Assist Device

The PediaFlow ventricular assist device (VAD; Ension, Inc; Pittsburgh, Pennsylvania) is an implantable, magnetically suspended mixed-flow turbodynamic blood pump [81–83]. The PediaFlow VAD is intended to provide chronic (6 months) of circulatory support for neonates to toddlers (3–15 kg body weight) with congenital or acquired heart disease (Plate 45.3, see plate section opposite p. 594). Anticoagulation therapy while on the device is intended to be limited to antiplatelet medications. The device is designed to provide a flow rate range from 0.3–1.5 L/minute, with a device weight of 30 g, a maximum volume of 5 mL, and a maximum priming volume 0.5 mL to help achieve the goal of being fully implantable. The design includes the requirement for only a single percutaneous lead crossing the skin for energy transmission.

The PediPump

The PediPump VAD (Cleveland Clinic; Cleveland, Ohio) is a magnetic bearing-supported, rotary dynamic blood pump designed specifically for children [84–88]. Because its capabilities are packaged into a small size, the resulting basic pump design provides support for the entire range of patient sizes encountered in pediatrics. The pump rotating assembly consists of an impeller in the front, front and rear radial magnetic bearings, and a motor rotor magnet in its center. Blood enters axially at the inlet and is turned to exit the pump at an intermediate angle through the pump's outside diameter. The use of passive, radial magnetic bearings to support the rotor is anticipated to result in exceptional device durability. In its latest iteration, the PediPump prototype measures approximately 10.5 mm × 64.5 mm with a priming volume of 0.6 mL, imparting less than 10% of the physical displacement of currently available axial flow pumps.

Pediatric Cardiopulmonary Assist System

The goal of Ension's Pediatric Cardiopulmonary Assist System (pCAS; Ension, Inc; Pittsburgh, Pennsylvania) development program is to improve on the performance of currently used ECMO leading to decreased clinical complications and increased opportunity for parent-child contact and bonding during support [89,90]. The paracorporeal design of the pCAS system affords modularity, allowing a separate device for each target patient population and the possibility of device exchange during the support period. Such modularity also permits the patient to be "upgraded" from a device appropriate for a neonate to one appropriate for an older child as growth or support needs change (Plate 45.4, see plate section opposite p. 594). In addition to steady flow, the pCAS system will include an option to deliver pulsatile flow at the higher heart rates of the intended patient population [91].

The Pediatric Jarvik 2000

The design of the Pediatric Jarvik 2000 device (Jarvik Heart, Inc; New York) is based on the Jarvik 2000 VAD, which has been implanted in more than 200 patients in the United States, Europe, and Asia. Two pediatric axial flow blood pumps are being developed for the Pediatric Jarvik 2000. These small child and infant Jarvik 2000 models are intended to be versatile and despite the similarity in appearance, are not simply scaled down models of the adult device (Plate 45.5, see plate section opposite p. 594) [92]. The pediatric models have incorporated new blade designs for the lower flow and pressure requirements of children and infants. The encouraging clinical performance of the adult Jarvik 2000 VAD has resulted in high expectations for the Pediatric Jarvik 2000 models; based on the design and clinical results to date for the adult device, the reliability of the pediatric Jarvik 2000 VAD is targeted to exceed 10 years.

Penn State Pediatric VAD

The Penn State Infant VAD (PVAD; Pennsylvania State University, Hershey, Pennsylvania) is a pulsatile, pneumatically actuated blood pump based on the design principles of the adult-sized Pierce-Donachy VAD, which was

Figure 45.5 The Penn State Infant VAD is a pneumatically actuated pulsatile pump with a dynamic stroke volume of 12–14 mL that utilizes Bjork-Shiley monostrut valves to minimize thrombus formation. (Courtesy of William J Weiss, Pennsylvania State University, Hershey, PA, USA.)

developed at Pennsylvania State University and is now known as the Thoratec VAD [93]. The PVAD, which underwent initial development in 1986 under the direction of William S. Pierce, MD, in collaboration with 3M Corporation, is intended to be used as an LVAD, RVAD, or BVAD for up to 6 months [24,94,95]. The device is intended primarily for paracorporeal placement but will also be implantable for bridge to transplantation applications [96]. The PVAD is being developed in two sizes: a 12 mL dynamic stroke volume size for infants ranging in weight from 5–15 kg and a 25 mL stroke volume size for children weighing 15–35 kg (Figure 45.5). The flow rate ranges of the infant and child-size devices are 0.5–1.3 L/min and 1.3–3.3 L/min, respectively. Each of the pumps consists of a seamless segmented polyether polyurethane urea blood sac positioned within a rigid titanium case, mechanical heart valves, and cannulae connectors. The pump shape encourages the development of a vortex flow pattern, which efficiently maintains high wall shear rates to help prevent thrombus formation. The PVAD is controlled by a new portable biventricular pneumatic driver, which is based on actuator technology developed by Pennsylvania State University for electrically powered implantable blood pumps.

The NHLBI Pediatric Circulatory Support Program's 5-year period of funding ended in March 2009. All five funded projects made important progress throughout the program. All programs were successful in satisfying the primary objectives originally established by the NHLBI, namely to make progress in development of these innovative devices through a rigorous preclinical testing program. All five projects gained considerable understanding of the engineering and other technical aspects of these devices in the pediatric setting. Substantial progress was also made in determining the physiologic impact of these systems, particularly documenting low levels of hemolysis and minimal thromboembolic potential during support. Of particular importance, progress was made during in vivo preclinical testing; all five programs established robust survival animal test programs and documented satisfactory performance of each of these devices during prolonged in vivo support.

Future Directions

In the spring of 2009, the NHLBI made funds available for clinical development projects to support activities necessary to obtain Investigational Device Exemptions (IDEs) from the US Food and Drug Administration (FDA) for investigational circulatory assist devices for infants and small children [97]. These activities include preclinical testing, development of manufacturing processes, and collaboration to develop IDE clinical studies to support Humanitarian Device Exemption (HDE) applications to market the devices as Humanitarian Use Devices (HUDs). Selected developers are asked to conduct all necessary activities with documentation necessary for the IDE in the first 3 years of the contract. During the third year, the developers will generate the clinical studies for their individual projects in partnership with a Data Coordinating Center and complete the requirements for FDA approval of their IDE. Following IDE approval, the contractors will provide regulatory, technical and clinical support for the investigational device during the clinical study, hopefully leading to devices that are clinically available as HUDs [97].

The PumpKIN solicitation represents yet another important milestone in the field of pediatric mechanical circulatory support. As stated in the introduction, educational and scientific progress during the last 5 years in the field of pediatric mechanical circulatory support will hopefully translate into improved clinical results for children with advanced heart failure. Although VADs and similar circulatory support technology had undergone relatively little progress for pediatric applications until recently, these exciting new clinical and research developments suggest that the near future will be a time of significant advances for mechanical circulatory support in children. While immediate prospects for device availability are improving with the introduction of devices such as the DeBakey VAD *Child* and increasing worldwide use of the Berlin Heart VAD for children, support of early stage development of a variety of devices under the NHLBI-funded pediatric circulatory support initiatives will expand treatment options in the future.

Acknowledgment

The PediPump has been funded in whole or in part with federal funds from the National Heart, Lung and Blood Institute, National Institutes of Health, under Contract No.HHSN268200448188C.

CHAPTER 46

Adult Congenital Heart Disease

Stamatia Prapa,[1,2] Konstantinos Dimopoulos,[1,2] Darryl F. Shore,[1,2] Mario Petrou,[1] and Michael A. Gatzoulis[1,2]

[1]Royal Brompton Hospital, London, UK
[2]Imperial College London, London, UK

The successful management and correction of congenital heart defects (CHD) during infancy has resulted in an increasing number of adults with CHD. Due to medical and surgical advances, 85% of children born with CHD now survive to adulthood [1]. It is imperative that this group of young adults is not lost to follow-up. Smooth transition of these individuals from pediatric to adult care is an essential but often difficult process for both the clinician and the patient. Important issues such as residual hemodynamic lesions, arrhythmia management, endocarditis prophylaxis, career, and family planning should be addressed in an appropriate and timely fashion [2]. In fact, as this population ages, long-term complications become more frequent posing a significant burden and challenge on healthcare [3].

Adults with CHD may be divided into those with previous repair or palliation and those with unrepaired lesions. While patients with repaired lesions are more likely to have had relief of the hemodynamic burden posed by the original cardiac defect, residual hemodynamic lesions and sequelae from surgery, such as scar-related arrhythmias, are frequent. Follow-up is thus essential in all, even the most stable, adult CHD (ACHD) patients. Patients with unrepaired lesions are those with a delayed or missed diagnosis and those in whom repair was impossible or considered too high-risk at the time. Those with persistent unrepaired lesions may at times undergo palliative procedures as a definitive approach or a bridge to repair, even though the latter is rare in adult life. Certain lesions may be amenable to late repair (e.g., atrial septal defects [ASD]), but long-term complications are frequent even after successful repair. In specialist ACHD centers, approximately one half of operations are first repairs, while the other half are reoperations following reparative or palliative procedures [4]. The number of operations on ACHD patients has increased dramatically in recent years and reflects the increasing number of patients and the increasing complexity of patients reaching adulthood (Plate 46.1, see plate section opposite p. 594).

General Considerations

There are numerous issues to be considered when caring for ACHD patients, many of which are unique to this population. Uncorrected lesions can lead to volume overload, heart failure, arrhythmias, or chronic cyanosis. Previously repaired or palliated patients are likely to require reoperations with an inherently higher risk (e.g., repeat sternotomy, adhesions, thrombotic or air embolism related to retrosternal conduits). Finally, as this population ages, the risk of acquired heart disease (e.g., coronary artery disease, valvar disease) increases and its burden superimposes to the congenital defect, accelerating deterioration.

Heart Failure

Heart failure is defined as symptoms of exercise intolerance and signs of fluid retention in the presence of a cardiac defect [5]. Exercise intolerance is common in ACHD and may result from a variety of mechanisms, both cardiac and extracardiac. A persistent or residual defect or hemodynamic lesion can result in chronic volume or pressure overload and ventricular dysfunction. Coronary anomalies, pericardial disease, arrhythmias, chronotropic incompetence, and myocardial injury during surgery may also affect cardiac function and output. Extracardiac factors include pulmonary parenchymal and vascular disease,

Pediatric Cardiac Surgery, Fourth Edition. Edited by Constantine Mavroudis and Carl L. Backer.

cyanosis and pulmonary arterial hypertension (PAH), skeletal abnormalities, and detraining.

Subjective evaluation of exercise intolerance using the New York Heart Association (NYHA) classification appears to underestimate the severity of functional impairment in ACHD [6]. In fact, asymptomatic ACHD patients often have subnormal exercise capacity and a high prevalence of asymptomatic ventricular dysfunction [7]. Objective assessment of exercise capacity with cardiopulmonary exercise testing and regular cardiac imaging by echocardiography and cardiovascular magnetic resonance (CMR) are a fundamental part of the preoperative assessment, perioperative management, and long-term follow-up. In particular, CMR imaging is considered ideal for quantifying right ventricular function, which is commonly affected in ACHD [8].

The primary aim when managing an ACHD patient with signs and symptoms of heart failure is to identify and treat residual hemodynamic lesions, especially those potentially amenable to surgical or percutaneous repair. These could be valve lesions (e.g., pulmonary valve regurgitation after repair of tetralogy of Fallot or tricuspid regurgitation in patients with congenitally corrected [L-] transposition of great arteries) or other obstructive lesions (e.g., baffle stenosis in patients with previous Mustard or Senning repair) [9]. While there is mounting evidence to suggest common pathophysiologic mechanisms between acquired heart failure and ACHD, including neurohormonal activation, established heart failure therapies counteracting neurohormonal activation are still not widely in use in ACHD. This is because of the lack of evidence supporting the efficacy and safety of these therapies in ACHD, which has prevented the establishment of evidence-based guidelines for the pharmacologic treatment of these patients. Few studies have examined the effect of angiotensin-converting enzyme (ACE)-inhibitors and beta-blockers in CHD, all of which were limited by a small sample size [10]. Current practice is still based on extrapolation from trials in acquired heart disease. This approach, however, ignores important differences between the two conditions and the unique characteristics of the individual with CHD, which could affect dosage, tolerability, and effectiveness [11]. Finally, new therapeutic approaches such as cardiac resynchronization have been reported in patients with severe left ventricular dysfunction associated with tetralogy of Fallot and could be considered in selected patients [12]. As the CHD adult population ages and increases in number, randomized controlled trials are urgently needed to rationalize treatment of heart failure in these patients.

Pulmonary Arterial Hypertension

Despite advances in cardiac surgery that have allowed repair of CHD at an early age, it is estimated that approximately 5–10% of patients with CHD develop PAH [13,14]. The current definition of PAH relies on the presence of mean pulmonary arterial pressure exceeding 25 mmHg at rest, a left atrial pressure or left ventricular end-diastolic pressure below 15 mmHg, and resting pulmonary vascular resistance above 3 Wood units [15,16]. According to the Venice classification, congenital systemic-to-pulmonary shunts associated with PAH can be divided into: 1) simple shunts, such as ASD, ventricular septal defect (VSD), patent ductus arteriosus, and unobstructed total or partial anomalous pulmonary venous return; 2) combined shunts; and 3) complex shunts such as truncus arteriosus, single ventricle with unprotected pulmonary circulation, and atrioventricular septal defects (AVSD) [15,17]. Ventricular septal defects are the most frequent simple defects causing PAH, with an estimated 10% of all VSDs and 50% of large VSDs having the potential to cause Eisenmenger syndrome if not repaired by age 2 [18,19].

Eisenmenger syndrome is the extreme manifestation of the spectrum of PAH secondary to CHD. It includes patients with large left-to-right shunts, which result in significant PAH (systemic or near-systemic levels) and subsequent reversal of the shunt, which may become right-to-left or bidirectional, and ultimately leads to cyanosis. Currently, approximately 4% of ACHD patients followed in tertiary centers have Eisenmenger syndrome, as opposed to 8% in previous eras when early diagnosis and repair were not available [20].

The clinical manifestations of PAH secondary to CHD can vary depending on the underlying heart defect, patient age, repair status, and degree and direction of shunting. Common nonspecific symptoms include breathlessness on exertion or at rest, chest pain, and syncope [20]. Exercise intolerance is the cardinal symptom of PAH and patients with significant PAH have greatly reduced exercise tolerance, which affects their functional status and quality of life [21]. Eisenmenger patients, in particular, have been found to have the lowest exercise capacity of all ACHD patients, followed by patients with complex cardiac anatomy and univentricular circulation. This is attributable to a combination of PAH and cyanosis, both of which contribute to a significant increase in physiologic dead space.

Eisenmenger syndrome also has important systemic effects. Long-standing hypoxia results in hematologic phenomena, such as secondary erythrocytosis with thrombocytopenia and coagulation disorders. Moreover, patients with Eisenmenger syndrome have a high prevalence of peripheral organ dysfunction such as renal disease and hepatic dysfunction as a result of long-standing hypoxia, on which we will expand later in this chapter.

Patients with PAH secondary to CHD are at increased perioperative risk for cardiac and noncardiac surgery, both

major and minor. Routine and preoperative evaluation of these patients should include a chest radiograph, electrocardiogram, measurement of arterial oxygen saturations at rest and during exercise, formal exercise testing, and echocardiography. Cardiac catheterization is often necessary to establish the diagnosis and severity of PAH as well as to assess pulmonary vasoreactivity. Routine laboratory testing should focus on hemoglobin concentration, platelet count, and the detection of iron deficiency. Finally, CMR imaging and high-resolution chest computed tomography (CT) may provide additional information on right ventricular size and function as well as on the pulmonary vascular bed [20].

The general care of patients with PAH consists of preservation of fluid balance, management of secondary erythrocytosis, appropriate iron supplementation, and abolition of routine venesections. Anticoagulation may be indicated, especially for patients with documented pulmonary thrombosis and embolic phenomena, in the absence of prior severe hemoptysis.

Recently, new pharmacologic options became available for patients with PAH, including those with CHD [15,20]. Based on the results of the BREATHE 5 (the only randomized trial in this cohort) and other nonrandomized trials, advanced pulmonary hypertension therapy is currently indicated for highly symptomatic patients with Eisenmenger syndrome (NYHA functional class III or IV) [15]. Advanced PAH therapies have also been used to reduce the risk of developing postoperative PAH and for treating this in patients undergoing surgical repair of CHD or acquired valve disease [22,23]. Whether such therapies could be used to treat and subsequently repair congenital defects that have already led to the development of pulmonary hypertension remains unclear [24]. In fact, the long-term efficacy and safety of advanced therapies in PAH related to CHD warrants further investigation. Moreover, available data on closure of intra- or extracardiac communications in the presence of severe PAH, with or without the use of advanced therapies, are scarce and limited to case reports [24]. Currently, reparative surgery is indicated only in patients with evidence of pulmonary arterial reactivity and/or at least 1.5:1 left-to-right shunting [25].

Arrhythmias

Arrhythmias are a prominent cause of morbidity and mortality in adolescents and adults with CHD [26]. Arrhythmias in ACHD are the result of sudden hemodynamic changes, or more commonly reflect the chronic interplay between the cardiac defects, hemodynamic lesions, and postoperative scarring (Table 46.1) [5]. The entire spectrum of rhythm abnormalities can be encountered in adults with CHD. Supraventricular arrhythmias are more frequent in patients with atrial dilatation (e.g., atriopulmonary Fontan) and those with history of surgery involving extensive atrial incisions (e.g., Mustard, Senning, or Fontan procedures).

Table 46.1 Rhythm disturbances in adults with congenital heart disease. (ASD, atrial septal defect; AV, atrioventricular; VSD, ventricular septal defect.) (Reproduced with permission from Warnes *et al*. [5].)

Rhythm disturbance	Associated lesions
Tachycardias	
Wolff-Parkinson-White syndrome	Ebstein anomaly Congenitally corrected transposition
Intra-atrial re-entrant tachycardia (atrial flutter)	Postoperative Mustard Postoperative Senning Postoperative Fontan Tetralogy of Fallot Other
Atrial fibrillation	Mitral valve disease Aortic stenosis Tetralogy of Fallot Palliated single ventricle
Ventricular tachycardia	Tetralogy of Fallot Aortic stenosis Other
Bradycardias	
Sinus node dysfunction	Postoperative Mustard Postoperative Senning Postoperative Fontan Sinus venosus ASD Heterotaxy syndrome
Spontaneous AV block	AV septal defects Congenitally corrected transposition
Surgically induced AV block	VSD closure Subaortic stenosis relief AV valve replacement

The type of arrhythmia most commonly encountered in ACHD patients is intra-atrial re-entry tachycardia. This is usually initiated and sustained by viable myocardial fibers embedded within areas of scar tissue [27]. Macro re-entrant circuits are also responsible for ventricular arrhythmias and are encountered in patients with repaired tetralogy of Fallot. In this case, the circuit involves the isthmus between the outflow tract patch and the tricuspid annulus [28]. Atrial fibrillation is common in ACHD, especially in patients with significant atrial dilatation due to unrepaired lesions or residual hemodynamic burden.

Bradyarrhythmias are also commonly encountered in ACHD patients, and their incidence and timing depend on the type of cardiac defect and/or previous palliation/

repair. Sinus node dysfunction can be present at birth due to congenital abnormalities such as sinus venosus ASD and atrioventricular (AV) discordance with left atrial isomerism. Sinus node dysfunction may also occur following cardiac surgery (Mustard, Senning, or Fontan procedures). Very often, loss of sinus rhythm in postoperative cases is gradual, suggesting a chronic hemodynamic process rather than an occurrence of direct surgical injury of the sinus node [29].

An AV block can occur spontaneously, especially in congenital defects with conduction system abnormalities (e.g., AVSD and congenitally corrected transposition) or postoperatively. Surgery commonly associated with acquired AV block includes closure of VSD, relief of subaortic stenosis, replacement or repair of an AV valve, and tetralogy of Fallot repair. Surgical manipulation of the ventricular septum may cause AV block because of either direct injury or secondary damage of the interventricular conduction system associated with an inflammatory response [29].

The clinical manifestations of arrhythmia in patients with CHD range from completely asymptomatic to rapid deterioration or sudden cardiac death. The onset of arrhythmia often heralds a hemodynamic decline and contributes to a vicious cycle of progressive clinical deterioration. Persistent atrial tachycardia may also lead to intracavity thrombus formation and thromboembolic events [30]. Most importantly, sudden cardiac death secondary to documented or presumed arrhythmia is the leading cause of mortality in adult patients with CHD, with a higher risk in patients with unrepaired cyanotic or left-sided obstructive lesions [31,32].

The first and most effective step in the management of recurrent or persistent arrhythmias in ACHD is identification and correction of hemodynamic abnormalities. Correction of hemodynamic lesions is usually accompanied, in our practice, by electrophysiologic mapping and ablation in the catheter laboratory, mostly before surgery. Catheter ablation and surgical interventions are, in fact, increasingly used in ACHD for both supraventricular and ventricular arrhythmias. Today, new three-dimensional mapping techniques and increasing expertise allow mapping and ablation of complex arrhythmogenic circuits. The rationale for preoperative ablation is that it reduces hemodynamic burden perioperatively, especially in the presence of persistent supraventricular tachycardia, by lowering the risk of hemodynamic instability during anesthesia induction. Moreover, preoperative targeted transcatheter ablation prevents the creation of unnecessary surgical scars that, in themselves, may provide the substrate for tachycardias. Therefore, our current practice is that supraventricular tachycardias should be treated by mapping and ablation in the catheter laboratory before surgery. If ablation fails to address the arrhythmia, surgical ablation becomes a viable alternative.

Patients with episodes of documented or strongly suspected ventricular tachycardia (VT) should also undergo preoperative mapping and ablation if possible. Implantable cardioverter defibrillators (ICD) are also increasingly used in patients with CHD, despite a lack of solid evidence to support this approach. Risk stratification is essential for identifying patients at a high risk of sudden death who would benefit from implantation of an automatic ICD or invasive electrophysiologic studies. Several predictors of sudden cardiac death have been proposed for patients with tetralogy of Fallot, including a prolonged QRS duration, presence of symptomatic dysrhythmias, and inducible VT on electrophysiologic study [33,34]. Currently, according to guidelines by the American College of Cardiology, the European Society of Cardiology and the American Heart Association, implantation of ICDs is recommended in patients with CHD who have survived a cardiac arrest, those with spontaneous VT that could not be ablated, and in patients with inducible VT, concomitant unexplained syncope, and impaired right or left ventricular function [5,35,36]. In our practice, patients with tetralogy of Fallot and poor left or right ventricular function, evidence of extensive scarring on CMR imaging and prolonged QRS duration, are referred for ICD implantation. While patients with preserved ventricular function, narrow QRS complex, and minimal scarring are not candidates for ICD implantation, there remains a group of patients of moderate severity who may be at risk of sudden death and for whom the indication for ICD implantation remains unclear.

Antiarrhythmic agents are often used in ACHD, but most have proved to be disappointing, especially long-term. Amiodarone and beta-blockers are the most commonly used drugs, with amiodarone being the most effective [35]. However, significant long-term amiodarone toxicity makes ablative treatment even more important.

Patients with atrial tachycardia will often require long-term anticoagulation to prevent thrombus formation. This is especially true in patients with a Fontan circulation and those with intracardiac communications. However, anticoagulation may prove problematic in Eisenmenger patients who are prone to hemoptysis and in patients with vascular malformations.

Pacing for bradyarrhythmias can prove challenging in ACHD patients. Limited access to the heart owing to congenital venous anomalies or acquired venous occlusion, surgical obstacles such as conduits and baffles, and the presence of intracardiac shunts with a significant thromboembolic risk may preclude endocardial lead placement and require an epicardial approach [37].

Cyanosis

Cyanosis can be defined as bluish coloration of the skin and mucous membranes that is a consequence of an increased

quantity of desaturated hemoglobin or derivates of hemoglobin, in the vessels of those districts [38]. Cyanosis is "peripheral" when it is secondary to slow peripheral flow of normally saturated blood, leading to increased oxygen extraction, and "central" when it is secondary to desaturation of arterial blood.

Persistent right-to-left shunting through unrepaired CHD results in central cyanosis. Shunting leading to cyanosis may occur through intracardiac (ASD or VSD) or extracardiac (e.g., patent ductus arteriosus) communications in the presence or absence of pulmonary hypertension (e.g., VSD, pulmonary stenosis). Cyanosis may also occur due to AV malformations within the lung or other organ segments [39].

Long-standing cyanosis is a multisystem disorder, causing multiorgan failure and a range of hematologic, neurologic, and metabolic disorders [40]. Chronic hypoxia results in an increase in erythropoietin production and an isolated rise in red blood cell count (secondary erythrocytosis). This a physiologic adaptation phenomenon to chronic hypoxia aimed at improving oxygen transport. The term "polycythemia" is often inappropriately used to describe this phenomenon. However, polycythemia implies proliferation of all three cell lines (red and white blood cells and the platelets). In chronic cyanosis, there is no increase in white cell count and the platelet count is normal or, most often, decreased [38,41,42]. Moreover, while polycythemic patients may benefit from regular venesections, this is not true for cyanotic ACHD patients with secondary erythrocytosis. Routine prophylactic phlebotomies in cyanotic patients pose the potential hazard of iron deficiency, cerebrovascular events, and decreased exercise tolerance [43–45]. In fact, venesections are hardly ever necessary today [46]. Hyperviscosity symptoms in cyanotic patients are often caused by iron deficiency or dehydration [47]. Hyperviscosity symptoms include headache, light-headedness, dizziness, blurred or double vision, paresthesias, altered cognitive functions, fatigue, tinnitus, and restlessness.

Venesection should not exceed 1 unit of blood and should always be accompanied by volume replacement [42]. In fact, dehydration may exacerbate the hyperviscous state and aggressive volume replacement should be undertaken when hyperviscosity symptoms occur. The beneficial effects of phlebotomy are usually evident within 24 hours and reflect the increase in systemic blood flow induced by isovolumetric reduction in erythrocyte mass [41].

Cyanotic ACHD patients are prone to iron deficiency because of increased iron requirements [42,45], recurrent phlebotomies, and blood loss (e.g., gastrointestinal, hemoptysis, menses) due to abnormal hemostasis (see below). Iron deficiency can increase blood viscosity through the production of microcytic hypochromic red blood cells, which are rigid and resistant to deformation [48]. Moreover, iron deficiency may limit the physiologic rise in hemoglobin (relative anemia), resulting in impaired oxygen-carrying capacity. Annual screening for iron deficiency is, thus, important and is best performed by measuring serum ferritin and transferrin saturation [45]. Oral or intravenous iron can be used to treat iron deficiency, with close monitoring of hemoglobin levels to avoid excessive erythrocyte production.

Hemostatic Dysfunction

Cyanotic patients are at increased risk of both thrombotic events and bleeding. Hemostatic defects in cyanotic ACHD patients include thrombocytopenia, primary fibrinolysis, coagulation factor deficiencies, and disseminated intravascular coagulation (DIC) [47]. Bleeding in cyanotic patients can occur spontaneously (gingival bleeding, epistaxis, hemoptysis, or menorrhagia) or perioperatively/periprocedurally. Hemoptysis is especially common in Eisenmenger syndrome and is the cause of death in 11–30% of patients, even though in most occasions they are not severe [49].

Low-normal platelet counts and thrombocytopenia are common in cyanotic patients [50]. The reduced platelet count can be caused by increased peripheral platelet consumption and decreased platelet life. It has also been suggested that megakaryocytes delivered into the systemic arterial circulation through right-to-left shunting cannot release platelets by cytoplasmic fragmentation, which would have normally occurred in the pulmonary circulation [50]. Moreover, there are data suggesting that platelet function is abnormal (thrombasthenia) and that this improves with surgical repair of the underlying cardiac defect. Nevertheless, bleeding time in these patients is not increased, possibly due to the high blood viscosity and marked platelet activation [47].

Disseminated intravascular coagulation has also been proposed as a mechanism responsible for the hemostatic abnormalities in cyanotic patients [47]. The increased viscosity caused by the erythrocytosis may lead to a reduction in tissue perfusion and stasis. Widespread intravascular deposition of fibrin and platelets may lead to factor and platelet consumption and an increased risk of hemorrhage. Intravascular coagulation is probably nongeneralized but localized to specific districts such as the pulmonary microcirculation. The reported increase in factor levels after heparin administration supports DIC as an important mechanism for increased bleeding diathesis in cyanotic ACHD patients.

Cyanotic CHD often results in congestive heart failure that may affect liver function and influence the production of coagulation factors. Even in the presence of normal liver function, gastrointestinal absorption of vitamin K could be impaired and affect production of factors II, VII, IX, and X. In the latter case, intramuscular administration of vitamin

K could increase factor levels, whereas, in the presence of abnormal liver function, this will have little effect [46,47].

Primary fibrinolysis has been reported in few cyanotic patients, but its role is uncertain. Recently, evidence of increased sensitivity of cyanotic patients to activated protein C was reported, which could predispose patients to bleeding [51]. Other authors reported suppression of the thrombomodulin-protein C–protein S pathway that could predispose towards thrombosis in the microcirculation and subsequent DIC phenomena [52].

Thrombosis in cyanotic heart disease is often a consequence of blood stasis occurring in dilated chambers, arrhythmias (atrial fibrillation or flutter), and prosthetic material (valves, pacemaker leads, conduits) [46]. Massive thrombosis of the pulmonary arteries was found in 29% of Eisenmenger patients in one study [53], and thrombosis of the proximal pulmonary arteries was found in 21% of patients in another study [54]. Female sex and lower arterial saturations were associated with the risk of thrombosis in the pulmonary arteries. Pulmonary infarction appears to be the most common cause of hemoptysis in these patients [49,55]. The coexistence of hemoptysis and thrombosis make clinical decision on anticoagulation arduous [49].

Treatment of the hemostatic dysfunction is not typically required. Moreover, administration of anticoagulants and antiplatelet agents in this group of patients remains controversial [46]. In our practice, indications for anticoagulation include atrial flutter or fibrillation, recurrent episodes of thromboembolic events in the absence of iron deficiency and dehydration, and the presence of mechanical heart valves or other high-risk anatomy. Monitoring of anticoagulation in these patients should be meticulous.

Cyanotic ACHD patients requiring surgery are at high risk of perioperative bleeding due to the aforementioned hemostatic abnormalities and the presence of fragile mediastinal collateral arteries. Therefore, coagulation parameters should be accurately measured before surgery and fresh frozen plasma and platelets administered accordingly. Special attention should be made when assessing coagulation parameters in cyanotic patients with secondary erythrocytosis. The increased hematocrit results in a decrease in plasma volume per unit of blood. Thus the amount of anticoagulant in the vials used for collection of blood should be adjusted accordingly. Other measurements include administration of aminocaproic acid and tranexamic acid, meticulous hemostasis during sternotomy, application of fibrin glue to suture lines when necessary, and continuous ultrafiltration during cardiopulmonary bypass (CPB) [56].

Stroke

Children less than 4 years of age with iron deficiency are at an increased risk of intracranial venous and sinus thrombosis [57]. In contrast, cerebral venous thrombosis has not been described in older patients with cyanotic CHD [58].

In adult patients with cyanotic heart disease, the risk of cerebrovascular thrombotic events was estimated at 14% (1/100 patient-years) in one study, whereas in another study no cerebrovascular events occurred (112 patients, 748 patient-years) [43,58]. Daliento and colleagues reported that 8% of Eisenmenger patients had a major cerebrovascular event by age 31 ± 16 years [59]. Systemic arterial hypertension, atrial fibrillation, and microcytosis are independent predictors of cerebrovascular events in cyanotic heart disease [43]. Multiple ischemic changes were identified by magnetic resonance imaging (MRI) in cyanotic patients with heart disease even in the absence of clinical history of major cerebrovascular events, atrial fibrillation, brain abscess, or prosthetic valves [60]. Patients with a hematocrit exceeding 60%, oxygen saturation less than 85%, and decreased protein C activity were at higher risk of subclinical ischemic cerebral changes on MRI. However, Perloff and colleagues [58] found no relation between stroke due to arterial thrombosis and hyperviscosity. In fact, blood viscosity may have less of an effect on flow rates in the adult cerebral microcirculation, and intrinsic autoregulation may preserve blood flow in the face of hyperviscosity [60].

Renal Dysfunction

Chronic cyanotic heart disease is associated with decreased glomerular filtration rate and proteinuria. This is secondary to hypercellular congested glomeruli with segmental sclerosis and basement membrane thickening [61]. In a recent study, 72% of patients with Eisenmenger syndrome were found to have moderate or severe reduction in glomerular filtration rate [62]. Moreover, renal dysfunction is an established marker of adverse outcome in acquired and CHD (Figure 46.1) [62].

Care should be taken when performing cardiac catheterization with angiography in cyanotic patients who are at increased risk for contrast induced nephropathy. Patients requiring cardiac catheterization should be well hydrated prior to the procedure and a minimal amount of contrast agent should be used for imaging. Postcatheterization monitoring of urinary output is required and rehydration should be used judiciously.

Metabolic Complications

Acute gout occurs in 2% of adults with cyanotic heart disease [63]. High uric acid levels require no treatment if gout is absent; acute symptomatic gout may be treated with colchicine. However, colchicine may produce vomiting or diarrhea, which requires discontinuation to prevent dehydration. Nonsteroidal anti-inflammatory agents may be

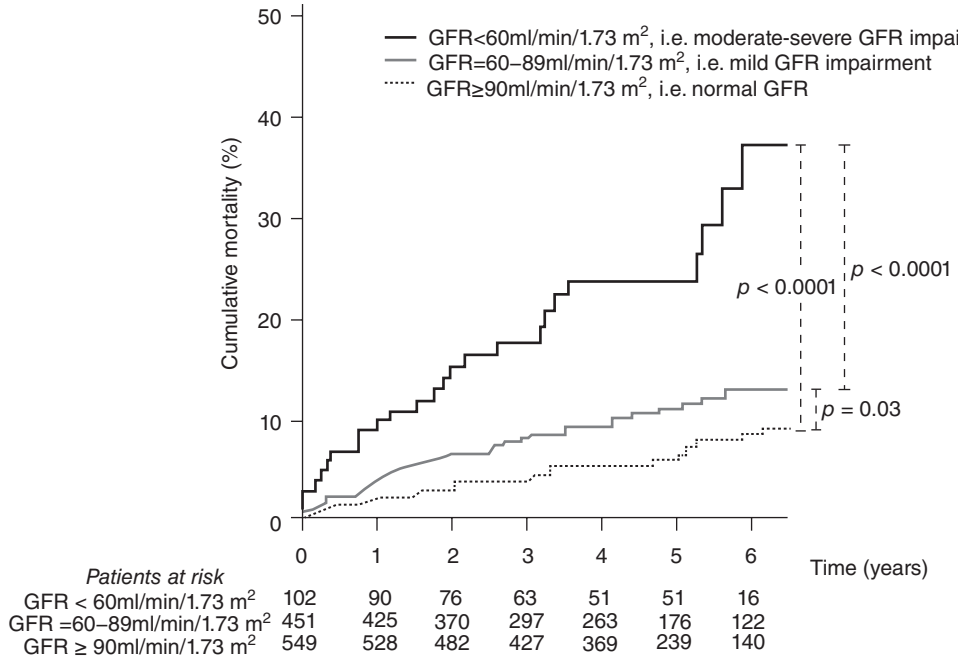

Figure 46.1 Unadjusted (Kaplan-Meier) cumulative mortality curves according to glomerular filtration rate (GFR) group. Patients with moderate or severe GFR reduction (<60 mL/min/1.73 m^2) had a five-fold increased unadjusted mortality risk, which was apparent even from the first year of follow-up. (Reproduced with permission from Dimopoulos *et al.* [62].)

used with caution, acknowledging the increased risk of bleeding with their use.

Hemoptysis

Pulmonary infarction due to pulmonary embolus may result in hemoptysis. Hemoptysis may also be caused by rupture of an enlarged friable bronchial artery. Prompt bronchoscopy should be performed to clear the airway and identify the site of the lesion. Measures to protect the contralateral bronchial tree are undertaken. CT or MRI may be beneficial in identifying pulmonary infarction and intraparenchymal hemorrhage. If bleeding persists despite bed rest and correction of coagulopathies, angiography to localize the site of bleeding is indicated. At the time of angiography, embolization of the vessel should be performed. If bleeding cannot be controlled with interventional catheterization techniques, then emergent pulmonary resection is required.

Re-Sternotomy

Re-sternotomy in patients who have undergone prior palliative or corrective procedures carries an increased risk. Lying just beneath or adherent to the posterior sternal table may be a dilated thin-walled right atrium, an enlarged right ventricle, a right ventricle-to-pulmonary artery conduit, the aorta (in patients with transposition of great arteries), or a markedly dilated aorta (common, for example, in tetralogy of Fallot). Meticulous review of the previous operative note, posteroanterior and lateral chest X-ray, CMR, and cardiac catheterization can aid in planning the re-sternotomy.

The groin should be prepped and draped into the operative field should rapid access be required during re-sternotomy. The femoral vessels can be dissected before the re-sternotomy for rapid cannulation and institution of CPB if risk of injury to the right-sided heart chambers appears high. Alternatively, femoral cannulation with institution of CPB may be accomplished before re-sternotomy to allow decompression of the heart, reducing the risk of injury. Peripheral cardiopulmonary artery bypass can be converted to central atrial–aortic bypass once the heart has been dissected free from the surrounding structures. This provides more effective venous drainage and reduces the risk of compartment syndrome due to reduced arterial flow in the limb.

Some authors prefer to develop a dissection plane just behind the posterior sternal table under direct visualization before sternotomy is attempted. Once the sternum has been successfully opened, early identification of the aorta and atrium should be achieved so that rapid institution of CPB may be accomplished in the event of mishap during dissection of the heart. During the course of the operation the dissection plane should remain medial to the pericardium to avoid injury to the phrenic nerve. In many cases, the pericardium has previously been harvested for

intracardiac repair; therefore, the phrenic nerves are at increased risk for injury. Entry into the cardiac chambers is to be avoided to reduce the risk of paradoxical air embolus occurring through residual intracardiac shunts. If entry into the cardiac chambers occurs, suture closure of the defect should be performed. Also during dissection, attention should be paid to the patient's hemodynamics. Cardiac output is reliant on adequate volume loading of the heart. Most patients are volume depleted secondary to their nothing by mouth status. In addition, retraction on the heart during dissection may result in severe hemodynamic instability. If exposure for dissection is difficult, then institution of CPB should be considered. With careful preoperative planning and great care during re-sternotomy, poor outcomes can be avoided.

Collateral Vessels

Chronic cyanosis may lead to the development of multiple thin-walled mediastinal collateral vessels. These vessels may become problematic at the time of sternotomy and during the operation. They do not coagulate well and may need to be sutured to avoid unnecessary persistent blood loss during preparation of the heart for CPB.

During the operation, systemic to pulmonary collaterals may produce excessive pulmonary venous return making visualization of intracardiac anatomy difficult and may result in myocardial distention and wash out of cardioplegic solution and myocardial rewarming. In these circumstances a left atrial vent will be required. Occasionally, systemic cooling and periods of low-flow CPB will be required.

Large collateral vessels identified on preoperative cardiac catheterization should be occluded at the time of cardiac catheterization (transcatheter coil occlusion). If cardiac catheterization is not performed or coil occlusion is unsuccessful, suture ligation of the collaterals should be performed during the initial stages of the operation to avoid complications during the course of the procedure.

Pregnancy and Heart Disease

As female patients with CHD reach reproductive age, the issue of pregnancy and labor naturally arises. Preconceptual counseling should start in adolescence, especially for high-risk patients. Patients should be educated about the risks and the precautions to be taken, allowing them to make informed decisions with regards to family planning. An important step in the management of ACHD patients who wish to become pregnant is prepregnancy assessment of cardiac status and counseling on the risks of pregnancy, intervention required before becoming pregnant, and the need for close follow-up during and after pregnancy and labor. The risk of maternal death is less than 1% for the majority of parturients with CHD. Certain conditions, however, are associated with significantly higher risk. These include all cyanotic defects and those associated with pulmonary hypertension, poor systemic ventricular function, severe left heart obstructive lesions, Marfan syndrome with dilated aortic root, previous repair of coarctation with a Dacron patch, and women with history of peripartum cardiomyopathy [64]. It is imperative that such women use highly effective methods of contraception appropriately tailored to the severity of their condition and possible adverse effects of contraception.

Inevitably, some women, regardless of the risks to their health, will decide to become pregnant. Minimization of risk by optimization of cardiac function before pregnancy is, thus, essential. This may include catheter or surgical intervention before gestation, surgical or medical treatment of arrhythmias, and appropriate management of medication, including anticoagulation and ACE inhibitors, which may harm the fetus. Patients with left-sided obstructive lesions should be recognized and considered for balloon valvotomy or surgery before pregnancy. The choice of bioprosthetic or mechanical valve requires careful discussion with the patients. Some reports suggest accelerated degeneration of bioprostheses during pregnancy [65,66]; however, this was not confirmed by several large series [67,68]. Nevertheless, it has been suggested that the appearance of accelerated degeneration associated with pregnancy might reflect the well established deterioration of bioprostheses in younger patients [69]. Mechanical prostheses are more problematic than tissue valves during gestation due to the increased risk of clotting [70]. Careful pregestation assessment of aortic root size is important in women with Marfan syndrome, bicuspid aortic valve, and aortic coarctation associated with hypertension. Elective aortic root replacement should be considered in patients with large or enlarging aortic roots [71]. Likewise, women with repaired tetralogy of Fallot, pulmonary regurgitation, and right ventricular enlargement may be considered for pulmonary valve replacement before pregnancy. In fact, recent studies have demonstrated an increase in right ventricular size with pregnancy, which persists after labor [72,73].

Arrhythmia is a frequent complication of pregnancy in women with CHD and may cause significant hemodynamic compromise to both the mother and the fetus [74]. DIC cardioversion is safe during pregnancy whereas antiarrhythmic drug therapy may have adverse effects and should be used with great care [75,76]. The management of anticoagulation is often problematic, especially in women with prosthetic heart valves. Warfarin is a more effective anticoagulant in pregnancy but it is also associated with increased fetal loss and embryopathy, especially when used between the 6th and 12th week of pregnancy [77,78]. Our current practice consists of low molecular weight heparin during the first trimester substituted by warfarin

during the second and early third trimesters. Warfarin is again replaced by unfractioned heparin at approximately 35 weeks of gestation [79]. The use of aspirin is also recommended until the 35th week of pregnancy in women with increased risk of thromboembolism, such as patients with a Fontan circulation, and in those at risk of paradoxical embolization across an intracardiac defect [80].

The timing of pregnancy is particularly important for women with a systemic right ventricle or a univentricular heart, as they are more likely to tolerate pregnancy earlier rather than later in their lives. In fact, progressive ventricular dysfunction is common and affects the risk and outcome of pregnancy.

Despite all efforts for optimal medical management of pregnancy in CHD, the need for surgical or catheter intervention during pregnancy may still arise. Most interventions involve women with an undiagnosed cardiac lesion, those lost to follow-up, or those with an acute, life-threatening situation. The most common indication for cardiac intervention during pregnancy is valvar heart disease, in particular mitral valve stenosis, which is usually secondary to rheumatic disease [81]. Other indications include severe aortic valve stenosis, pulmonary valve stenosis, acute dissection of the aorta, pacemaker insertion, and insertion of an inferior vena cava filter. CPB is associated with a high risk of fetal loss and should only be considered in women with symptoms refractory to medical treatment, for whom no percutaneous options are available [82].

Surgical Considerations in Patients with Previous Operations

Blalock-Taussig Shunt

The classic Blalock-Taussig shunt involves ligation of the subclavian artery with anastomosis of the subclavian to the pulmonary artery. The radial pulse is absent on the side of the shunt, therefore arterial monitoring must be performed on the contralateral side. The modified Blalock-Taussig shunt is an interposition polytetrafluoroethylene (PTFE) graft between the subclavian or innominate artery and the pulmonary artery. Arterial blood pressure monitoring should be preformed on the opposite side of the shunt. Blood flow through the shunt, and thus the pulmonary blood flow, is dependent on systemic blood pressure. During the induction of anesthesia, care must be taken to prevent systemic hypotension, which can result in both systemic and pulmonary hypoperfusion.

Aspirin is often prescribed in patients with Blalock-Taussig shunts and should be discontinued 5 days before reoperation. The shunt is dissected free from the surrounding tissue before institution of CPB. Injury to the shunt during the dissection may have disastrous consequences if the shunt is the only source of pulmonary blood flow. At the start of CPB, the shunt is ligated and divided to avoid excessive pulmonary blood flow and prevent systemic hypotension during CPB. Pulmonary artery distortion or stenosis may occur at the site of the PTFE–pulmonary artery anastomosis. These anatomic abnormalities are repaired using arterioplasty techniques to restore unobstructed blood flow to the lungs.

Glenn Shunt

The classical Glenn shunt is an end-to-end anastomosis between the divided right pulmonary artery and the superior vena cava. Therefore all superior vena caval blood flow is directed to the right lung. The bidirectional Glenn is an end-to-side anastomosis of the superior vena cava to the superior margin of the right pulmonary artery, thereby maintaining continuity between the right and left main pulmonary arteries. This permits bidirectional flow from the superior vena cava to the right and left lungs.

With both the classical Glenn and the bidirectional Glenn shunt, the inferior vena cava is left intact, resulting in right-to-left shunting and hypoxemia. As previously discussed, chronic hypoxemia leads to erythrocytosis, abnormalities of hemostasis, development of collateral circulation, and systemic-to-pulmonary arterial shunts. If patients with classical Glenn shunts become candidates for the Fontan operation, the classical Glenn shunt is taken down, pulmonary artery continuity is re-established, and a bidirectional Glenn is constructed. During dissection of the Glenn shunt, care must be taken to avoid injury to the phrenic nerve.

Pulmonary Artery Band

Pulmonary artery banding protects the pulmonary circulation from excessive blood flow during infancy, thereby reducing the risk of PAH. A pulmonary artery band results in focal supravalvar stenosis of the main pulmonary artery. At the time of reoperation, repair of the stenosis must be addressed. Repair is typically performed by pericardial or prosthetic patch arterioplasty. If the band has migrated distally on the artery, then bilateral pulmonary artery stenoses or distortion of the pulmonary arteries may occur. The anatomic defect can be repaired with pericardium, homograft, or prosthetic material.

Anesthesia Considerations

Planning for an anesthetic procedure requires in-depth knowledge of the cardiac anatomy and physiology and the patient's medical history. Successful delivery of anesthesia requires modification of techniques to account for specific pathophysiologic states. Adequate premedication is needed to prevent anxiety, tachycardia, and increased myocardial demands. In patients with physiology dependent on

preload (Fontan patients) avoidance of myocardial depression, vasodilatation, and hypotension are critical for maintenance of hemodynamic stability. Moreover, large tidal volumes or high levels of positive end-expiratory pressure should be avoided to avoid a reduction in pulmonary blood flow. Hypoxemia and acidosis may also induce pulmonary vascular constriction and, thus, reduce pulmonary blood flow. A balance between pulmonary and systemic blood flow may be obtained by adjusting the fraction of inspired oxygen and ventilation. Patients with increased pulmonary blood flow should be maintained on minimal oxygen, with permissive hypercapnia and mild acidosis to prevent excessive pulmonary blood flow producing dilatation and failure of the systemic ventricle.

Monitoring

The degree of invasive monitoring required during anesthesia depends on the severity of the congenital defect and associated physiology. Continuous electrocardiographic monitoring is essential for identifying arrhythmic or ischemic events, especially during the onset of general anesthesia and before the institution of CPB. Pulse oximetry and end-tidal carbon dioxide (CO_2) monitoring assess the adequacy of oxygenation and ventilation throughout the procedure. Particular attention to the balance between oxygenation and ventilation is important in those patients in whom the pulmonary flow, filling of the systemic ventricle, and cardiac output is dependent on the resistance of the pulmonary vascular bed (i.e., Glenn, Fontan). Systemic arterial catheters provide continuous blood pressure monitoring and arterial access for blood gas analysis throughout the course of the operation. Placement of the catheter may be problematic due to numerous prior cannulations, arterial cut-downs, and the presence of systemic-to-pulmonary shunts (i.e., Blalock-Taussig shunt). Use of the femoral or lower extremity arteries may be limited due to associated coarctation of the aorta.

Central venous pressure monitoring is important for assessing preload and the fluid management in patients who require high central pressures to maintain adequate pulmonary perfusion. Insertion of central venous catheters in ACHD patients may be difficult due to abnormal venous anatomy and thrombosis of previously cannulated central veins. Extreme care should be taken to avoid systemic air embolism during insertion of central lines in patients with right-to-left shunts. Pulmonary artery catheters are not used routinely but may be beneficial in patients with anticipated postoperative hemodynamic instability.

Intracardiac Shunts

Patients with left-to-right shunts may benefit from a mild increase in pulmonary vascular resistance induced through a low fraction of inspired oxygen (to the lowest acceptable level to maintain sufficient partial pressure of arterial oxygen), and hypercapnia with mild acidosis. This limits excessive pulmonary blood flow and distention of the systemic ventricle during anesthesia.

In patients with right-to-left shunts due to a large intracardiac communication and fixed right ventricular outflow tract (RVOT) obstruction (which protects the pulmonary vascular bed from excessive blood flow) pulmonary blood flow can be improved by increasing systemic vascular resistance.

In patients with PAH resulting from an intracardiac shunt, the maintenance of a balance between systemic and pulmonary vascular resistance during surgery is vital. Factors that may affect that balance include hypercarbia, hypoxia, atelectasis, uncontrolled vasodilation by anesthetics, altered intrathoracic pressures by artificial ventilation, and hypovolemia. A combination of meticulous fluid administration, norepinephrine infusion, and inhaled nitric oxide can preserve a stable circulation.

Tetralogy of Fallot

High catecholamines levels result in increased dynamic right ventricular outflow obstruction resulting in worsening cyanosis in patients with tetralogy of Fallot. Adequate preoperative premedication is required to limit the catecholamine surge associated with anxiety and pain. Use of pre-bypass inotropic agents may also increase the dynamic right ventricular outflow obstruction and result in hemodynamic deterioration. Hypovolemia and vasodilating agents can also worsen right-to-left shunting. Beta-adrenergic antagonists decrease dynamic right ventricular obstruction and can reduce the risk of "tet" spells during the perioperative time period. In severe cases of acute cyanosis, phenylephrine may be used to increase systemic vascular resistance, reducing right-to-left shunting, which may lead to hemodynamic improvement. If supportive and pharmacologic measures fail, rapid institution of CPB is required.

Postoperative Care

On completion of the operation, the patient is transported to the intensive care unit (ICU). It is during this time of decreased monitoring that complications may occur. Portable monitors are used during transport to monitor blood pressure, oxygen saturation, and the electrocardiogram. All intravenous infusions should be maintained during transport. Equipment for reintubation and medication for the treatment of cardiac arrest should be promptly available. On arrival to ICU, mechanical ventilation is reinstituted, temporary monitoring is converted to permanent monitoring, and infusion of medication is established and

confirmed. Adequate hand-over is also fundamental for ensuring a smooth transition.

Blood is drawn for routine laboratory tests (e.g., complete blood count, electrolytes, coagulation factors, arterial blood gases). Electrolyte abnormalities and coagulation deficiencies should be corrected promptly. Portable chest X-ray is obtained to confirm proper position of the endotracheal tube and rule out hemothorax or pneumothorax. Adequate warming is begun with warm blankets, forced warm air blankets, or radiant heat lamps, as body is heat is often lost during transport from the operating room to the ICU.

Respiratory Management

The respiratory management of ACHD patients may differ significantly from that of adults undergoing repair of acquired cardiac lesions. In ACHD patients, alterations in respiratory mechanics can have profound effects on hemodynamics. An increase in intrathoracic pressure can affect systemic venous return, right ventricular ejection, left atrial filling, and cardiac output. Postoperative pulmonary arterial vasodilatation is desirable in patients with previous right-to-left shunts and PAH. The goal of ventilator management is to maintain partial pressure of arterial oxygen between 100 to 150 torr, mild respiratory alkalosis with a pH of 7.50 to 7.60, and a CO_2 between 30 to 35 torr. Sedation and analgesia are administered using intermittent or continuous infusions of morphine and midazolam to help prevent transient pulmonary hypertensive crises associated with painful stimulation. In cases of severe pulmonary hypertension, temporary paralysis with pancuronium bromide may be beneficial.

Ventilator strategies differ for patients with shunt-dependent pulmonary blood flow. These patients require a reduction in oxygen saturation (75% to 80%) and an increase in CO_2 (45 to 50 torr). This management protocol improves systemic blood flow by increasing pulmonary vascular resistance, thereby reducing pulmonary blood flow and increasing systemic flow [83, 84]. In patients with a bidirectional Glenn, hypoventilation (PCO_2 48 to 52 torr) has been shown to improve pulmonary blood flow [85]. Hypoventilation results in cerebral vascular vasodilatation thus increasing cerebral blood flow and the volume of blood return to the pulmonary arteries through the superior vena cava. Fontan physiology is dependent on passive pulmonary blood flow. Low tidal volumes, minimal positive end-expiratory pressure, and early extubation minimizes respiratory inhibition of passive pulmonary blood flow [86].

Cardiovascular Monitoring

Close cardiovascular monitoring is required during the initial postoperative period. Hemodynamic changes occur frequently due to rewarming, vasodilatation, variations in acid–base status, and changes in the catecholamine levels in response to the level of sedation and pain control. Continuous monitoring of arterial blood pressure, central venous pressure, cardiac output, oxygen consumption, and body temperature are extremely helpful. Hypotension often occurs during rewarming. Hypovolemia may occur due to fluid shifts from the intravascular space to the extravascular space. Postoperative hypothermia may also cause intravascular volume depletion but can be associated with normal systemic blood pressure due to peripheral vasoconstriction. Crystalloid, colloid, or blood may be used for fluid replacement.

Mild sodium and water retention occurs with CPB resulting in increased bodyweight. Spontaneous mobilization of interstitial fluids and diuresis typically occur once the patient is rewarmed and capillary leak has subsided. Diuretics may be used to enhance the diuretic phase, depending on the patient's clinical status.

Hypokalemia and hypomagnesemia often occur due to hemodilution. Potassium should be replaced through central lines to maintain serum levels above 3.5 mEq/L. Magnesium should be normalized to reduce the incidence of atrial and ventricular arrhythmias [87]. Metabolic acidosis should also be promptly corrected, as it may result in decreased cardiac function, impaired tissue perfusion, and reduced efficacy of inotropic agents. Causes of metabolic acidosis (e.g., hypothermia, hypovolemia, ischemia) should be addressed. Treatment with sodium bicarbonate (1 mEq/kg) may be required while correcting the cause of the acidosis.

Low Cardiac Output

There is no single sign or symptom diagnostic of low cardiac output syndrome. Frequent postoperative assessments and a low threshold of suspicion are imperative. Assessment includes capillary refill time, absent or weak peripheral pulses, cool mottled skin, decreased urinary output, acid–base balance, and core body temperature. Treatment of low cardiac output is based on identification and reversal of the etiology.

Cardiac output is the product of heart rate and stroke volume. Stroke volume is the difference between end-diastolic volume and end-systolic volume. Diastolic volume is dependent on preload and compliance of the ventricle. Systolic ejection is a function of afterload and contractility. Fluctuations in heart rate, preload, afterload, and contractility often occur during the postoperative period. The inter-relationship between the determinants of cardiac output can be manipulated to maintain adequate tissue perfusion. In general low cardiac output may be caused by: 1) alterations in heart rate and rhythm; 2) decreased preload due to hypovolemia, cardiac tamponade, or excessive

intrathoracic pressures; 3) increased afterload from PAH and increased systemic vascular resistance; 4) decreased contractility from acidosis, myocardial injury/ischemia due to poor myocardial protection during the operation, ventriculotomy, or acidosis; and 5) pump failure with myocardial injury. Detailed review of each determinant of cardiac output can be found in Chapter 7, *Perioperative Care*.

Mechanical Assist Devices

Mechanical assist devices were initially developed for the treatment of postcardiotomy cardiogenic shock. In recent years, however, they have also been used to provide temporary cardiac support in patients with irreversible cardiomyopathy until a donor heart becomes available for transplantation (i.e., "bridge to transplantation"). Less commonly these devices may be used in patients with reversible heart failure as a "bridge to recovery" by unloading the ventricle while it is in the recovery phase following an acute insult such as viral cardiomyopathy. Destination therapy refers to the use of some of these pumps to permanently support the heart in patients who are not transplant candidates because of major contraindications.

Several types of devices currently exist, and major technological advances in their development have been made in recent years. The basic left ventricular assist device (LVAD) configuration consists of an inflow or drainage cannula placed into the left atrium (via the left atrial appendage or right superior pulmonary vein/left atrial wall junction) or the left ventricle through the apex. The pump, which may lie in the paracorporeal or intracorporeal position, is filled by the inflow cannula and then pumps the blood either in a pulsatile or nonpulsatile manner into the outflow cannula, which is connected directly to the ascending aorta. In cases where the patient has established severe biventricular failure then a biventricular assist device (BIVAD) is used with the inflow cannula of the right-sided (RVAD) device draining the right atrium and the outflow cannula anastomosed to the main pulmonary artery. Similarly, a BIVAD may be required when right ventricular dysfunction or failure becomes unmasked shortly after the start of LVAD support. Once LVAD or BIVAD support has been established and the hemodynamics have been stabilized, catecholamine-based inotropes are weaned off to minimize the oxygen consumption and metabolic stress imposed on the unloaded ventricle, thus facilitating the process of recovery.

Further assessment to determine the likelihood of recovery is made with regular multidisciplinary discussions between the cardiac surgeon, cardiologist, and intensivist. Close monitoring of the central hemodynamics (Swan–Ganz catheter), mixed venous oxygen saturations, end-organ perfusion (renal output), metabolic status, and transesophageal echocardiogram parameters should all be used to determine whether the ventricle is showing convincing signs of recovery. The level of anticoagulation should be intensified during a 6–8-hour period of "low-flows" (<1.2 L) as part of the trial of weaning protocol. Once the decision has been made to remove the device, inotropes are re-established to support the patient in the early post-texplant period.

Short-Term Devices

Patients who develop postcardiotomy cardiogenic shock or acute decompensation of background chronic heart failure are often very ill and sometimes in extremis. Such patients can be successfully rescued by the expeditious use of short-term mechanical assist devices. Ideally a simple device is chosen that can be inserted relatively easily and often without the need for CPB support. This helps to minimize the inflammatory response and reduce postoperative bleeding. Furthermore, the management of the pump should be user-friendly for the medical and nursing staff on the ICU.

The ABIOMED, Inc (Danvers, MA) device has in the past been used successfully in patients requiring temporary support (a few days to a few weeks). It provides either univentricular or biventricular pulsatile mechanical support. The pump, which lies extracorporeally, consists of a 100 cc inflow and outflow polyurethane bladder separated by a trileaflet valve. The upper (atrial) chamber fills passively by gravity and as the inflow bladder fills the console detects the displacement of air around the bladder and sends a bolus of compressed air to the lower (outflow) chamber, pumping blood back to the patient. As the upper atrial bladder fills passively by gravity, preload is controlled simply by raising and lowering the level of the ABIOMED pump. Anticoagulation with systemic heparin is mandatory. The recognized complications include bleeding, respiratory failure, renal failure, neurologic deficit, and infection [88]. Several centers have reported good results with this device in the setting of postcardiotomy heart failure, with discharge rates of 50–59% and for bridge to transplantation of 50% [89,90].

More recently the Levitronix (CentriMag®) VAD has been used by many centers to provide temporary support for patients with acute decompensated heart failure. This device consists of a magnetically levitated rotating impeller without any mechanical bearings. This unique design minimizes trauma to the blood elements even at high flows. Cannulation is relatively simple and can often be done without CPB. The cannulae are exteriorized and connected to the pump, which sits at the bedside on a retort stand next to the relatively small console. Potential flow rates of up to 9.9 L/min can be achieved at 5500 rpm. There are no flexing valves, diaphragms, or sacs, and the unique design helps to minimize the risk of blood stagnation, turbulence,

and component failure. The degree of hemolysis associated with the CentriMag VAD, as measured by plasma-free hemoglobin levels, has been shown to be significantly lower compared to other similar devices. The CentiMag VAD has been used successfully in the setting of bridge to transplantation [91] and as a bridge to recovery for post-cardiotomy cardiogenic shock [92,93].

Long-Term Devices

The Thoratec Paracorporeal Ventricular Assist Device (PVAD; Thoratec Laboratories, Pleasanton, CA) is a pneumatic driven pulsatile assist device that can be used as an RVAD, LVAD, or BIVAD to provide medium- to long-term support. The pump is paracorporeal lying outside the anterior abdominal wall. The inflow and outflow ports contain a Bjork–Shiley tilting disc valves to maintain unidirectional flow. The device permits the patient to be ambulatory when connected to a mobile pneumatic console and has been used successfully as a bridge to transplantation as shown in many published series [94–96].

The HeartMate XVE® LVAD (Thoratec Laboratories) is a totally implantable pneumatically or electrically driven dual-chamber pump in titanium housing. The pump itself is positioned within the left upper quadrant of the abdomen or preperitoneally without entering the abdomen. The metallic side of the blood chamber is made of sintered titanium microspheres and this surface promotes the development of a neointima, which minimizes clot formation. These patients are therefore given only antiplatelet agents and do not require vitamin K antagonists. This device can generate up to 8 L/min of flow and allows the patient to mobilize and indeed be sent home while waiting for a heart transplant.

The HeartMate II® LVAD (Thoratec Laboratories) is a miniaturized rotary pump with axial flow design and represents a second generation of implantable assist devices. It is designed to be small, portable, and offers reliable long-term outpatient left ventricular support. The system consists of an internal blood pump with a percutaneous lead connected to an external system, driver, and power source. The pump itself is implanted preperitoneally below the left costal margin and under the rectus abdominis muscle. The inflow cannula is placed into the left ventricular apex and tunneled through the diaphragm at the costophrenic angle into the preperitoneal pocket. The outflow cannula traverses across the midline under the sternum and is anastomosed to the ascending aorta. Miller and colleagues [97] reported the results of a prospective multicenter study in 133 patients with end-stage heart failure who were on the waiting list for heart transplantation and were bridged using the HeartMate II device. The survival rate during support was 75% at 6 months and 68% at 12 months. At 3 months there was a significant improvement in functional status and in quality of life. Major adverse events included postoperative bleeding, stroke, right heart failure, and percutaneous lead infection.

Specific Congenital Heart Defects

Atrial Septal Defects

Atrial septal defects are the third most common ACHD [98]. There are several types of ASD, according to the region of the atrial septum involved. Secundum ASDs are the most common and can be amenable to percutaneous closure, provided that their anatomy is suitable. Primum, sinus venosus, and coronary sinus ASDs all require surgical closure.

Common presenting symptoms in the adult are arrhythmia and exercise intolerance with dyspnea on exertion, while many are identified during routine medical screening. Repair of an ASD is usually indicated when significant left-to-right shunt results in dilatation of the right ventricle. Other indications for closure include documented paradoxical embolism and platypnea–orthodeoxia syndrome [5]. In patients with unrepaired ASD the incidence of atrial arrhythmias increases with age. The incidence of atrial arrhythmias is as high as 83% in patients greater than 50 years of age [99]. Atrial arrhythmias may precipitate atrial thrombosis and the potential for paradoxical emboli. Moreover, as patients become older, the incidence of congestive heart failure due to right heart failure increases. Tricuspid regurgitation has been identified by echocardiogram in 28% of patients greater than 50 years of age and in 50% of patients greater than 60 years of age [99].

Secundum Atrial Septal Defects

Patients with a secundum ASD and adequate rims around the defect are amenable to transcatheter closure of the ASD. The Amplatzer® Septal Occluder (AGA Medical Corporation, Plymouth, MN) has been shown to be safe and effective for this purpose. Chan and colleagues [100] used the Amplatzer Septal Occluder in 100 patients (86 ASD, 7 Fontan fenestrations, and 7 patent foramen ovales [PFOs]), failing to close the defect only in seven. There was one device embolization requiring surgical removal. The immediate total occlusion rate was 20.4%, increasing to 98.9% complete occlusion at 3 months' follow-up. Numerous subsequent reports have confirmed these data [101–103].

Patients who do not meet the criteria for transcatheter closure of the ASD require CPB for closure. Anatomic indications for surgical closure usually include a stretched secundum ASD with a diameter of more than 36 mm, inadequate atrial septal rims, and proximity of the defect to the AV valves, the coronary sinus, or the vena cavae [104]. All patients older than 40 years of age undergoing surgical or transcatheter ASD closure should also be assessed for possible coexistent acquired heart disease, including coronary

artery disease [105]. Primary suture closure, autologous pericardial patch closure, or prosthetic patch closure can be used. Minimally invasive direct-access surgery has also been used for ASD closure. Byrne and colleagues [106] reported 34 cases of minimally invasive ASD closure. Access to the mediastinum was obtained through a right parasternal, submammary, or upper hemisternotomy incision. There were no operative deaths, but 12% developed major complications (one adult respiratory distress syndrome, one ASD recurrence, one upper extremity deep venous thrombosis, and one reoperation for bleeding). As experience in minimally invasive cardiac procedures increases, safety and efficacy have improved. Bichell and colleagues [107] reported ASD closure through a 3.5–5.0-cm midline incision with division of the xiphoid process alone or with opening the lower portion of the sternum. No early deaths or major complications were reported, with a very brief hospital stay (mean, 2.7 days).

Standard open median sternotomy remains a safe and effective approach to the mediastinum for ASD closure. Following bicaval cannulation, the patient is cooled to 32 °C and the heart arrested with cold blood antegrade cardioplegia. A right atrial atriotomy is then performed, taking care not to injure the crista terminalis, which may lead to an increased risk of postoperative atrial arrhythmias. For small defects or defects with redundant septum primum, the ASD is closed primarily by a two-layer running suture technique. If the defect is too large, or adequate septum primum is not present for a tension-free primary repair, pericardial or prosthetic patch closure is performed. Once de-airing maneuvers have been accomplished, the patient is weaned from CPB. In patients with associated mitral valve disease, valve repair or replacement is performed through the ASD before closure.

Surgical outcomes of ASD repair in adults are excellent. Perioperative mortality is less than 2% and morbidity (primarily atrial arrhythmias) is 8–13% [99,108,109]. Long-term mortality is 1–2% and morbidity 12–13% for a mean follow-up of 9.6 and 7.5 years, respectively [99,109]. Improvement in NYHA functional class is reported in most patients [99]. Patient age greater than 40 years at the time of closure is considered an independent risk factor for the development of postoperative atrial flutter or fibrillation [110]. Postoperative embolic events have been reported in 4% of patents undergoing either primary or patch closure of ASD [99].

Long-term follow up of adult patients following closure of ASD (mean, 42.2 years of age; range, 18.5–74.9 years), revealed that 22% of late deaths were due to stroke, occurring in patients with atrial flutter or fibrillation [111]. Stroke was also the main cause of death in patients who had undergone closure of ASD after the age of 60 years [112]. Because of the risk of postoperative emboli, anticoagulation should be maintained for 3 months following closure of ASD. Anticoagulation is continued in patients with persistent atrial arrhythmias. For patients with preoperative atrial flutter or fibrillation, the right-sided maze or Cox-maze III operation has been advocated in addition to ASD closure [113].

The management of adult patients with an ASD is determined by a number of factors, including symptoms, age, size of the defect, associated lesions, and pulmonary vascular resistance. Patients with a significant ASD with signs of right heart dilatation and a pulmonary artery systolic or mean pressure of less than 50% of the corresponding aortic pressures should be offered elective closure, irrespective of age [104]. Young adults and older asymptomatic patients with indications for closure should undergo closure of the ASD on diagnosis to prevent long-term sequelae [110]. If left untreated, the risk of death is 25% by 27 years of age, 50% by 36 years, 75% by 50 years, and 90% by the age of 60 [114]. Death occurs due to the sequelae of prolonged increased pulmonary blood flow, PAH, atrial arrhythmias, embolic events, and congestive heart failure.

The management of unrepaired ASDs in patients of over the age of 60, especially when significant comorbidities exist, remains controversial. A few studies have reported percutaneous closure of ASD in elderly patients, with conflicting results [111,115]. In fact, ASD closure can result in abrupt elevation of left ventricular overload, leading to left ventricular dysfunction and acute pulmonary edema, especially in patients with impaired systolic or diastolic left ventricular function [116,117]. Preexisting left ventricular dysfunction may also be concealed by the presence of left-to-right ventricular shunting at atrial level, which unloads the left ventricle [118]. Yalonetsky and colleagues have reported successful transcatheter ASD closure in elderly patients who presented with normal left ventricular function [115]. Patients who were thought to be at high risk of developing hemodynamic compromise on ASD closure (moderate to severe elevated pulmonary pressure, impaired ventricular diastolic function, and modest left ventricular size) underwent transient balloon occlusion of the ASD with repeated measurements of pulmonary wedged pressure, left ventricular end-diastolic pressure, systemic arterial pressure, and cardiac output. No cases of postoperative acute pulmonary edema were reported.

Patients with an ASD and suspected PAH should undergo right heart cardiac catheterization to measure pulmonary artery pressures. Pulmonary hypertension is a complication of the prolonged increased in pulmonary blood flow due to the ASD. Pulmonary artery hypertension and pulmonary artery resistance increase significantly between the age groups of 18–40 years and 40–60 years, with no further increase in patients over 60 years of age [119]. The incidence of PAH (mean pulmonary artery pressure >25 mmHg) is variable, ranging from 9 to 33% [108,119]. Gatzoulis and colleagues [108] showed that the

outcome of surgical repair was independent of pulmonary artery pressure in the presence of a left-to-right atrial shunt. However, the patient with the highest pulmonary artery pressure in their study had a mean pressure of 45 mmHg. In contrast, the experience of Vogel and colleagues [119] with patients who had repair of ASD and PAH was not as encouraging. In their series there was one death (mean pulmonary artery pressure, 68 mmHg, Qp/Qs 1.8:1) and two patients were listed for heart transplantation (mean pulmonary artery pressures, 55 mmHg and 76 mmHg, respectively). Balint and colleagues performed a similar study with patients undergoing percutaneous ASD closure and moderate to severe PAH, defined as moderate (50–59 mmHg) or severe (≥60 mmHg) according to the right ventricular systolic pressure (RVSP) [120]. Early follow-up showed no deaths and an overall decrease of the RVSP from 57 (11) mmHg to 51 (17) mmHg ($p = 0.003$) whereas late follow-up showed a decrease in the overall mean RVSP but only 44% of patients had complete normalization of pressures (defined as RVSP <40 mmHg). In addition, two deaths occurred during late follow-up, one due to bowel obstruction and another due to recurrent pulmonary embolism.

ASD closure in patients with PAH remains a controversial issue. In the past operability in this group of patients was often decided based on lung biopsy. Currently, it relies on cardiac catheterization and the degree of vasoreactivity of the pulmonary circulation by means of inhaled 100% oxygen or nitric oxide, intravenous epoprostenol, or adenosine. In patients with evidence of vasoreactivity during acute testing but high pulmonary vascular resistance and bidirectional shunting, balloon test occlusion may provide additional information on the suitability for closure and the possible post-procedural outcome [24]. Detailed history, physical examination, resting oxygen saturations, chest X-ray, ECG, and echocardiography are also important in the clinical decision [121]. In our practice, left-to-right shunting, that is to say in the absence of reversal of shunting and, thus, absence of resting or exercise-induced cyanosis, is a favorable marker for operation.

Sinus Venosus Atrial Septal Defect

Sinus venosus ASD is a much rarer entity than secundum ASD. Commonly, the defect occurs at the junction between the superior vena cava and the right atrium. Typically there is associated partial anomalous drainage of the right superior pulmonary vein into the lateral aspect of the superior vena cava at the level of the defect. When compared to patients with secundum type ASD, patients with sinus venosus ASD have a three-fold greater incidence of pulmonary hypertension (26% vs. 9%) and a four-fold greater incidence of increased pulmonary artery resistance (16% vs. 4%) [119]. Pulmonary artery hypertension and increased pulmonary artery resistance occur at an earlier age in patients with sinus venosus type defects than in those with secundum defects [119]. Therefore, adults with sinus venosus ASD should undergo right heart catheterization to rule out severe PAH, which would preclude closure of the defect. Because PAH and increased pulmonary artery resistance occur at an earlier stage, early closure of the sinus venosus ASD is indicated to avoid the consequences of chronic pulmonary hypertension.

Sinus venosus ASD can only be repaired surgically. Intraoperative transesophageal echocardiography can be used to define the anatomy and physiology both before and after the repair. Following median sternotomy, CPB is instituted using aortobicaval cannulation. Once the heart is arrested with antegrade blood cardioplegia, a vertical atriotomy is made from the atrial appendage to the pulmonary vein. This incision improves visualization of the defect, which can be repaired using autologous pericardium. Following de-airing maneuvers, the patient is weaned from CPB. Echocardiography is performed to confirm unobstructed flow from the superior pulmonary vein to the left atrium and to rule out obstruction of superior vena cava flow from the pericardial patch.

Patients should be placed on thromboprophylaxis for 3 months following repair to reduce the risk of postoperative embolic events.

Ostium Primum Atrial Septal Defect

Ostium primum ASD are part of the spectrum of AVSD. With ostium primum ASD, the ventricular septum may be intact or there can be an associated restrictive (partial AVSD) or nonrestrictive inlet VSD (complete AVSD) [122]. In partial AVSD, the defect is adjacent to a common AV junction guarded by a common AV valve. In partial AVSD, the common five-leaflet valve is divided into a trileaflet left and quadrileaflet right AV valve, which differ anatomically to the normal mitral and tricuspid valves. The trileaflet left AV valve has been described as "cleft" mitral valve, as the commissure between the two bridging leaflets may resemble this. However, cleft mitral valve is a different anatomic entity to AVSD and the two should not be confused.

The age of clinical presentation is variable depending on various hemodynamic factors. In fact, the hemodynamic consequences of partial AVSD are similar to those of secundum ASD, with varying degrees of left-to-right shunt depending on the physiology of the left and right ventricles, the presence and severity of left AV valve insufficiency, and the presence and size of a VSD. Many individuals present in the third and fourth decades of life due to atrial arrhythmias or symptoms of congestive heart failure [123]. Atrial arrhythmias occur in 25% of patients by age 30 and in 80% by age 45 [124]. Transthoracic echocardiography is usually sufficient for the diagnosis, based on identification of the anatomic defect and typical

left AV valve anatomy. Owing to the high incidence of atrial arrhythmias and hemodynamic sequelae, repair should be undertaken once the diagnosis is made. Cardiac catheterization should be performed in individuals greater then 40 years of age to determine the presence of associated acquired cardiac disease that needs to be repaired at the time of the operation.

Intraoperative transesophageal echocardiogram is used for preoperative assessment of anatomy and function, and postoperatively to determine adequacy of left AV valve repair. The surgical approach includes bicaval cannulation, antegrade blood cardioplegia, and topical cooling. Following cardiac arrest, the right atrium is entered through a longitudinal incision taking care not to injure the crista terminalis. The left AV valve is approached through the ASD. Repair of the "cleft" is accomplished by interrupted suture technique aligning the edges of the anterior leaflet and reapproximating the body of the leaflet. Rarely, inadequate leaflet tissue is present necessitating extensive mitral valve repair or mitral valve replacement. The ASD is closed with an appropriately sized pericardial patch. Prosthetic patches are avoided because of the possibility of residual mitral regurgitation that could cause hemolytic anemia from the jet striking the prosthetic patch. The displaced AV node is avoided during suturing of the ASD patch by staying on the left atrial side and suturing only on valve tissue and the fibrous rim of the defect or by placing the sutures in the right AV valve tissue and circling around the AV node area. If necessary, the patch can be sutured around the coronary sinus leaving the coronary sinus blood flow to the left atrium. Following rewarming and separation from CPB, if normal sinus rhythm is not present, atrial and ventricular pacing wires should be placed due to the risk of developing complete heart block.

Surgical results are excellent, with no patient mortality reported in some recent series [123,125]. The majority of patients undergoing repair show significant improvement in NYHA functional class following operation. Preoperative pulmonary hypertension has not precluded repair. Burke and colleagues [123] reported successful operative outcomes in nine patients with pulmonary artery pressures greater than 25 mmHg and in four patients with a pulmonary vascular resistance of greater than 4 Wood units. They did not find any relationship between elevated pulmonary artery pressures and postoperative mortality. Gatzoulis and colleagues [125] reported on 13 patients with elevated pulmonary artery pressures (pulmonary artery systolic pressure greater than 45 mmHg) who underwent successful repair. However, preoperative pulmonary artery pressures were greater than 50 mmHg in four of the six patients who died. Overall, preoperative systolic pulmonary artery pressure was significantly higher in those who died (56.8 ± 9.1 mmHg) than in survivors (42.7 ± 13.4 mmHg). Others have also noted an association between late mortality and elevated preoperative pulmonary artery pressures [126].

Atrial arrhythmias occur in up to 30% of patients before operation and typically persist after repair. Increased pulmonary artery pressure is associated with an increased incidence of preoperative atrial arrhythmias that persist postoperatively [126]. Patients with atrial arrhythmias that are refractory to medical therapy should be considered for either the right-sided maze or the Cox-maze III at the time of operation [127]. Following repair, complete AV node block requiring permanent pacemaker implantation has been reported in 2–6% of patients [123,125].

Patients should receive anticoagulation for 3 months after repair due to the risk of thromboembolic events from patch closure of the ASD. Anticoagulation should be continued in those patients who have persistent atrial arrhythmias.

Late complications include left AV valve regurgitation, left ventricular outflow tract (LVOT) obstruction, and residual intracardiac shunts. Reoperation for residual ostium primum defect or left AV valve regurgitation is approximately 6–10% [123,125,126]. Left AV valve replacement is often required under these circumstances. Therefore, these patients require continuous lifelong follow-up.

Fossa Ovalis Membrane Aneurysm

Fossa ovalis membrane aneurysm (FOMA) has been identified in 4–8% of adult patients undergoing echocardiography [128]. FOMA is defined as a greater than 10-mm deviation of the membrane from the atrial septal plane during the cardiac cycle [129]. FOMA has been reported in 5–39% of patients with cerebral ischemic events studied with transesophageal echocardiography [130]. Patients with FOMA and cerebral embolism have an associated interatrial communication more frequently than patients without such embolic events [129]. The degree of foramen ovale membrane redundancy is directly related to the incidence of a PFO; 45% of patients with >15 mm membrane redundancy have a PFO compared with an 8% incidence in patients with <15 mm of redundancy [131].

In patients with a large redundant fossa ovalis membrane, a PFO should be ruled out by transesophageal echocardiography. Injection of microbubbles (agitated saline) into the right atrium improves the identification of the PFO. The association of FOMA and PFO with cerebral embolic events could suggest closure of PFO at the time of identification. However, this finding remains controversial as several other studies have failed to show a higher risk [132,133]. According to the American Heart Association guidelines, due to lack of data, PFO closure may only be considered for patients with recurrent episodes of cryptogenic stroke despite medical therapy [134].

Ventricular Septal Defects

Ventricular septal defect is the most commonly recognized CHD, constituting over 20% of all forms of CHD [135]. Most VSDs are restrictive (< 5 mm in diameter) and undergo spontaneous closure during the first year of life [136]. Mechanisms responsible for spontaneous closure include apposition of tricuspid valve tissue to the defect (with or without formation of a tricuspid pouch), hemodynamic changes resulting in fibrosis of the defect, or hypertrophy of interventricular muscle bundles (muscular VSDs). Prolapse of the right coronary cusp or the noncoronary cusp of the aortic valve may also result in VSD closure. Patients who reach adulthood with restrictive VSDs may experience spontaneous closure of the VSD during any decade of life, but this is less likely. Neumayer and associates [137] observed spontaneous closure of VSDs in 10% of their adult population (a 0.8%/year spontaneous closure rate). However, 25% of the total population experienced complications related to the VSD, including infective endocarditis (11%), aortic regurgitation secondary to leaflet involvement (20%), and symptomatic arrhythmias (8.5%).

Large unrestrictive VSDs may lead to Eisenmenger syndrome. Niwa and colleagues [138] reported an 83% prevalence of Eisenmenger syndrome in adults with nonrestrictive VSD. They also reported a 67% 5-year actuarial survival rate after initial diagnosis of the VSD. Large unrestrictive VSD are usually identified in infancy and require full evaluation with right heart catheterization before closure. If Qp/Qs ratio is greater than 1.5:1.0 and the pulmonary vascular resistance is less than 6 Wood units, closure of the VSD is recommended. The approach to VSD repair depends on the type and size of the VSD, as well as the presence of associated lesions. Following aortobicaval cannulation, systemic cooling, and antegrade cardioplegic arrest of the heart, the right atrium is opened with a linear medial atriotomy. The VSD is usually closed through the tricuspid valve with a Dacron patch and interrupted pledgeted suture technique.

If PAH precludes closure of the VSD, right heart function is evaluated at the time of cardiac catheterization and with the use of CMR imaging and echocardiography. If right heart function is adequate, lung transplantation with concomitant closure of the VSD may be undertaken. If the right heart function is poor, or if significant associated cardiac lesions are present, heart–lung transplantation is recommended. The experience with this approach is limited due to donor availability.

Closure of small restrictive VSD is somewhat controversial because of the 10% spontaneous closure rate. Moreover, most patients with restrictive VSD remain asymptomatic and free of complications. However, with a 25% complication rate, we recommend Dacron patch closure of the VSD. Doubly committed subarterial VSD with prolapse of the aortic valve can be approached through the aortic valve via an aortotomy. Indications to close a restrictive VSD are significant left-to-right shunt causing left ventricular dilation, aortic cusp prolapse with significant aortic regurgitation, recurrent endocarditis, and when patients undergo surgery for other reasons such as double-chambered RV or RVOT obstruction. In the case of aortic cusp prolapse, the aortic valve leaflets are resuspended to alleviate aortic insufficiency after VSD closure. Long-term follow-up is required to evaluate pulmonary artery pressure because pulmonary vascular resistance may continue to rise following closure of a large VSD during adulthood [139,140].

Successful transcatheter closure of multiple muscular VSD has been reported to be safe and effective [141,142]. Percutaneous occluders have also been used for perimembranous VSD. Chessa and colleagues have reported successful transcatheter VSD closure in 40 patients, (28 perimembranous and 12 muscular VSD) with two different Amplatzer devices (the mVSD and pVSD Occluder) [143]. In six patients complications occurred, most commonly conduction and rhythm abnormalities during or immediately after VSD closure (one left transient anterior hemiblock, one transient complete AV block, and two ventricular fibrillations). One month after the procedure, one patient had a residual shunt, one aortic regurgitation, and another tricuspid regurgitation. However, larger controlled studies are needed to assess the effectiveness and safety of the percutaneous closure of perimembranous VSD owing to their proximity to the aortic and tricuspid valves.

Tetralogy of Fallot

Today, complete repair of tetralogy of Fallot is typically performed during infancy. Early repair improves overall survival and long-term ventricular function and reduces the development of late-onset atrial and ventricular arrhythmias [144]. Patients with unrepaired tetralogy of Fallot rarely survive to adulthood: 34% of patients die within the first year of life and only 24% survive until the age of 10 [145]. Mortality is a constant 6.4%/year thereafter [145,146]. The clinical picture of an adult with unrepaired tetralogy of Fallot depends on the severity of the RVOT obstruction. Patients with "pink" tetralogy are those with mild RVOT obstruction, which may not be sufficient to protect the pulmonary circulation from the effects the large VSD. Eisenmenger syndrome may develop as a result. Typically, however, RVOT obstruction is sufficient to protect the pulmonary circulation but results in right-to left shunting and cyanosis. Patients, thus, often present with the sequelae of chronic cyanosis and/or Eisenmenger syndrome: erythrocytosis, coagulation, massive hemoptysis, cerebral vascular accidents secondary to abscesses and emboli, epistaxis, and infective endocarditis [144,147].

Once the echocardiographic diagnosis of tetralogy of Fallot is made, surgical correction should not be delayed. The principles and surgical techniques for complete repair are similar to those adhered to during complete neonatal repair with emphasis on the transatrial transannular approach to avoid a right ventriculotomy and with preservation of pulmonary valve function. Repairs are performed with hypothermic CPB, bicaval cannulation, and cold blood cardioplegic arrest. Systemic to pulmonary artery shunts are ligated. Local stenosis or arterial distortion is dealt with by a variety of arterioplasty techniques. Through a right atriotomy and through the tricuspid valve, parietal and septal muscle bundles are excised to relieve subvalvar stenosis. The size of the RVOT can be evaluated with dilators following resection. The pulmonary artery is incised and a pulmonary valvotomy performed. The pulmonary artery is repaired using a pericardial patch that, when necessary, can be fashioned into a pantaloon shape extending into the sinuses. If annular enlargement is required, a limited incision is performed where possible through an anterior commissure onto the RVOT. If to relieve RVOT obstruction significant pulmonary regurgitation is created, it is our practice in adults to replace the pulmonary valve with a homograft, as in our experience acute pulmonary incompetence is tolerated poorly in the adult with tetralogy undergoing repair.

Contemporary series [147–149] report early mortality in adult patients undergoing complete repair of tetralogy of Fallot to be 2.5–16%. Older age at the time of the initial operation has been shown to be a risk factor for surgical mortality and decreased long-term survival. High early mortality may be due to the negative influences of chronic cyanosis and the development of right ventricular dysfunction [149]. Despite the high mortality, surgical results are superior to the natural history of uncorrected tetralogy of Fallot.

The incidence of perioperative supraventricular and ventricular arrhythmias has been reported to be greater then 35% and may be associated with right ventricular dysfunction at the time of operation [148,150]. Avoidance of right ventricular incisions and earlier repair may reduce the incidence of ventricular arrhythmias.

Patients who survive the first postoperative year have an actuarial 10-, 20-, 30-, and 35-year survival of 94%, 93%, 83%, and 72%, respectively [151]. Long-term survival did not differ significantly from the normal population. The majority of patients report clinical improvement following complete repair; 80–90% of patients are reported to be in NYHA class I or II [147,148,151]. Ventricular arrhythmias following complete repair of tetralogy of Fallot have been reported in 33–35% of patients [144,152] and may occur from 2 months to 21 years postoperatively (mean, 7.3 years) [153]. Ventricular arrhythmias were significantly related to longer follow-up duration, an older age at follow-up, older age at time of operation, and higher postoperative right ventricular systolic and end-diastolic pressures. Right ventriculotomy has been associated with late right ventricular dilatation and subsequent dysfunction leading to increased risk of ventricular ectopy. Misaki and associates identified abnormal histopathology at the site of the prior right ventriculotomy scar [154]. These scar sites were found to be within the region of delayed activation and were part of the re-entry circuit. A site of VT predominantly in the infundibular septum adjacent to the VSD patch has also been described. There is also an association between chronic right ventricular volume overload and ventricular arrhythmias [155,156]. Deal and colleagues studied nine patients with symptomatic ventricular arrhythmias after complete repair of tetralogy of Fallot (mean follow-up after repair, 16 years). They concluded that patients with inducible sustained VT showed improvement with antiarrhythmia drug therapy, whereas patients with right ventricular hypertension and VT were likely to be refractory to drug therapy. Oechslin and colleagues [151] showed a 26% reduction in ventricular arrhythmias after reoperation on patients with prior complete repair of tetralogy of Fallot. Reoperation included intraoperative electrophysiology, mapping, cryoablation of re-entry circuits, and relief of right ventricular volume overloading (repair of RVOT obstruction, reduction of pulmonary insufficiency [PI], or closure of residual VSD).

Ventricular arrhythmias have been associated with sudden death in up to 6% of individuals following complete repair of tetralogy of Fallot [157]. The high incidence of sudden cardiac death has led to an increased utilization of ICDs in repaired tetralogy of Fallot, which should be considered for selected patients [158]. Several factors predicting sudden cardiac death have been proposed, including poor exercise capacity, cardiac enlargement, severe systemic ventricular systolic dysfunction, symptomatic dysrhythmias, prolonged QRS duration, and inducible VT [33,34,159]. In a multicenter study by Khairy and colleagues, indications for ICD therapy in repaired tetralogy of Fallot were primary prevention of sudden cardiac death in high-risk patients with no near-fatal events and secondary prevention in patients with resuscitated cardiac arrest or clinical sustained ventricular arrhythmias [160]. When used in tetralogy of Fallot appropriate ICD shots have been noted for both primary (23.5%) and secondary (30.2%) intervention. However, Witte and colleagues noted an inappropriate shock rate of 20% in a total of 20 patients with repaired tetralogy of Fallot [161] which was considered to be due to the high incidence of atrial arrhythmias.

Right ventricular dysfunction and PI are common following intracardiac repair of tetralogy of Fallot. The need for transannular patch placement or previous large ventriculotomy for relief of RVOT obstruction results in variable degrees of PI. The preservation of pulmonary valve

function and avoidance of right ventriculotomy in contemporary surgical management of tetralogy is aimed at reducing the incidence of these important long-term problems.

Shimazaki and colleagues [162] show that despite PI, most patients remained asymptomatic until 30 years of age. Beyond the age of 30–40 years, progressively more patients become symptomatic with onset of right heart failure. In addition to time, the effects of PI are aggravated by additional residual lesions, including pulmonary stenosis, aneurysm of the RVOT or residual VSD. Several reports [163,164] show a correlation between pulmonary valve incompetence with right ventricular volume overload, and significant reduction in cardiovascular response to exercise in the absence of symptoms. Symptoms of increasing fatigue and dyspnea typically result from advanced irreversible myocardial damage. Pulmonary valve insufficiency may also be associated with development of arrhythmias and possible sudden death [156,157,165,166].

Timing of intervention in patients with complete repair of tetralogy of Fallot and PI is controversial. The presence of symptoms, heart size, arrhythmias, evidence of right ventricular dysfunction, QRS prolongation, tricuspid regurgitation, and impaired exercise capacity may all influence the decision. Interval change in one or more of these parameters is an important consideration [56]. Ilbawi and associates [164] showed that once a patient becomes symptomatic, irreversible right ventricular myocardial damage has occurred. Valve insertion did not reverse the RV dysfunction but prevented further progression, supporting the view that valve insertion should occur before the development of symptoms. However, early pulmonary valve replacement in all asymptomatic patients with severe PI would lead to overtreatment of a large proportion of patients and possible future reoperations for a failing prosthetic valve. Meijboom and colleagues, in a long-term follow-up study, showed that 89% of patients with severe PI who were asymptomatic and had not undergone pulmonary valve replacement, had a satisfactory outcome 12 years later [167] but 11% were considered to have had an unsatisfactory result on the basis of prolongation of the QRS complex beyond 180 msec, the development of new arrhythmias or persistent symptoms after pulmonary valve replacement.

Based on the above studies, patients with significant PI and associated residual defects and patients who are symptomatic with significant PI should undergo insertion of a pulmonary valve. Asymptomatic patients should be followed with serial echocardiography and MRI studies, together with exercise stress testing (Plate 46.2, see plate section opposite p. 594) [168]. Cardiac catheterization should be reserved for patients older than 40 years of age referred for surgery or when catheter intervention is contemplated.

Idriss and colleagues [169] reported the first series of patients undergoing pulmonary valve insertion following complete repair of tetralogy of Fallot. Since the initial report, several authors [163,164,170,171] have reported on pulmonary valve insertion after complete repair. These studies confirm the low morbidity and mortality, improvement in NYHA functional class, decrease in right ventricular volume, improved RV function, and tentative reduction of arrhythmias following pulmonary valve insertion.

The type of valve to be inserted into the RVOT is debated; mechanical valve versus bioprosthetic valve versus pulmonary homograft, although few authors advocate the use of mechanical valves. Mechanical valves require long-term anticoagulation with its attendant risks. Kawachi and colleagues [172] compared St. Jude Medical mechanical valves and bioprosthetic valves placed in the RVOT. Thrombotic events occurred in $5.5 \pm 2.5\%$/valve-year versus 0%/valve-year in patients with mechanical versus bioprosthetic valves. Freedom from reoperation rate was $83 \pm 9\%$ in mechanical valves versus $94 \pm 4\%$ in bioprosthetic valves. There were also more frequent overall valve-related events with mechanical versus bioprosthetic valves ($6.6 \pm 2.7\%$ versus $1.1 \pm 0.6\%$/valve year).

Long-term durability of the bioprosthetic valve in the pulmonary position has been demonstrated. Ten-year actuarial freedom from reoperation has been reported to be 86% [171]. Ilbawi and associates [164] reported a 10-year complication-free actuarial life of 82% and a functional actuarial life of 84%. Fukada and coworkers [173] reviewed the long-term outcome of 10 patients who underwent pulmonary valve replacement with bioprostheses. They reported no valve dysfunction with a maximal follow-up of 12.2 years. The improved results of the bioprosthetic valve in the RVOT when compared to a similar valve in the LVOT may be due to a reduced hemodynamic load.

Pulmonary homografts have been used successfully for the reconstruction of the RVOT. d'Udekem and colleagues [174] reported on 15 patients who had prior transannular patch repair of tetralogy of Fallot and presented with dyspnea on exertion and fatigue. All patients had insertion of a pulmonary homograft at reoperation. At a mean follow-up of 25 months (range, 3–54 months) there were no deaths, no reoperations, and all patients had decreased RV dilatation and functional recovery of the right ventricle. Long-term durability of pulmonary homografts has been demonstrated after the Ross operation [175]. Freedom from reoperation for homograft obstruction was $94 \pm 3\%$ at 8 years' follow-up.

Despite the very good outcomes of surgical pulmonary valve replacement, patients with repaired tetralogy of Fallot who received their first pulmonary valve replacement at a relatively young age may need numerous reoperations in the future. The recent introduction of

percutaneous pulmonary valve replacement as an alternative option for carefully selected patients is currently limited by the size of the RVOT [176]. The feasibility of percutaneous pulmonary valve replacement in each patient can be assessed by means of MRI, which provides useful images of the RVOT and its dimensions. Additional CT imaging is required before intervention to assess the anatomy of the proximal coronary arteries and their anatomic relation to the RVOT.

In our center when surgically replacing the pulmonary valve in patients with tetralogy of Fallot, in selected cases we disconnect the right ventricle from the pulmonary artery and use a homograft as a short conduit between these two structures. This policy is based on the theory that as the homograft calcifies and becomes rigid by the time the pulmonary valve fails; this will provide a suitable bed for potential implantation of a stented valve. This policy has been supported by a recent publication describing percutaneous implantation of the pulmonary valve in the RVOT following the Ross procedure [177].

Coarctation of the Aorta

Coarctation of the aorta has a biphasic presentation. Initial presentation is shortly after birth when the ductus begins to close resulting in the sequelae of decreased blood flow distal to the coarctation. The second phase of presentation occurs beyond early childhood when patients present with proximal hypertension and weak and delayed femoral pulses. If left untreated, less than 10% of patients with coarctation of the aorta survive beyond the age of 50 due to cardiovascular or cerebrovascular complications [178], including premature coronary artery disease, congestive cardiac failure, myocardial infarction, intracranial hemorrhage, aortic dissection, and aortic rupture.

The most commonly congenital malformation associated to aortic coarctation is bicuspid aortic valve, seen in 20–40% of patients with coarctation of the aorta [179]. Congenital aneurysm of the circle of Willis is seen less commonly and predisposes to rupture [180].

Following identification of proximal hypertension on physical examination, imaging studies are obtained to define the anatomy of the aortic arch and descending aorta, collateral vessels, and gradients across the coarctation. Advances in imaging techniques provide a variety of methods to evaluate aortic coarctation preoperatively. Angiography remains the standard, providing information regarding anatomy and hemodynamics. Noninvasive imaging with transesophageal echocardiography, high-resolution spiral CT, and magnetic resonance angiography provide similar information and, in some cases, have replaced angiography in the diagnostic stage. Routine coronary angiography should be performed in patients over 40 years of age because of the increased incidence of coronary artery disease. The internal mammary artery is often dilated, with enlarged collateral branches and associated severe atherosclerosis. Significant aortic valve disease (aortic insufficiency and aortic stenosis) occurs in up to 58% of adult patients [181]. Thus, thorough evaluation of aortic valve function is required. Excellent results have been obtained in patients undergoing repair of coarctation and simultaneous myocardial revascularization or aortic valve repair [182].

Treatment for coarctation may be achieved by operation or catheter interventions, including angioplasty and stent implantation. Repair is indicated when the peak to peak coarctation gradient is greater or equal to 20 mmHg or when the peak to peak coarctation gradient is less than 20 mmHg in the presence of significant anatomic obstruction in the presence of left ventricular hypertrophy [5]. Resting gradients may be normal despite significant anatomic stenosis, therefore measurements should be repeated during exercise. In the presence of native discrete coarctation, the choice of catheter versus surgical treatment remains controversial and should be determined jointly between cardiologists and surgeons specialized in ACHD. There is a broad consensus, however, that angioplasty with stenting is the preferred approach to recoarctation or residual stenosis after previous surgery. In patients with previously repaired coarctation, surgical repair should be performed in the presence of concomitant hypoplasia of the aortic arch or long coarctation segment [5].

Surgical repair of coarctation of the aorta is typically approached by a left posterolateral thoracotomy through the fourth or fifth interspace. The patient is positioned so that adequate exposure of the left femoral vessels can be obtained if necessary. Enlarged friable chest wall collateral vessels must be identified and ligated to conserve blood loss during thoracotomy. The aorta is extensively mobilized including the arch, great vessels, and descending aorta. The ligamentum is ligated and divided. Care must be taken during dissection to avoid injury to the recurrent laryngeal and phrenic nerves. Enlarged lymphatics are ligated to prevent subsequent chylothorax. Test occlusion of the aorta is performed to determine the need for distal bypass. Distal pressures are maintained above 40 mmHg during the procedure. If the pressure falls below 40 mmHg, pharmacologic attempts at correction are initially performed. If pharmacologic measures fail, distal bypass is instituted with either atriofemoral bypass or femoral–femoral bypass. Other techniques of spinal cord protection include short cross-clamp times, local and systemic hypothermia, intraoperative monitoring of somatosensory-evoked potentials, cerebral spinal fluid drainage, and pharmacologic intervention. Despite these various techniques, no single method has been shown to impact significantly on the incidence of spinal cord injury. Spinal cord ischemia and motor impairment incidence remains low

(1–2%) but is increased in those patients with poorly developed collaterals [183].

Correction of the coarctation is by resection with end-to-end anastomosis, prosthetic patch aortoplasty, or tube graft. In adults, the usefulness of primary repair (end-to-end anastomosis) is limited due to the immobility of the aorta and the necessity to resect multiple, often enlarged intercostal arteries. Aortotomy with prosthetic patch aortoplasty can be performed with partial occluding vascular clamps therefore avoiding complete occlusion of the aorta during repair. The patch should extend from the proximal origin of the left subclavian artery to 1 cm below the coarctation. Intercostal arteries are temporarily occluded with snares to provide adequate visualization. The coarctation ridge is not resected. Resection of the ridge is associated with a 20% incidence of aneurysm formation at the site of resection [184]. Long-segment stenosis can be repaired with resection and interposition tube graft. This requires cross-clamping of the aorta and the inherent risk of paraplegia. The risk of paraplegia can be reduced with the above-described protective measures and limiting the cross-clamp time. Extra-anatomic bypass grafting with a tube graft from the left subclavian artery to the distal descending aorta can be performed without occlusion of the aorta. The procedure is performed through a left thoracotomy and is especially useful in patients who have undergone previous repair of a coarctation [185,186].

Postoperative hypertension is aggressively treated with sodium nitroprusside. The paradoxical hypertension is due to an initial response to increased circulating catecholamines. Once the catecholamine response subsides, hypertension is sustained owing to elevated levels of norepinephrine and angiotensin. Once oral intake is begun sodium nitroprusside is discontinued and oral antihypertensive agents begun. Severe acute arteritis may occur below the coarctation [187,188]. Mesenteric arteritis may develop leading to ischemic bowel or infarction requiring resection. Therefore, enteral nutrition is withheld for 24 hours following the operation.

The long-term effects of coarctation repair on adult systemic hypertension are debated. It is generally accepted that the risk of postoperative hypertension increases with increasing age at repair and the degree of preoperative hypertension. Late hypertension is more prevalent in patients who have had repair after 1 year of age (27%) when compared to those who have had surgery during infancy (4%) [189]. Despite successful surgical repair of aortic coarctation, Kaemmerer and colleagues [190] showed that in a total of 44 patients who underwent repair as adults, 72% had hypertension at rest, 20% during exercise, and 53% during ambulatory blood pressure monitoring. However, others [185] have shown significant reduction in blood pressure with many patients normotensive without the use of antihypertensives. This difference may be explained by the fact that patients may be normotensive at rest but develop significant hypertension during exercise. Vigano reported that nearly 50% of their patients who were normotensive at rest became hypertensive during exercise [191]. Therefore measurements of blood pressure should be taken during exercise at follow-up visits. Because of the risk of recurrent hypertension, coronary artery disease, and recoarctation, patients with repaired coarctation should be followed closely. Either beta-blockers or ACE inhibitors should be instituted if hypertension occurs. The incidence of recurrent coarctation, after initial repair, is between 5% and 30% [192–194]. The occurrence of recoarctation in the adult population is usually a complex problem associated with cardiovascular disease, including aortic arch hypoplasia, aneurysmal dilatation of the ascending aorta, and valvar disease in the form of bicuspid aortic valve, mitral valve disease, or subvalvar aortic stenosis [195]. Several factors have been sited as possible predictors for aneurysm formation at the site of coarctation repair. Oliver *et al*. looked at predictors for major aortic wall complications, including aortic aneurysm, dissection and acute rupture, and their results indicated advanced age and bicuspid aortic valve as independent risk factors [196]. Aneurysm formation has also been reported to be related to the type of primary surgical repair, with a higher incidence late after previous patch aortoplasty, and to transcatheter relief of the coarctation [197,198]. Both true and false aneurysms occur and if not detected on routine follow-up and left untreated, they may present at the time of rupture with a mortality as high as 36% [199]. Cardiovascular magnetic resonance imaging is the diagnostic modality of choice and, therefore, recommended for all patients with previous coarctation repair. Small aneurysms can be followed by repeated MRI but large aneurysms, those with rapid progression in size, and those producing symptoms, are associated with rupture and should be repaired [200]. The traditional surgical approach for coarctation and recoarctation repair has been through a left thoracotomy. However, postoperative complications of reoperation for recoarctation in the adult through a left thoracotomy are common and include postoperative bleeding, false aneurysm formation, residual coarctation, and recurrent laryngeal nerve palsy [201]. For this reason in cases of complex recoarctation (with hypoplasia of the aortic arch, aortic/mitral valve involvement, or ischemic heart disease), we would consider repair through a median sternotomy placing a conduit between the ascending and descending aorta approached through the posterior pericardium. The advantage of this approach is that it deals effectively with associated arch hypoplasia [202]. It avoids the often difficult dissection of the lung and collateral circulation associated with rethoracotomy and eliminates the risk of damage to the recurrent laryngeal nerve, which is often intimately bound to vascular structures by fibrous tissue at the site of re-coarctation [56].

Approach through a rethoracotomy may still be required for the excision of expanding or ruptured aneurysms associated with recoarctation or occurring at the site of previous coarctation repair. In cases of recoarctation, where the collateral circulation is often inadequate, our preference is to use CPB, either atriofemoral or femoral–femoral, to maintain descending thoracic perfusion during the period of aortic cross-clamping. In the most complex cases of ruptured aortic aneurysm, CPB with hypothermia and circulatory arrest may be required.

In the past years there has been a dramatic increase in the use of endovascular stenting and angioplasty in adults with coarctation, utilized for primary repair, repair of recoarctation, and associated aneurysms [203–205]. However, no prospective, randomized, controlled trial of surgical versus endovascular therapy is available in the adult population, and only two studies have been reported in children [206,207]. Hernandez-Gonzalez and colleagues [207] showed that angioplasty had higher rates of recurrence (50% vs. 21%) and a higher incidence of persistent hypertension (49% vs. 19%) compared to surgery. Cowley and colleagues [206] showed, as well, a higher rate of recurrence with repeat intervention after angioplasty repair but also a higher incidence of aneurysm formation (35% vs. 0%) in patients treated with angioplasty. An extensive review of the different methods for treatment of coarctation in adults has showed that surgical repair has a very low morbidity and mortality that is comparable to transcatheter treatment [203]. However, the shorter hospitalization and lower costs of endovascular repair have increased the use of this method in many centers. Today, the current view is that percutaneous intervention in patients with recoarctation after surgical repair is the preferred approach. However, this requires the absence of complex concomitant features such as aneurysm formation and coarctation affecting the adjoining arch arterial branches [5]. In cases of uncomplicated native coarctation, balloon angioplasty with or without stent placement may be considered as an alternative to surgery, although it is still thought to be a less suitable method for long-segment or tortuous forms of coarctation. In conclusion, each case of adult patient with native or recurrent coarctation should be discussed jointly between surgeons and cardiologists to determine the most appropriate management strategy. A hybrid approach may be considered for patients with coarctation of the aorta and significant concomitant aortic valve disease. Aortic valve replacement in this case may follow suit after endovascular relief of coarctation with primary stenting.

Fontan-Type Repair

The Fontan operation establishes a separation between the pulmonary and systemic circulation by directing right atrial blood flow or total caval blood flow to the pulmonary arteries. The Fontan operation is used for congenital lesions in which biventricular repair is not possible. These lesions include tricuspid atresia (or absent right AV valve connection), double-inlet left ventricle, and other complex anatomic defects. Eligibility criteria for the Fontan operation include normal distal pulmonary artery anatomy, low pulmonary vascular resistance, adequate systolic and diastolic function, and no AV valve insufficiency.

Atriopulmonary Fontan Connection

Atriopulmonary Fontan connections are associated with significant long-term complications. Over time, the right atrium becomes severely dilated and is a source of arrhythmias and thromboembolic events (Figure 46.2) [208]. Moreover, it results in excessive energy dissipation from sluggish blood flow within the cardiac chamber, compromising Fontan hemodynamics. Anatomic obstruction of the right-sided pulmonary veins can also occur due to external mechanical compression by the right atrium [209]. However, arrhythmias are the most common complication,

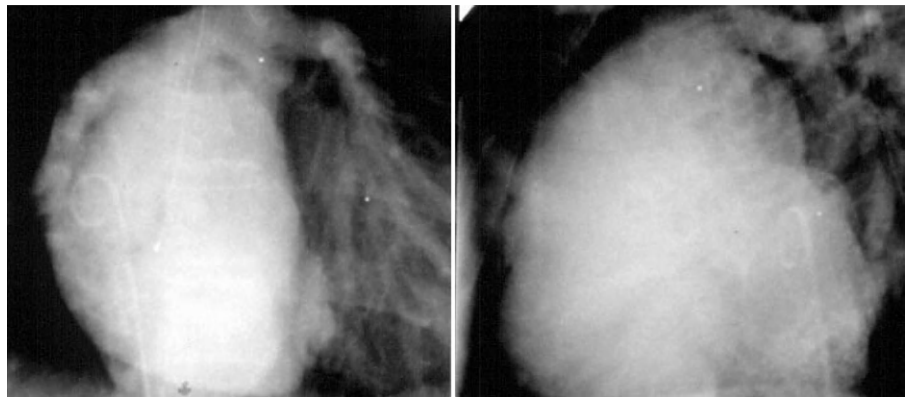

Figure 46.2 Cardiac catheterization of a patient with an atriopulmonary Fontan to the left pulmonary artery and a classic Glenn shunt to the right pulmonary artery. Note the huge dilated right atrium.

the incidence and severity of which increases with time and causes further deterioration in a vicious circle of arrhythmia, right atrial enlargement, and heart failure [210].

Efforts to circumvent these complications have resulted in the present-day modifications of the Fontan procedure. These modifications include total cavopulmonary artery connections using intracardiac (lateral tunnel) or extracardiac techniques with or without fenestration. Encouraging results with total cavopulmonary artery connections have nowadays made the atriopulmonary Fontan connection obsolete. However, there remain a significant number of adult patients with atriopulmonary connection, who require close follow-up and treatment of sequelae and may need further surgical intervention. Therefore it is important for the adult congenital heart surgeon to be familiar with this technique.

Intracardiac Fontan Connection

The intracardiac lateral tunnel connects the inferior vena caval blood flow to the pulmonary artery using an intra-atrial baffle. The baffle, which is constructed of PTFE patch material, is sutured to the lateral wall of the right atrium and directs blood from the inferior vena cava through the cardiac end of the transected superior vena cava, which is anastomosed to the pulmonary artery. The superior vena caval blood flow is directed to the right pulmonary artery through a bidirectional Glenn shunt.

When compared with the atriopulmonary Fontan connection, the intracardiac lateral tunnel minimizes the risk of pulmonary venous obstruction due to dilatation of the right atrium. In addition, the lateral tunnel reduces atrial enlargement by decreasing the right atrial surface area exposed to elevated venous pressures. The lateral tunnel has also been shown to improve the Fontan circuit hemodynamics by allowing laminar flow through the baffle, thus reducing energy loss from turbulent flow within the dilated right atrium [211]. Further improvement in flow dynamics can be obtained by offsetting the superior vena cava–pulmonary artery anastomosis from the inferior vena caval flow and directing the superior vena cava blood flow to the left pulmonary artery by flaring the superior vena cava pulmonary artery anastomosis [212].

The benefit on flow hemodynamics may, however, be lost with the development of atrial arrhythmias due to unidirectional block at the suture line [213]. In addition, extensive dissection and suturing in the region of the sinoatrial node and nodal artery increase the risk of developing postoperative atrial arrhythmias [214–216]. The incidence of late arrhythmias may be reduced by limiting the dissection around the sinoatrial node and nodal artery, avoiding suturing the lateral patch near or to the crista terminalis, and by using multiple shallow bites when suturing the baffle to the atrium rather than broad deep advances [217].

Extracardiac Fontan Connection

The extracardiac total cavopulmonary connection uses a PTFE tube graft to connect the inferior vena cava to the right pulmonary artery. This has several potential advantages when compared to the lateral tunnel intracardiac Fontan connection. Prolonged cardioplegic arrest and extended CPB times with intracardiac Fontan are associated with an increased risk of early postoperative death or failure necessitating takedown of the Fontan circulation [218–220]. Extracardiac total cavopulmonary connection does not require cardioplegic arrest and CPB time is reduced or eliminated completely [221,222] optimizing early postoperative outcomes. Fluid dynamic studies have also shown that the extracardiac connection with offset between the conduit and superior vena cava provides superior hemodynamics compared to the intracardiac lateral tunnel technique [223].

In addition to improved hemodynamics, the extracardiac Fontan may reduce the incidence of supraventricular arrhythmias [224]. Exposure of the right atrium to elevated systemic venous pressures is eliminated. Atrial incision and suture lines are avoided. Dissection in the region of the sinoatrial node and nodal artery is reduced. Ventricular dysfunction due to cardioplegic arrest and prolonged CPB times is minimized. Petrossian and colleagues [224] reported a 10% incidence of new-onset transient supraventricular tachyarrhythmias and an 8% incidence of transient sinus node dysfunction during the early postoperative period in patients undergoing extracardiac Fontan procedures. The extracardiac conduit technique also permits extensive reduction arterioplasty of the right atrium thereby eliminating the dysfunctional and arrhythmogenic right atrial tissue [225]. Although early results are promising, longer follow-up will be necessary to establish the benefits of the extracardiac total cavopulmonary connection.

Arrhythmias Following Fontan Operations

Atrial arrhythmias following the Fontan operation continue to be a source of significant morbidity and mortality. The incidence of arrhythmias following the Fontan operation has been reported to be 14–32% [219,226,227]. The type of Fontan circulation has been identified as an independent risk factor for atrial arrhythmias, with a higher risk after atriopulmonary connection [227–229]. Gelatt and colleagues [230] followed up 228 patients who underwent the Fontan operation for a mean interval of 4.4 years and found that late atrial tachyarrhythmias were noted in 29% of patients who received an atriopulmonary connection and 14% of those who received a total cavopulmonary connection. It has been postulated that, following atriopulmonary connection, the extensive atrial incisions and the exposure of the right atrium to the increased systemic pressure are significant factors predisposing to atrial

rhythm disturbances. These factors have lead to a metamorphosis of the Fontan operation in an attempt to reduce the incidence of late-onset arrhythmias. The intracardiac lateral tunnel reduced the incidence of arrhythmias by decreasing exposure of the right atrium to elevated systemic venous pressures [213–216]. The extracardiac total cavopulmonary connection further reduces the number of atrial incisions and suture lines, which further reduces the substrate for arrhythmias.

The results of medical therapy for recurrent symptomatic arrhythmias in the Fontan population have been disappointing. Amiodarone appears to be the most effective drug, but is associated with significant long-term complications. Moreover, many patients experience recurrent arrhythmic episodes despite treatment with antiarrhythmics. Medical therapy for recurrent symptomatic arrhythmias in the Fontan population is associated with significant morbidity and mortality as high as 22% [231]. Radiofrequency catheter ablation is increasingly being used in Fontan patients but is associated with a relatively low success rate (at most 50%) and a high recurrence rate during short-term follow-up (at least 50%) [232–234]. Abnormal hemodynamics, massive dilation of the right atrium, and a thickened fibrotic atrial wall resulting in suboptimal ablation lesions all contribute to these disappointing results [127]. The use of new mapping techniques may result in a greater short- and long-term success rate of ablation, but this will always be suboptimal as long as the dilating right atrium remains part of the Fontan circuit.

The rationale for reoperation in patients with medically refractory symptomatic arrhythmias is based on the concept that improving flow hemodynamics by reduction atrioplasty and elimination of the high-pressure atrium by lateral tunnel or extracardiac techniques will reduce the arrhythmia burden. However, reoperation for refractory atrial arrhythmias without specific antiarrhythmia intervention is associated with a high incidence of recurrent tachycardia (76% recurrence rate) (Table 46.2) [208,209, 228,231,235–239]. In fact, preexisting Fontan intra-atrial suture lines are the substrate for re-entry atrial tachycardias and should be dealt with by arrhythmia intervention (arrhythmia circuit cryoablation) [214,215].

Takahashi and colleagues [240] demonstrated a reduction in prevalence (95% vs. 28%, $p < 0.0001$) and severity (severity score 7.3 vs. 3.3, $p = 0.001$) of atrial tachyarrhythmias in patients who underwent Fontan conversion with concomitant arrhythmia surgery, in contrast to patients without arrhythmia intervention (47% vs. 53%; 3.3 vs. 3.9, p = NS). Survival at 3 years postoperatively was noted to be 84% in the total patient population, without a significantly different probability of survival between the two groups. Mavroudis *et al.* [241] have reported a combined technique of Fontan conversion with concomitant arrhythmia surgery in a total of 111 patients from 1994 to 2006. The first group (nine cases from 1994–1996) underwent isthmus cryoablation for arrhythmia control, the second group (51 patients from 1996–2003) underwent early modified right atrial maze and Cox-maze III and the third group (51 patients from 2003–2006) had recent modifications of the modified right atrial maze and left atrial Cox-maze III procedure for both atrial fibrillation and left macro re-entrant atrial tachycardia (see Figure 41.11) [241]. One (0.9%) early and six (5.4%) late deaths were reported and six patients (5.4%) required cardiac transplantation 1 week and 6, 8, 10, 11, and 33 months after Fontan conversion with arrhythmia surgery. Late recurrence of atrial tachycardia (30 days after surgery) occurred in 13.5% of total patient population. The recurrence rate was 33% in the first group, 15.7% in the second group, and 7.8% in the third group of patients ($p = 0.3$, group 2 versus group 3) (Figure 46.3) [241]. Importantly, cardiac transplantation is not precluded as a significant mode of therapy for the failed Fontan. However, the current metamorphosis of arrhythmia surgery to a modified right-sided maze procedure for right atrial re-entry tachycardia, and to left atrial Cox-maze procedure for atrial fibrillation and left atrial re-entry tachycardia, has made Fontan conversion with arrhythmia surgery an efficacious alternative for Fontan patients with concomitant atrial arrhythmias.

Table 46.2 Results of Fontan conversion without arrhythmia surgery.

Author	# Patients	Mortality	Transplant	Arrhythmia recurrence
Balaji *et al.* [228]	3	33% (1)	–	0/2
Kao *et al.* [235]	3	0	–	2/3
Vitullo *et al.* [209]	9	11% (1)	–	3/3

Protein-Losing Enteropathy Following Fontan Operations

Protein-losing enteropathy (PLE) has been reported in up to 20% of patients following the Fontan operation [242,243].

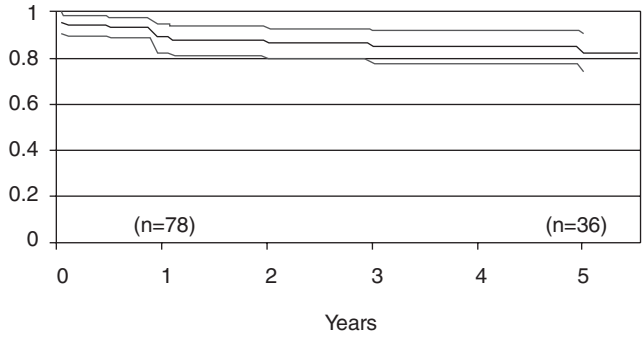

Figure 46.3 Kaplan-Meier curve with 95% confidence interval showing actuarial freedom from arrhythmia recurrence in 111 patients who underwent Fontan conversion with arrhythmia surgery. (Reproduced with permission from Mavroudis *et al.* [241].)

The etiology of PLE is poorly understood, and, as such, PLE treatment remains inadequate. It is thought that chronic venous congestion and persistent elevated pressure in the superior vena cava result in altered lymphatic drainage through the thoracic duct [244]. In addition, increased inferior vena caval and portal pressures lead to intestinal congestion and increased lymphatic production which allows proteins and lymphocytes to leak from the lymphatics [243]. Chronic congestion and enteric loss of proteins can also cause an inflammatory response, which may play a role in the pathogenesis of PLE.

Because the exact pathophysiologic mechanism of PLE remains undefined, several treatment strategies have emerged that can be loosely divided into medical only, surgical, and interventional. In reality, most patients receive a combination of all three approaches as no single approach is effective.

Medical Treatment of PLE

Medical therapy is directed towards the improvement of symptoms (diuretics, intermittent infusion of albumin), hemodynamics (digitalis, ventricular afterload reduction), and the inflammatory response associated with PLE (steroids) as well as prevention of further complications with antiarrhythmics and anticoagulants [243].

Steroids. Suppression of the inflammatory response to chronic enteric protein loss may account for the improvement seen with steroids. Rychik and colleagues [245] reported improvement in two patients following use of steroids. Mertens and colleagues [243], reported near-complete resolution of PLE symptoms in five of 16 patients treated with steroids, while seven had some subjective improvement, and four patients showed no improvement. As no consistent improvement following the addition of steroids has been reported, steroids are used on an individual case-by-case basis.

Heparin. Sulfated glycolsaminoglycans may play an important role in the regulation of vascular and renal albumin loss [246,247]. Murch and colleagues [247] reported three infants with congenital PLE who had complete absence of enterocyte heparan sulfate on histochemistry. These infants had profound enteric protein loss with secretory diarrhea and absorption failure despite having histologically normal intestines. Two of the three infants did not survive. Donnelly and colleagues [246] reported on the use of heparin infusion in three patients with PLE. The decision to use heparin was made after a parent noted that her son's symptoms of PLE improved whenever his anticoagulation therapy was changed from warfarin to intravenous heparin. All three patients showed dramatic improvement in symptoms, marked elevations in serum albumin levels, and quantitative reversal of enteric protein loss within a few weeks of beginning therapy. Each time heparin therapy was discontinued their symptoms recurred and thus daily subcutaneous heparin therapy was continued indefinitely. While heparin may have a role in the treatment of PLE, once again results are inconsistent.

Surgical Treatment of PLE

Several surgical approaches to PLE have been suggested. Initial interventions are directed towards correction and relief of anatomic obstructions within the Fontan circuit. This may be achieved either surgically or through a percutaneous approach. Obstruction may be due to stenosis within the Fontan circuit or the pulmonary arteries. Resolution of PLE symptoms following successful intervention and complete relief of the obstruction has not been consistent [243].

Conversion to total cavopulmonary connection. Conversion of the Fontan circuit (e.g., atriopulmonary to total cavopulmonary connection) has also had varying results on PLE. Identification of patients who will definitely benefit from total cavopulmonary connection conversion remains problematic. Abella *et al.* [248], Conte and colleagues [249], van Son and colleagues [239] have all reported on patients in whom PLE symptoms improved following total cavopulmonary connection conversion, however mortality remains high in this subgroup of patients.

The high perioperative mortality may be due to reluctance to refer these debilitated patients to surgery. Oftentimes, surgery is undertaken after all other efforts to treat the patient have failed. The variable results following total cavopulmonary connection conversion may be explained by differences in flow dynamics between different Fontan circuits and their effect on individual patients [211,212,223]. Total cavopulmonary connection conversion should be undertaken early in this subset of patients before significant ventricular dysfunction and clinical deterioration occur.

Fenestration. Baffle fenestration either surgically or by percutaneous catheter techniques has been reported to improve symptoms of PLE [250–252]. In the Rychik series [252] three of five patients showed significant sustained (greater than 2 years) improvement in PLE symptoms. Improvement was noted when arterial saturations were ≤86%, consistent with diversion of approximately one-third of the systemic venous return through the fenestration [252,253]. Improvement was felt to be due to increased cardiac output resulting in greater blood flow and increased oxygen delivery to the tissues. Mertens and colleagues [243] reported similar encouraging results with percutaneous creation of an intra-atrial fenestration in five patients. Three patients had complete resolution of symptoms while two patients had mild improvement. However, two patients suffered thromboembolic events with neurologic complications. Therefore, anticoagulation before and after fenestration is recommended.

Cardiac transplantation. Cardiac transplantation has also been used for patients with a failing Fontan circulation and PLE. Gamba and colleagues have published a study regarding 14 failed Fontan patients who underwent cardiac transplantantion [254]. Seven of them had PLE. They reported a total of 10 late survivors with a mean follow-up of 64 ± 42 months (range, 9.2 to 123 months). In the six surviving patients with PLE, the serum protein levels reached a normal value within 18 months after discharge. Another study by Mertens and colleagues reported 10 Fontan patients with PLE who underwent heart transplantation [255]. Out of seven long-term survivors, one patient had continuous problems with PLE despite excellent graft function and another patient had temporary improvement of PLE with recurrence after 1 year, despite normal graft function. Based on the results of these studies, one concludes that cardiac transplantation is yet another treatment strategy for symptomatic PLE; however postoperative morbidity and mortality remain high.

Medical Versus Surgical Therapy for PLE

In an international multicenter registry [243] of patients with Fontan circulation (35 centers, 3029 patients) the incidence of symptomatic PLE was 4%. Comparison was made between medical and surgical management (Figure 46.4) [208, 243]: patients with PLE following the Fontan operation had a poor prognosis (5-year survival, 59%). Medical therapy alone was associated with a 46% mortality rate and only 25% of patients treated showed improvement. Patients treated surgically did not fare better. There was a 62% mortality rate and only 19% of patients reported symptomatic improvement following surgery, perhaps reflecting late referral to surgery. It is clear that PLE following the Fontan operation is associated with significant morbidity and mortality. New approaches to the single ventricle and new treatment strategies are needed.

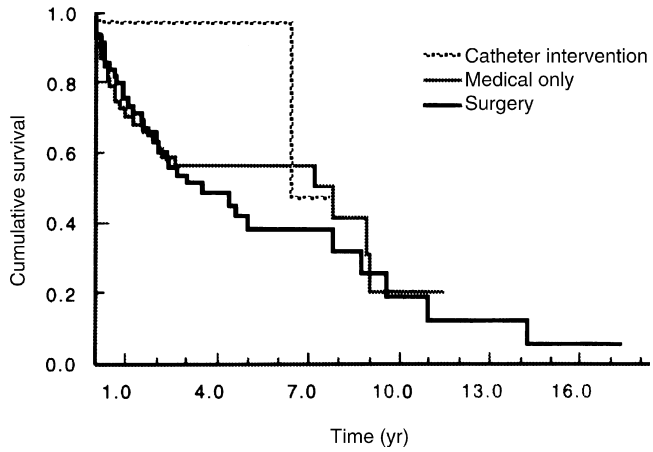

Figure 46.4 Survival analysis of different treatment groups. A Kaplan-Meier analysis of the different treatment subgroups is represented. Time zero represents the date of diagnosis of protein-losing enteropathy. Log-rank analysis did not show a significant effect of treatment on survival. (Reproduced with permission from Mertens *et al.* [243].)

Features of the Fontan Operation in Adult Patients

In appropriately selected adult patients, the Fontan operation results in a reduction of left ventricle size, normalization of mass-to-volume ratio and an increase in myocardial contractile function [256]. Improvement in NYHA functional class is seen in most patients after the operation. Long-term function is best when a morphologic left rather than right ventricle is present [257].

Extracardiac Fontan reduces the number of atrial incisions and atrial suture lines with the expectation of developing fewer atrial arrhythmias. Despite diversion of blood from the right atrium to the pulmonary artery, atrial arrhythmias can still develop within the dilated high pressure right atrium. Reduction atrioplasty and elimination of the high pressure right atrium have been proposed to control atrial arrhythmias [210,230,242]. Mavroudis [258] and others [236,237] have noted that conversion of an atriopulmonary Fontan to a total cavopulmonary artery connection without arrhythmia surgery continues to be associated with a high incidence of recurrent atrial arrhythmias. Preoperative electrophysiology studies have identified three consistent sites of re-entry circuits that may predispose to the development of atrial arrhythmias. These sites of reentry circuits include 1) the area between the coronary sinus os and the inferior vena cava os; 2) the area

between the AV valve annulus and the inferior vena cava; and 3) the lateral atriotomy and its relationship to the length of the crista terminalis, and the region at the superior limbus corresponding to the rim of the prior ASD patch. Mavroudis and coworkers [258] reported a series of 20 patients (mean age, 17.3 ± 6.8 years) who underwent conversion to a total cavopulmonary artery connection. All patients had cryoablation of the re-entry sites at the time of the conversion operation. There were no deaths, and all patients experienced improvement in NYHA class. Pacemakers were placed in all patients as a "back up" in the event future arrhythmias were to occur. Only two patients developed late postoperative arrhythmias that were controlled with long-term antiarrhythmia medication.

Postoperative care following extracardiac Fontan and arrhythmia surgery includes maintenance of adequate preload by the infusion of intravenous fluids at 25% above the calculated maintenance rate. This additional fluid is discontinued on the first postoperative day. Early arrhythmias have been noted despite performance of the right-sided maze operation or the Cox-maze III operation. Aldactone has had some effect on reducing the development of early postoperative atrial arrhythmias. Therefore, aldactone is started in the early postoperative period. The risk of recurrent arrhythmias persists for up to 3 months postoperatively until scarring of the cryoablation lesions develops. To reduce the recurrence of arrhythmias, amiodarone is added in the immediate postoperative time period and weaned during subsequent months. Anticoagulation with coumadin is begun once the chest tubes are removed and titrated to an INR of 2.5 times normal. Anticoagulation should be continued for lifetime to help prevent thrombus formation and subsequent embolic events.

Late Fontan-Type Repair

Originally, Fontan recommended operation in children greater than 4 years of age but less then 15 years old [259]. Currently, definitive repair between the ages of 18 months and 6 years of age is being recommended [260]. Occasionally adult patients with uncorrected cardiac lesions, with or without previous palliative procedures (systemic-to-pulmonary artery shunts, pulmonary artery band) are candidates for a Fontan-type operation. In 1986, Castaneda and colleagues [261] reported on their experience with the Fontan procedure in patients greater than 15 years of age. Their favorable results suggested that age alone should not be a contraindication to the Fontan operation. They identified that pulmonary vascular resistance index >2.0 Um^2 and distorted pulmonary artery anatomy not amenable to repair were the only significant risk factors of poor outcomes following the Fontan operation in adults.

Previous palliative procedures (systemic-to-pulmonary artery shunt, Glenn procedure, or pulmonary artery band) are not a contraindication to the Fontan operation in the presence of favorable hemodynamics. However, anatomic distortion of the pulmonary arteries due to palliative procedures must be repaired at the time of the Fontan operation to reduce postoperative risk.

The outcomes of the Fontan operation performed in adults have been promising (Figure 46.5) [208,262]. Results obtained at the University of California-Los Angeles between 1982 and 1994 are similar to those reported by others [262]. In 21 patients aged 18–40 years who underwent Fontan operation at the University of California between 1982 and 1994, there was a 5% early mortality and 81% survival rate at 12 years. However, almost one-third of patients experienced major perioperative complications, mainly prolonged pleural effusions. Long-term complications include

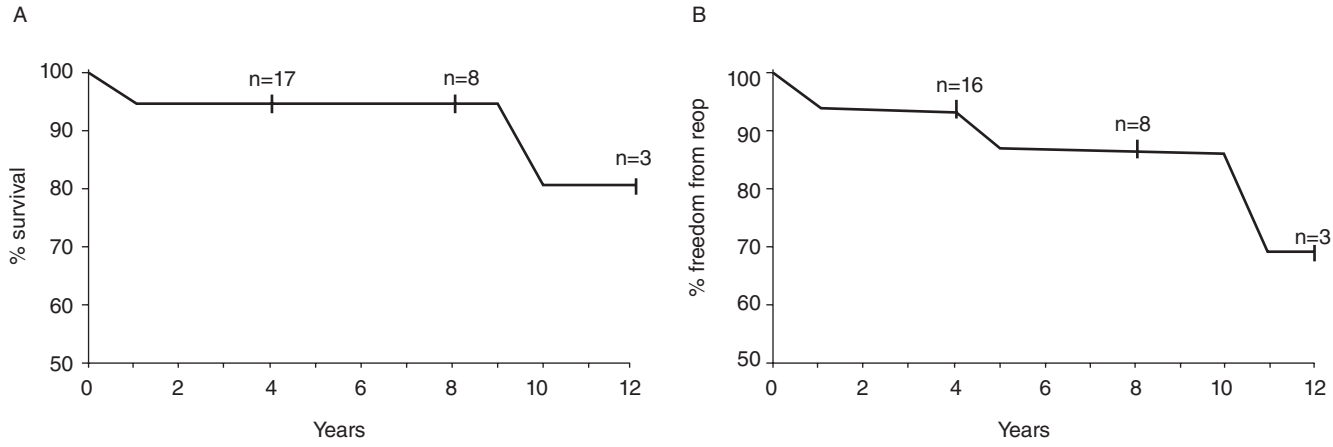

Figure 46.5 A, Actuarial survival after Fontan procedure in 21 adult patients. **B,** Actuarial freedom from reoperation in 19 adult patients after Fontan procedure. (Reproduced with permission from Gates *et al.* [262].)

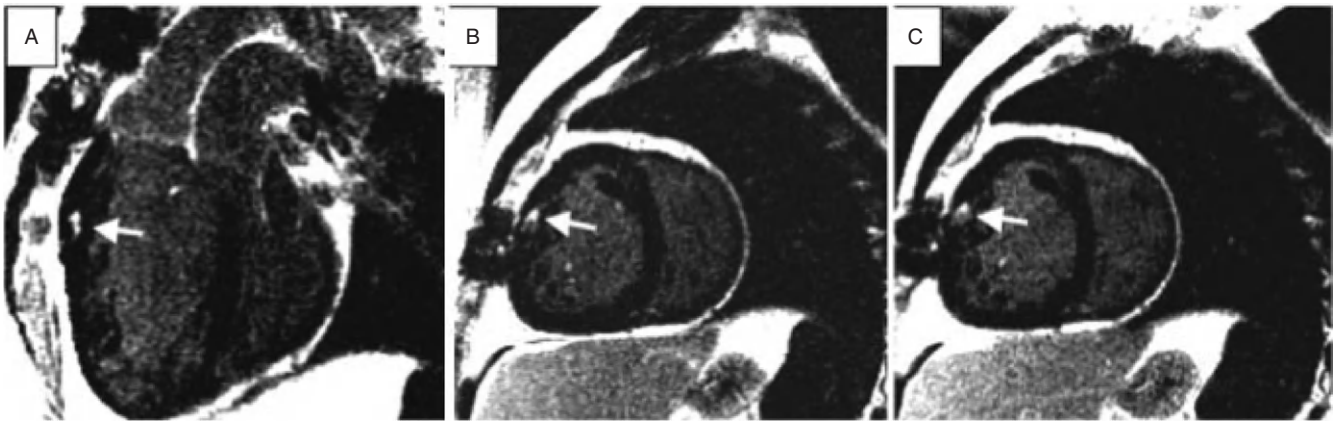

Figure 46.6 A, Inversion recovery cardiovascular magnetic resonance image demonstrating focal late gadolinium enhancement in the trabeculated free-wall of the right ventricle (arrow). **B,** The same region is seen in the short-axis view (arrow) and (**C**) is still present when the phase encoding has been swapped (arrow). There is also subtle enhancement at the junction between the right and left ventricle. (Reproduced with permission from Babu-Narayan *et al*. [8].)

atrial arrhythmias in 24–37% of patients, and PLE in up to 28% of patients [262,263].

Recently Fujii *et al*. [264] reported on the mid- to long-term outcome of total cavopulmonary connection in high-risk adult candidates. Twenty-five consecutive adult patients aged 18 years or more who underwent total cavopulmonary connection had at least two of the following risk factors: age more than 30 years, systemic ventricular ejection fraction of <50%, AV valve regurgitation moderate, pulmonary arterial index <200, mean pulmonary arterial pressure ≥15 mmHg, pulmonary arterial resistance of 2 units or greater, arrhythmia, PLE, NYHA functional class III or greater, previous Fontan procedure, systemic ventricular outflow tract obstruction, and end-diastolic pressure in the systemic ventricle ≥11 mmHg. There were one early death and two late deaths occurring in a mean follow-up period of 57 ± 45 months.

Although the majority of the adult total cavopulmonary connection candidates tolerated the total cavopulmonary connection procedure in the early postoperative period, the accumulation of risk factors influenced late mortality.

Transposition of the Great Arteries

The current treatment of choice for complete (D) transposition of great arteries is the arterial switch operation performed during the neonatal period. However, until the early 1980s, repair of transposition of the great arteries consisted of atrial switch (Mustard or Senning) procedures. With atrial switch operations, venous return is redirected at atrial level by means of an intra-atrial baffle. The Mustard procedure uses either pericardium or Dacron to construct the baffle, whereas the Senning operation uses the native atrial wall. Atrial switch provides physiologic but not anatomic correction of the defect. In fact, while early and intermediate-term results are excellent, the presence of a morphologically right systemic ventricle and extensive atrial scarring account for the significant late morbidity and mortality due to progressive right ventricular dysfunction and high arrhythmic burden (mechanoelectric interaction: interaction between the failing ventricle and arrhythmias) [265–267]. Both intra-atrial re-entrant tachycardia and sinus node dysfunction are common in these patients, the latter being more common late after Mustard (rather than Senning) repair due to direct injury of the sinus node during surgery or progressive fibrosis related to surgical scars (Figure 46.6) [8,268].

Patients with sinus node dysfunction often require pacemaker implantation, with more than 20% of Mustard and Senning patients being paced [269]. Before lead insertion stenosis of the superior vena cava baffle limb and baffle leaks should be identified. Atrial arrhythmias can be treated through catheter ablation or medically. Ablation is increasingly used nowadays with a reported success rate in the region of 80% [270]. In refractory cases, medical therapy with amiodarone is an option, although side effects are a significant issue [271].

Patients with previous Mustard or Senning repair are at high risk of sudden cardiac death, presumably due to rapidly conducted atrial arrhythmias or primary ventricular arrhythmias [272]. Predictors of sudden cardiac death include a history of concomitant VSD, impaired systemic ventricular function, atrial flutter, and increased QT dispersion [266,273,274]. Limited data are available on prophy-

lactic implantation of ICDs in high-risk patients, which currently relies on clinical judgment.

Other late complications of the Mustard or Senning repair include baffle leaks and baffle stenosis. In the case of baffle leaks, percutaneous closure may be achieved using septal occlude devices and/or stents [275]. Baffle obstruction develops most commonly in the systemic venous pathway with a frequency of 5–15% [261], usually affecting the superior vena cava limb. Surgical baffle revision for this complication is, however, uncommon as flow is redirected to the inferior vena cava through collaterals. Transcatheter repair may be achieved with balloon dilatation and stent implantation of the baffle stenosis [276,277]. If acquired atresia has taken place, a Brockenbrough needle or a radiofrequency wire can be used in order to perforate the atretic site, followed by stent implantation to ensure patency of the superior vena cava baffle [276]. In case of pulmonary venous pathway obstruction, transcatheter balloon dilatation can also relief the obstruction successfully [277].

When right ventricular dysfunction occurs, a cycle of right ventricular dilatation and tricuspid insufficiency develops leading to worsening right ventricular function and poor clinical outcomes. Treatment options include conversion to the arterial switch or cardiac transplantation. Arterial switch conversion can be performed in two stages. During the first stage, the left ventricle is prepared to become the systemic ventricle by banding the pulmonary artery. The second stage involves takedown of the baffle, closure of the ASD, removal of the pulmonary artery band and arterial switch. Arterial switch conversion is only possible if the left ventricle can tolerate systemic pressures. In patients with poor left ventricular function unable to tolerate or support systemic pressures following pulmonary artery banding, cardiac transplantation should be considered.

As patients with atrial repair operations become older, identification of suitable candidates for arterial switch conversion and the appropriate timing of the procedure have become problematic [265]. The goal is to identify symptomatic patients who have enough reserve to tolerate the multiple operations required for conversion. Older age has been reported as a significant risk factor for conversion and patients aged 16 years or more appear to be less likely to have a successful conversion [265,278].

Significant improvement after arterial switch conversion has been noted [279,280]. Pulmonary artery banding can significantly reduce tricuspid regurgitation owing to shift of the ventricular septum towards the systemic right ventricle resulting in improved coaptation of the tricuspid valve leaflets [281]. Tricuspid regurgitation is further reduced following the arterial switch. Even when arterial switch is not possible due to inability of the left ventricle to sustain systemic pressures, pulmonary artery banding alone may result in symptomatic improvement [267]. If, however, functional deterioration occurs, cardiac transplantation should be considered.

Subpulmonary stenosis (LVOT obstruction) is common following atrial switch repair [282] due to deviation of the ventricular septum towards the low-pressure left ventricle. As mentioned above, pulmonary/subpulmonary stenosis may be beneficial in patients with a systemic right ventricle as it allows the subpulmonary left ventricle to maintain a high systolic pressure, thus avoiding excessive deviation of the ventricular septum, which may result in tricuspid incoaptation and insufficiency.

Once selected for the two-stage arterial switch conversion, patients undergo pulmonary artery banding, either through a left thoracotomy or a median sternotomy. Systemic and pulmonary arterial pressure (a reflection of left ventricular pressures) are monitored. The pulmonary artery band is fully tightened occluding the pulmonary artery for 2–3 seconds and maximal left ventricular pressure is recorded. The band is released allowing the heart to fully recover. The band is then tightened until there is a fall in systemic arterial pressure or a rise in systemic venous pressure (typically a proximal peak pressure about 70% of maximal left ventricle pressure) [265]. Intraoperative transesophageal echocardiography is also used to monitor the effect of pulmonary artery banding on right and left ventricular function, ventricular septal deviation, and improvement of tricuspid regurgitation [265]. Intraoperatively, a dopamine infusion (5–10 μg/kg/min) is begun and sodium bicarbonate is administered to correct acidosis that occurs during the perioperative period [283]. Postoperatively the dopamine infusion is continued and the patient is fully ventilated for 24–72 hours. A postoperative transthoracic echocardiogram is obtained to document progression of left ventricular adaptation and guide in the weaning from inotropic support.

The timing of the arterial switch operation following the first-stage pulmonary artery band is variable, determined by the rate at which the left ventricle is retrained to support the systemic circulation. Interval assessment of left ventricular function is made by echocardiography and cardiac catheterization. Most patients require about 1 year for complete training of the left ventricle [265,267]. In general, patients are referred for arterial switch operation when left ventricular systolic pressure is greater than 80% of the right ventricular (systemic) pressure and the left ventricular free-wall thickness has returned to normal (indexed for patient age and weight) [265].

Following the arterial switch conversion a high incidence of neoaortic valve insufficiency due to annular dilatation has been reported. Chang and associates [284] reported one of five patients requiring aortic valve replacement 4 months after arterial switch operation. Cochrane and colleagues [265] reported that two of 16 patients undergoing arterial switch operation conversion developed severe

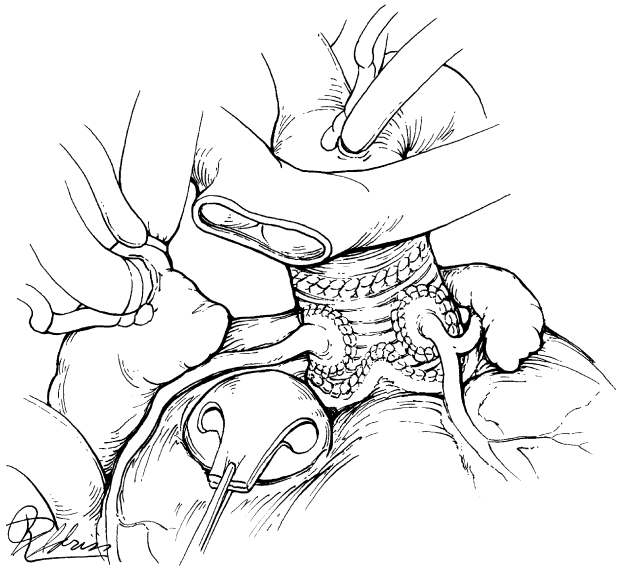

Figure 46.7 Hemashield (Boston Scientific/Medi-tech, Natick, MA) neoaortic valve-sparing reconstruction used to prevent proximal neoaortic dilatation and resultant neoaortic insufficiency. The pulmonary artery wall is removed and the contoured Hemashield graft is sewn into the resected sinuses of Valsalva. Appropriately sized holes are made in the corresponding facing sinuses for coronary reimplantation. The distal Hemashield graft is sutured end-to-end into the ascending aorta, thereby reconstructing the neoaorta. (Reproduced with permission from Mavroudis *et al*. [267].)

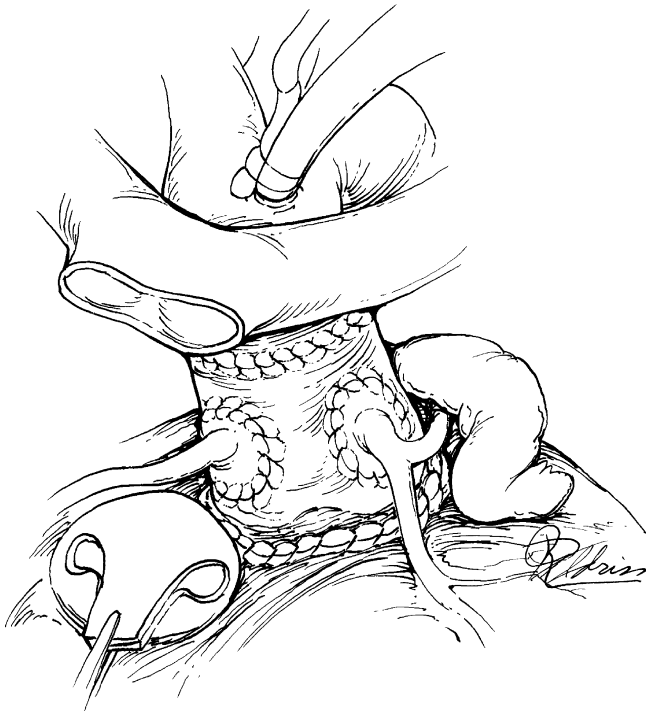

Figure 46.8 Aortic homograft implantation in a patient who had a Senning operation for transposition of the great arteries and moderate pulmonary stenosis. The patient underwent a preparatory pulmonary artery band placement en route to arterial switch operation conversion by neoaortic reconstruction using an aortic homograft because of the poor quality of the existing pulmonary valve (neoaortic valve). (Reproduced with permission from Mavroudis *et al*. [267].)

neoaortic valve insufficiency and required aortic valve replacement (12%), and an additional five patients (31%) developed mild aortic insufficiency. To address the issue of annular dilatation and subsequent neoaortic valve insufficiency, Mavroudis and Backer [267] have performed neoaortic reconstruction in four of six patients at the time of the initial conversion procedure. In three patients, a Hemashield (Boston Scientific/Medi-tech®, Natick, MA) neoaortic valve-sparing reconstruction was used to prevent proximal neoaortic dilatation (Figure 46.7) [208,267]. The fourth patient had reconstruction of the neoaorta using an aortic homograft because of the poor quality of the existing valve (Figure 46.8) [208,267]. To date, no neoaortic valve insufficiency has been identified in the patients who had neoaorta reconstruction. In addition to neoaortic valve insufficiency, atrial arrhythmias have occurred in patients following arterial switch operations. Atrial arrhythmias occur due to persistent elevation in atrial pressures following conversion. Mavroudis and colleagues [285] have successfully performed the right-sided maze cryoablation procedure in twopatients with atrial re-entry tachycardia and nodal re-entry tachycardia. Initial results of arterial switch conversion operation are promising. Long-term results remain to be seen.

Left Ventricular Outflow Obstruction

Obstruction of the left ventricular outflow tract covers a wide range of anatomic lesions. Obstruction may be caused by discrete or diffuse subvalvar stenosis, valvar stenosis, or may involve the supravalvar portion of the aorta. In addition, obstruction may occur due to abnormal insertion of the mitral valve, abnormal insertion of the papillary muscles, accessory mitral valve leaflet, and hypertrophied muscle bands within the LVOT or following repair of partial AV canal. Finally, subaortic stenosis may be part of a complex syndrome of multiple levels of left ventricular obstruction (e.g., Shone's complex of mitral stenosis, hypoplastic aortic annulus, and coarctation). Subaortic stenosis is considered a progressive lesion with a variable rate of progression. Patients with subaortic stenosis are at an

increased risk of bacterial endocarditis and aortic insufficiency when fibrous strands extend onto the base of the aortic leaflets [286]. Chronic obstruction of the LVOT may lead to left ventricular hypertrophy resulting in congestive heart failure, angina, arrhythmias, and sudden death.

Surgical repair is the mainstay of LVOT obstruction repair. The timing and technique to be used remain, however, controversial. Discrete subaortic membranes may be treated by simple excision with or without myotomy or myectomy. Early excision of discrete subaortic membranes reduces the development of aortic insufficiency but recurrent membrane formation remains a long-term complication [287]. Diffuse subaortic stenosis has been treated with medical therapy, ventricular pacing, and resection with extensive reconstruction of the LVOT. Aortic valve stenosis has been treated with procedures directed towards enlargement of the aortic annulus (Manougian, Konno) and insertion of a larger valve. Detailed discussion of aortic annular stenosis and annular enlargement is beyond the scope of this chapter, but is fully addressed in Chapter 29, *Ebstein Anomaly*. Supravalvar stenosis is the least common form of aortic stenosis. Treatment is directed toward relief of the obstruction.

Discrete Subaortic Stenosis

Discrete subaortic stenosis causes LVOT obstruction and may lead to significant aortic insufficiency if left untreated. In an attempt to identify the etiology of the subaortic membrane, Cape and colleagues [288,289] noted the potential role of mechanical stress and septal shear stress in the development of subaortic stenosis. A small change in the aortoseptal angle produces changes in the septal shear stress. A steepened aortoseptal angle leads to an increase in septal shear stress and results in cellular proliferation and the development of discrete subaortic stenosis. Conventional resection relieves the obstruction but recurrence rate is high. Serraf and associates [287] reported on their 17-year experience of 120 patients with discrete subaortic stenosis. Thirty-nine patients underwent isolated resection of the membrane, 67 had excision of the membrane plus myotomy, and the remaining 14 patients underwent resection of the membrane plus myectomy. Overall there was a 27.1% recurrence rate and 12% required reoperation (5 of 39 with membranectomy, 7 of 67 with membranectomy plus myotomy, 2 of 14 with membranectomy plus myectomy). Two patients developed complete heart block and two patients died following the operation (one each in the membranectomy plus myotomy or myectomy subsets). In this study, coarctation of the aortic isthmus and the quality of the primary surgical relief were independent risk factors for recurrence. They also found a positive correlation between higher early postoperative gradients, and increased rates of recurrence. Therefore they recommend that patients with residual gradients >30 mmHg at the end of CPB should undergo reoperation with more aggressive resection at the time of the initial procedure. Results from Parry and colleagues [290] support these findings. Thirty-seven patients age 0.5–35 years (median, 7.5 years) underwent aggressive resection of a discrete subaortic membrane. No patients required reoperation for recurrent obstruction at mid-term follow-up (27 months, range 2–59 months). However, long-term results are required to confirm if the benefits of aggressive resection are maintained.

Extensive myectomy increases the risk of heart block and iatrogenic VSD. Use of intraoperative transesophageal echocardiography has been shown to reduce the complications of complete heart block and iatrogenic VSD during the performance of aggressive subaortic resection [291]. Considering the work of Cape and colleagues [288] regarding the importance of the aortoseptal angle and septal sheer stress, it is not surprising that recurrence occurs following resection alone. In addition to aggressive resection of the membrane, development of procedures to relieve the morphologic abnormalities and restore the normal aortoseptal relationship may reduce the recurrence of subaortic stenosis.

Diffuse/Tunnel Subaortic Stenosis

Tunnel subaortic stenosis represents a more severe and more complex form of LVOT obstruction. Tunnel subaortic stenosis is associated with higher mortality rates and higher reoperation rates when compared to less complex forms of LVOT obstruction [287]. Treatment of tunnel subaortic stenosis has been both medical and surgical.

Nonsurgical Therapy

Beta-adrenergic blocking agents and verapamil have been used in the treatment of diffuse subaortic stenosis. Patients who do not initially respond to one class of agent may in fact respond to the other class of agent. Therefore drug selection has not been standardized and is for the most part based on the bias of the clinician [292]. The mechanism by which negative inotropic agents provide therapeutic benefit is poorly understood. Sherrid and colleagues [293] studied the effects of medical therapy in 11 patients with obstructive hypertrophic cardiomyopathy. They concluded that negative inotropic agents decrease the acceleration of left ventricular ejection leading to reduced hemodynamic forces on the mitral valve leaflet. By decreasing the acceleration forces on the mitral valve, anterior motion of the anterior leaflet of the mitral valve towards the interventricular septum is reduced, thereby diminishing the degree of LVOT obstruction. Several studies [293–295] have confirmed the beneficial effects of negative inotropes. Ostman-Smith and colleagues [296] showed that high-dose beta-blockade therapy (propranolol 5–23 mg/kg/day) produced a 5–10-fold reduction in the risk of

disease-related deaths. Despite reports supporting medical therapy for the treatment of obstructive cardiomyopathy, LVOT obstruction is not significantly improved in many patients. Seiler and colleagues [297] reported on 139 patients with obstructive hypertrophic cardiomyopathy followed for 8.9 years (range, 1–28 years). Patients were divided into four treatment groups: 1) propranolol, 2) verapamil, 3) verapamil plus surgical myectomy, and 4) surgical myectomy only. They concluded that survival was significantly better in the verapamil plus surgical myectomy group when compared to all other groups. Based on the above studies, patients with obstructive hypertrophic cardiomyopathy who are symptomatic or have failed to respond to medical therapy should undergo surgical treatment.

Dual-Chamber Pacing

The role of dual-chamber pacing for relief of diffuse LVOT obstruction is unclear, with conflicting reports in the literature. Some studies have reported significant clinical improvement and substantial reduction in the LVOT gradient with chronic dual-chamber pacing. Sakai and colleagues [298] reported on their results of chronic dual chamber pacing in 11 patients with obstructive hypertrophic cardiomyopathy. All patients had resolution of their symptoms within 1 month. The LVOT pressure gradient diminished from 99 ± 56 mmHg to 21 ± 13 mmHg at 1 week and 17 ± 12 mmHg at 1 year. There was significant reduction of the septal hypertrophy and disappearance of the systolic anterior motion of the mitral valve. Results from the Mayo Clinic [299] were not as encouraging. Thirty-eight patients with hypertrophic cardiomyopathy received dual chamber pacemakers. At a mean follow-up of 24 ± 14 months, subjective improvement was reported in 47% of the patients and there was no statistically significant improvement noted in maximal oxygen consumption. Ommen and colleagues [300] compared septal myectomy to dual-chamber pacing. Ninety percent of septal myectomy patients experienced symptomatic improvement as compared to 47% of patients in the pacing group. In the myectomy group, exercise duration was significantly greater than for the dual-chamber pacing group. Maximal oxygen consumption increased significantly following myectomy whereas the pacing group did not experience any significant change. Despite early enthusiasm for dual-chamber pacing for the treatment of obstructive hypertrophic cardiomyopathy, recent more carefully controlled investigations have proven pacing to be less favorable then septal myectomy.

Transcoronary Ablation of Septal Hypertrophy

Recently, injection of alcohol into the first major septal coronary artery has been proposed to reduce interventricular septal thickness and diminish LVOT obstruction. Transcoronary ablation of septal hypertrophy (TASH) is based on conventional percutaneous transcoronary angioplasty techniques with the aim of inducing a controlled septal infarction by injection of 97% ethanol into the first septal branch of the left anterior descending artery. This leads to scarring and contraction of the subaortic septum and results in decreased septal bulge and opening of the LVOT. Gietzen and colleagues [301] reported 50 patients who underwent TASH for hypertrophic obstructive cardiomyopathy. TASH led to a reduction in septal wall thickness and eliminated the LVOT pressure gradient (51 ± 41 mmHg vs. 6 ± 41 mmHg) which was sustained at 7 ± 1 months' follow-up. However, 17% of the patients suffered from permanent high-grade AV node block. In addition there was a 4% early mortality rate. Experience with this technique is limited and further prospective randomized trials are required.

Surgical Treatment of Diffuse/Tunnel LVOT Obstruction

Early surgical treatment protocols for diffuse LVOT obstruction included implantation of apical-aortic prosthetic valved conduits. Conduit obstruction due to bioprosthetic valve calcification and a high incidence of reoperation because of conduit valve failure has decreased enthusiasm for this treatment option. Apical-aortic conduit placement has given way to more contemporary procedures that have reduced the need for reoperation.

Konno Procedure

The Konno operation can be used to treat all levels of LVOT obstruction. Tunnel-like subaortic stenosis, diffuse obstructive hypertrophic cardiomyopathy, congenital aortic valve stenosis, and proximal ascending aortic stenosis can all be treated with the Konno operation. The Konno operation was described in 1975 for the treatment of congenital aortic stenosis associated with hypoplasia of the aortic annulus [302]. A longitudinal incision is made on the anterior aspect of the ascending aorta just distal to the aortic valve. The incision is continued to the left of the right coronary artery and into the right ventricle and carried down the interventricular septum below any subvalvar stenosis. A PTFE patch is cut into an appropriately sized ellipse and sutured to the left ventricular side of the VSD. The patch is continued across the aortic annulus and onto the aorta thereby enlarging the aortic annulus. The prosthetic valve is sutured to the native aortic annulus and the synthetic patch neoannulus. The RVOT is then reconstructed with an appropriately shaped prosthetic patch. The Konno operation relieves subaortic stenosis and augments the aortic annulus, which permits the insertion of a larger prosthetic valve than the native annulus would allow [170]. Cobanoglu and colleagues [303] reported on 20 patients at a mean age of 9.2 years (range, 1.7–25.7 years) who underwent a Konno operation for LVOT obstruction. Mean follow-up time was

61.1 ± 31.7 months. Ten-year actuarial survival was 90 ± 7% and the reoperation-free survival was 89 ± 7%. All patients had resolution of their left ventricular hypertrophy with insignificant gradients across the LVOT. Despite current era enthusiasm for homograft and autograft reconstruction of the LVOT, the Konno operation remains among treatment options.

The modified Konno operation permits the enlargement of the LVOT obstruction without the need for insertion of a prosthetic valve. This procedure is used when LVOT obstruction is present in the face of a normal-sized aortic annulus. Vouhe and colleagues [304] used the modified Konno procedure in 11 patients with subaortic stenosis and a normal aortic orifice (six patients with tunnel subaortic stenosis and five patients with diffuse hypertrophic obstructive cardiomyopathy). There were one early death, one reoperation for iatrogenic aortic regurgitation, and one reoperation for residual VSD. At follow-up (mean, 3.8 ± 4.2 years; range 2 months to 10 years) all patients had LVOT gradients of less than 25 mmHg. Jahangiri [305] reported excellent relief of subaortic stenosis in 15 patients and no evidence of iatrogenic injury to the conduction system. The modified Konno operation is advantageous for patients with LVOT obstruction and normal aortic annular size because the native aortic valve is preserved and prosthetic or homograft valves are avoided.

The Ross-Konno operation provides an excellent treatment option for diffuse subaortic stenosis with aortic valve stenosis or insufficiency. In 1987 McKowen and colleagues [306] described the use of a pulmonary allograft for extended aortic root replacement to treat recurrent tunnel stenosis with a hypoplastic aortic annulus. Subsequent reports of excellent results support the Ross-Konno operation as the procedure of choice for the treatment of subaortic stenosis and aortic annular hypoplasia. Daenen [307] reported on the management of 16 patients with complex LVOT obstruction. These patients underwent aortoventriculoplasty and extended aortic root replacement with a pulmonary autograft. There were one early death and one late death due to congestive heart failure. One patient developed complete heart block and another required reoperation 4 years post-procedure for aortic valve insufficiency. At 23 ± 12 months' follow-up, all other patients showed laminar flow in the LVOT and excellent function of the allograft and pulmonary homograft valve. Left ventricular stroke volume was increased after the Ross-Konno operation, van Son and colleagues [308] showed, with improvement in ventricular diastolic function and reduced systolic anterior motion of the mitral valve. The Ross-Konno avoids the use of bioprosthetic tissue valves in the LVOT, which degenerate over time, there is no risk of thromboembolic events due to mechanical valves, and anticoagulation is avoided. Because of these advantages, the Ross-Konno operation is the procedure of choice for the treatment of complex LVOT obstruction and annular hypoplasia.

Index

Note: Page numbers in *italics* refer to figures. Those in **bold** refer to tables. In cross-references, commas may indicate that the phrase following is a subheading. Thus, "see also abscess, crypt" means "see also the subheading 'crypt' under the main heading 'abscess'". Entries are in word-by-word alphabetical order, ignoring hyphens, so that "fasting" comes after "fast tracking" and "D-shaped" comes after "dropped".

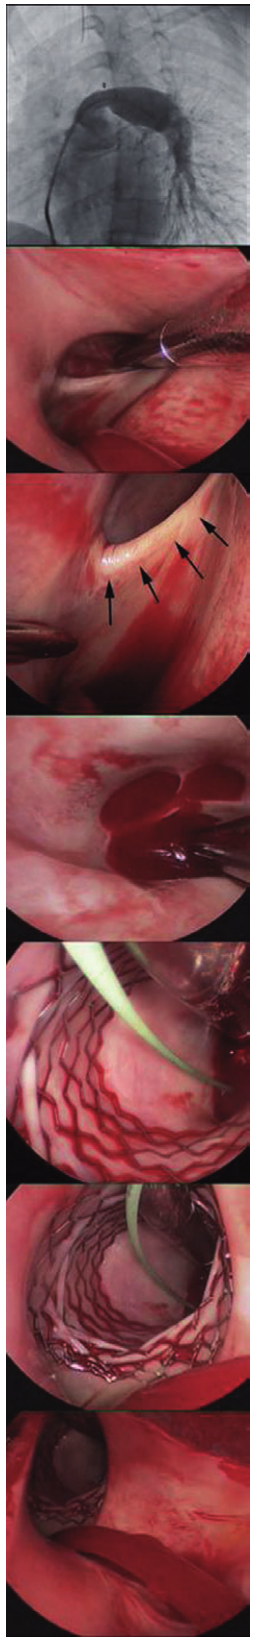

Plate 5.3 19-year-old female with a history of tetralogy of Fallot repair (including RVOT patch), who underwent pulmonary valve replacement as well as intraoperative placement of a Max LD stent to treat a proximal LPA fold, using direct vision with endoscopic guidance. The top image shows the LPA kink, identified during preprocedural cardiac catheterization. The following images document the endoscopic evaluation of the LPA intraoperatively. Notable is the ridge/fold at the LPA origin (arrows). Before stent placement, endoscopic evaluation is used to evaluate the lobar branching. After stent deployment, endoscopic evaluation documents sufficient distance of the stent from lobar branching of the LPA. The LPA appears to be wide open. After deployment, the stent was "crimped" manually over the crest between LPA and RPA. The bottom image shows the LPA origin from a distance, with the vessel being widely patent (note the difference to the preprocedural images). (RVOT, right ventricular outflow tract; LPA, left pulmonary artery; RPA, right pulmonary artery.)

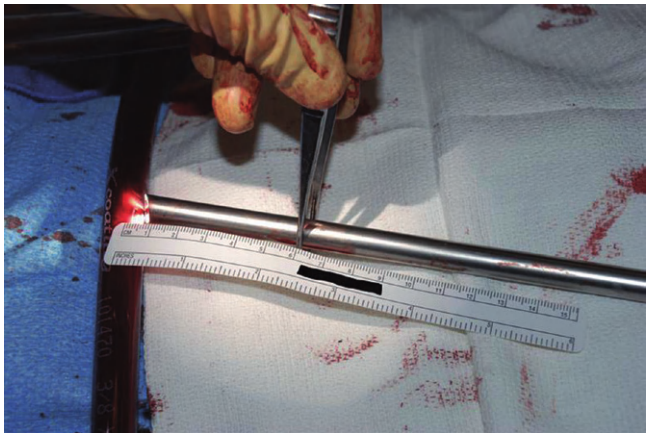

Plate 5.4 Stryker endoscope used for "hybrid" stent delivery under direct vision. The endoscope can be helpful in assessing the distance towards the origin of the pulmonary arterial side branches [2].

Plate 5.5 Lower midline sternotomy.

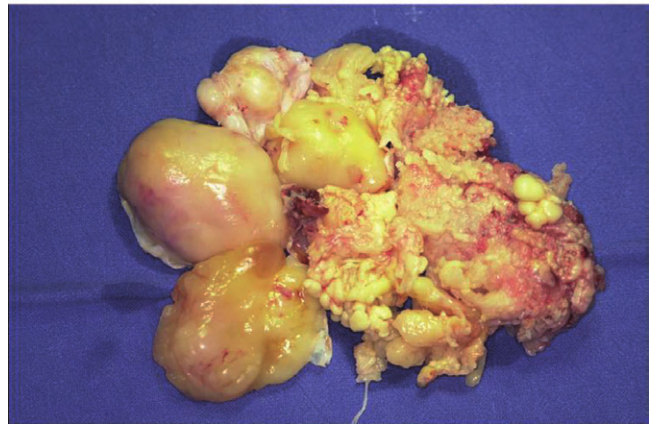

Plate 39.8 Intraoperative view of a left atrial myosarcoma (top). Surgically resected myosarcoma (bottom).

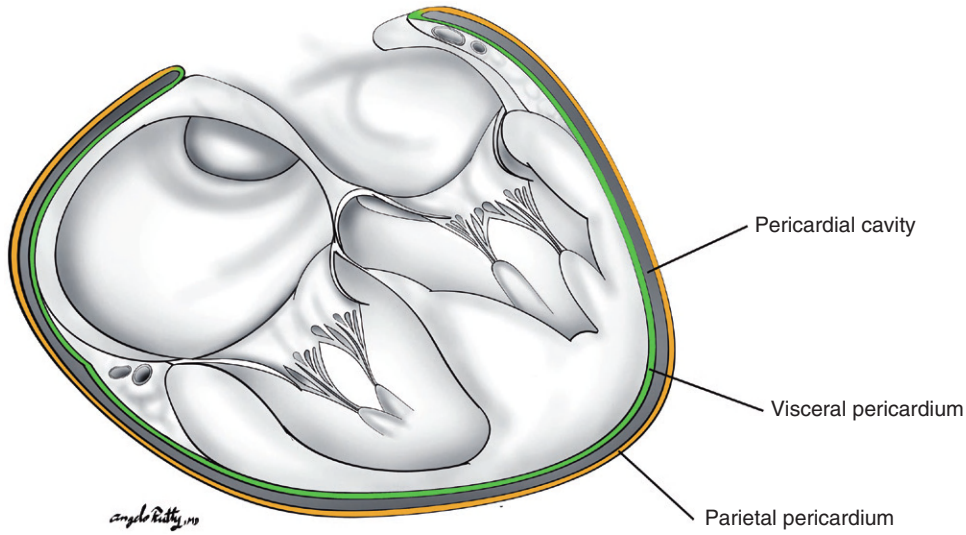

Plate 40.1 Heart and pericardium. The pericardial cavity exists between the visceral and parietal pericardium.

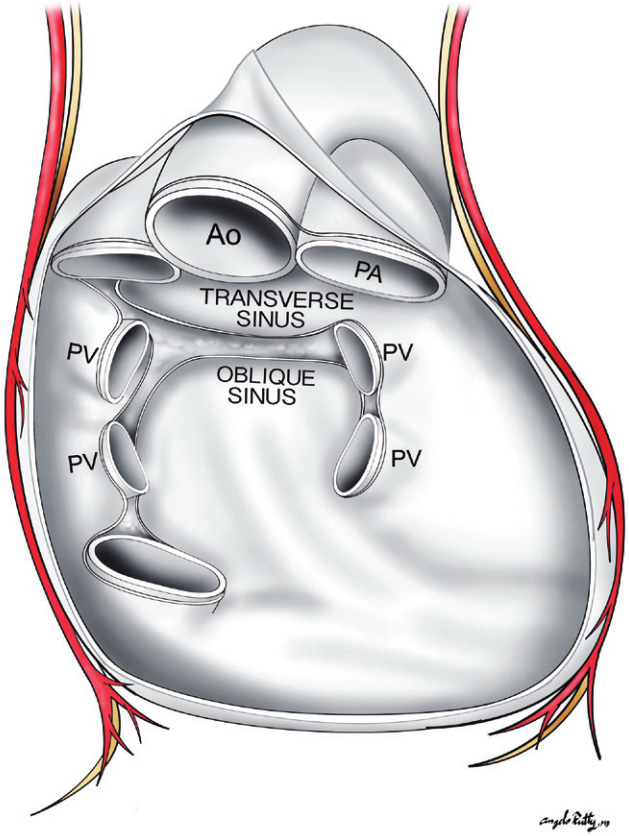

Plate 40.2 Pericardial recesses. The transverse sinus lays behind the aorta (Ao) and main pulmonary artery (PA) and the oblique sinus extends behind the left atrium in the region between all four pulmonary veins (PV).

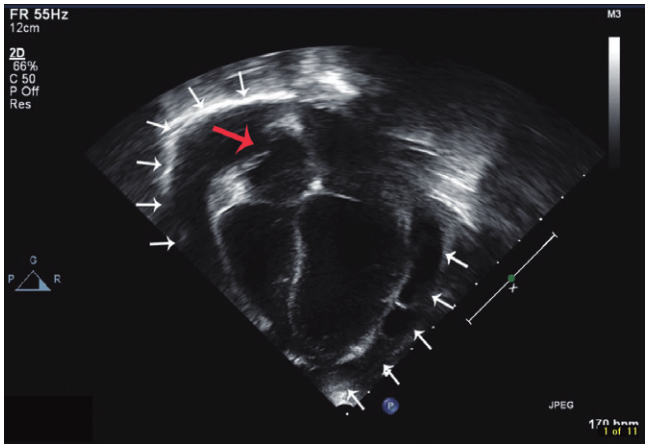

Plate 40.3 Transthoracic echocardiogram showing a large pericardial effusion with signs of tamponade. Note the large circumferential pericardial effusion (white arrows) with right atrial diastolic collapse (red arrow).

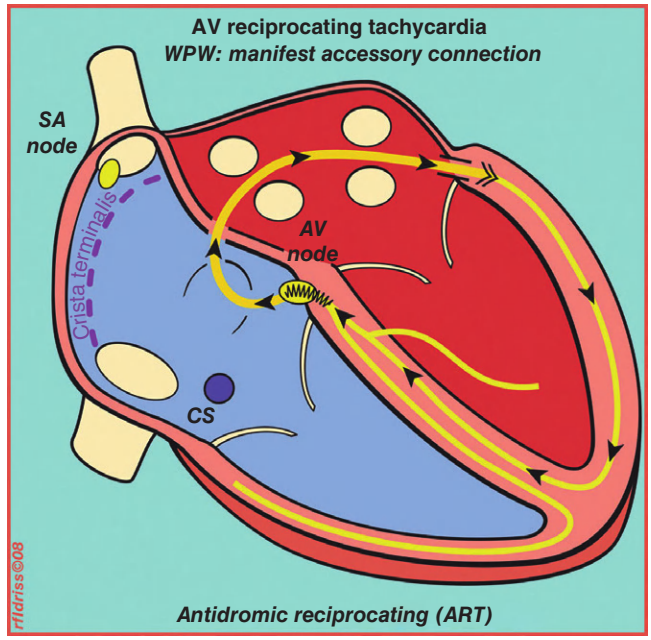

Plate 41.1 Atrioventricular (AV) reciprocating tachycardia. Wolff-Parkinson-White (WPW) syndrome or manifest accessory connection. During sinus rhythm with preexcitation, conduction from the sinus node to the ventricles proceeds simultaneously over two routes, the atrioventricular node and the accessory connection. The wave front traversing the accessory connection depolarizes ventricular tissue first, because of intrinsic slowing of conduction at the atrioventricular node. The accessory connection thus "preexcites" ventricular depolarization, giving rise to the delta wave. As depicted, there is blocked conduction in the atrioventricular node, with conduction proceeding to the ventricles via the accessory connection (preexcited). Conduction delay is encountered in ventricular muscle, allowing the wave front to proceed up the atrioventricular node (which has had time to regain conduction) to the atrium. This re-entrant circuit is termed "antidromic reciprocating tachycardia"; the "playing field" includes the atria, accessory connection, ventricles, and the atrioventricular node. Reproduced with permission from Mavroudis *et al.* [37,41]. Arrhythmia surgery in patients with and without congenital heart disease. Ann Thorac Surg 86, 857–868. Copyright © 2008 Elsevier for Society of Thoracic Surgeons.

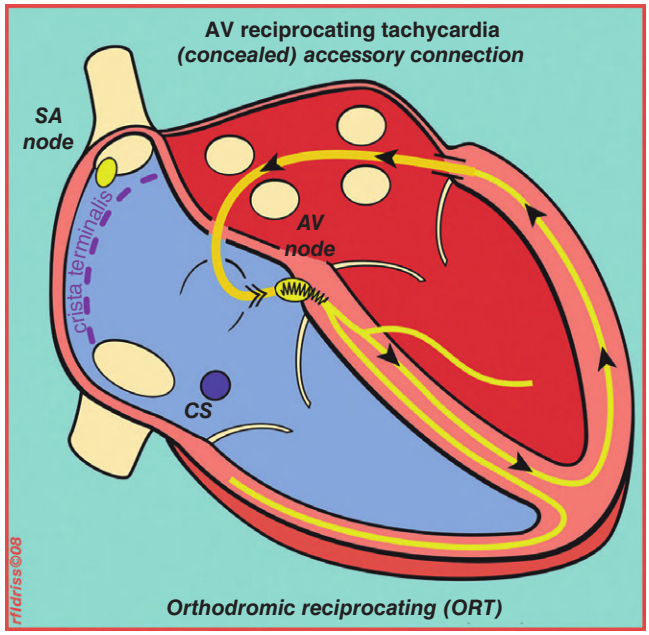

Plate 41.2 Atrioventricular reciprocating tachycardia depicting concealed Wolff-Parkinson-White (WPW) syndrome. Orthodromic reciprocating tachycardia, the more common form of tachycardia, utilizing an accessory connection. Conduction is blocked in the accessory connection, thus losing the delta wave (now "concealed"). Conduction proceeds normally through the AV node to the ventricle. The delay encountered in the AV node allows the accessory connection to regain electrical function, and the electrical impulse then enters the atria from the opposite direction, from ventricle to atrium, across the accessory connection. This "playing field" includes the atria, atrioventricular node, ventricles, and accessory connection. Reproduced with permission from Mavroudis *et al*. [37,41]. Arrhythmia surgery in patients with and without congenital heart disease. Ann Thorac Surg 86, 857–868. Copyright © 2008 Elsevier for Society of Thoracic Surgeons.

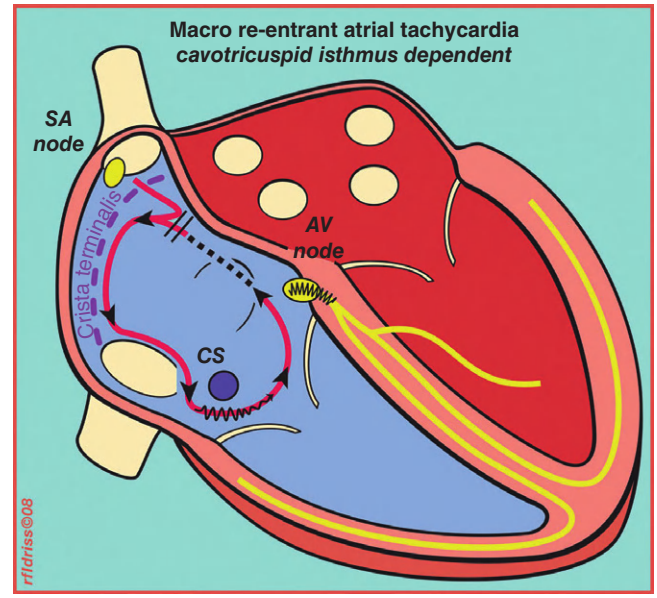

Plate 41.3 Cavotricuspid isthmus dependent macro re-entrant atrial tachycardia. As depicted, the "playing field" is the right atrium, where a premature atrial contraction might encounter block in the atrial septum (broken line) and proceed in an alternate route down the right atrial free wall. The wave front may encounter an area of slow conduction (squiggly arrow), in this case between the inferior vena cava, tricuspid valve, and the coronary sinus (CS). The delay encountered as the wave front traverses the area of slow conduction allows the atrial septum to recover conduction. The wave front exits the isthmus and proceeds up the atrial septum. Interruption of this circuit is targeted at the inferior isthmus owing to the clearly identified landmarks in proximity. (AV, atrioventricular; CS, coronary sinus; SA, sino-atrial.) Reproduced with permission from Mavroudis *et al*. [37,41]. Arrhythmia surgery in patients with and without congenital heart disease. Ann Thorac Surg 86, 857–868. Copyright © 2008 Elsevier for Society of Thoracic Surgeons.

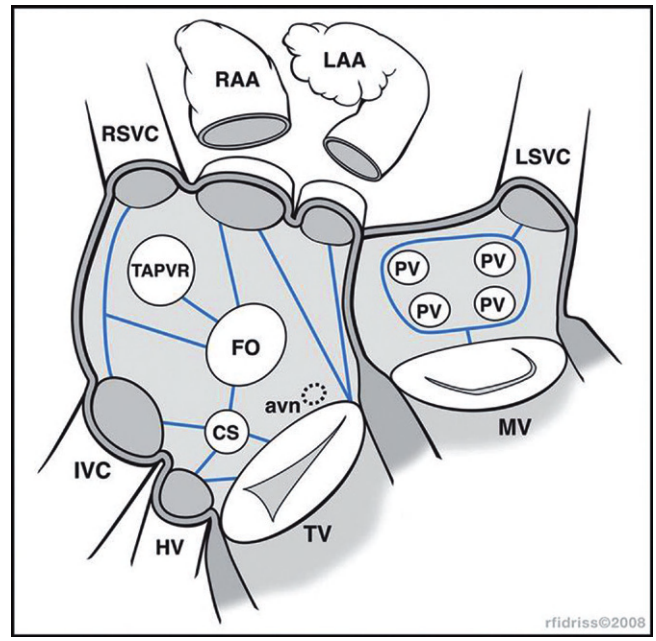

Plate 41.4 Schematic representation of the possible lines of ablation to treat macro re-entrant atrial tachycardia in the presence of various atrial anomalies associated with complex congenital heart disease. These atrial anomalies do not generally occur together, and the demonstrated lines of block are not meant to be incorporated into every operation. They are depicted only as guidelines on which to base an ablative operation when unusual anatomic obstacles are encountered in the performance of the maze procedure. (avn, atrioventricular node; CS, coronary sinus; FO, foramen ovale; HV, hepatic vein; IVC, inferior vena cava; LAA, left atrial appendage; LSVC, left superior vena cava; MV, mitral valve; PV, pulmonary veins; RAA, right atrial appendage; RSVC, right superior vena cava; TAPVR, total anomalous pulmonary venous return; TV, tricuspid valve.) Reproduced with permission from Mavroudis *et al*. [37,41]. Arrhythmia surgery in patients with and without congenital heart disease. Ann Thorac Surg 86, 857–868. Copyright © 2008 Elsevier for Society of Thoracic Surgeons.

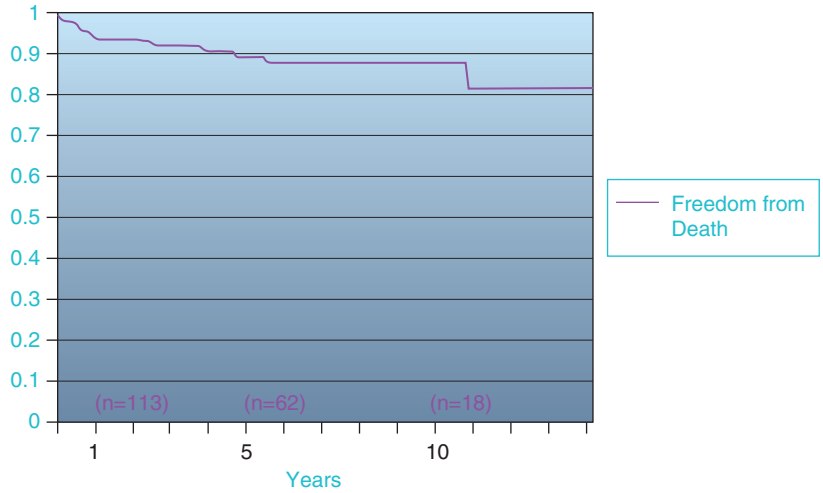

Plate 41.5 Kaplan-Meier curve showing freedom from death in 126 patients who underwent Fontan conversion with arrhythmia surgery. Reproduced with permission from Mavroudis *et al.* [37]. Late reoperations for Fontan patients: state of the art invited review. Eur J Cardiothorac Surg 34, 1034–1040. Copyright © 2008 Oxford Journals for European Association for Cardio-Thoracic Surgery and the European Society of Thoracic Surgeons.

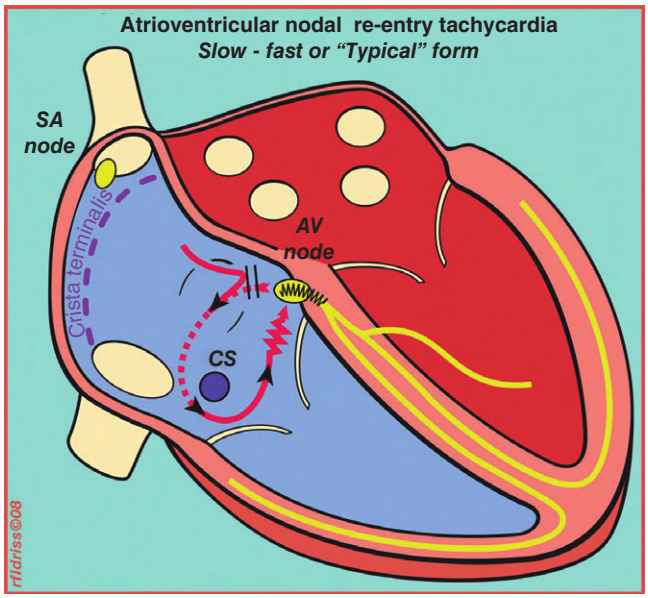

Plate 41.6 Slow-fast or "typical" form of atrioventricular (AV) nodal re-entry tachycardia. Atrioventricular conduction encounters a block in the normal fast pathway fibers superior to the compact AV node. The wave front proceeds towards the atrial isthmus, between the coronary sinus (CS) and tricuspid valve, and encounters slowing through the "slow pathway" fibers of the AV node. Exiting the isthmus, conduction is now able to reenter the fast pathway fibers, located anteriorly and superiorly, and perpetuate a reentrant circuit; simultaneously, conduction proceeds inferiorly to the ventricles. Of note, conduction to the ventricles is not relevant to the tachycardia circuit. Cryoablation of the inferior isthmus region will interrupt the circuit. (AV, atrioventricular; CS, coronary sinus; SA, sinoatrial). Reproduced with permission from Mavroudis *et al.* [41]. Arrhythmia surgery in patients with and without congenital heart disease. Ann Thorac Surg 86, 857–868. Copyright © 2008 Elsevier for Society of Thoracic Surgeons.

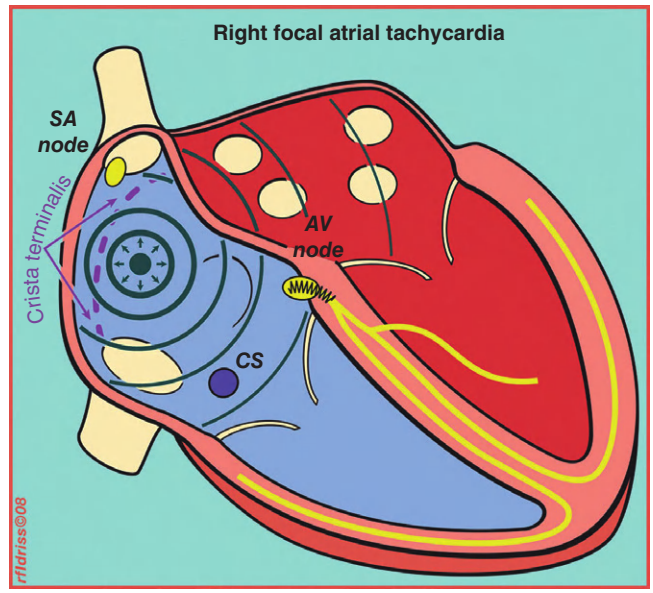

Plate 41.7 Right focal atrial tachycardia. Focal atrial tachycardia, a localized area of "impulse initiation" that is most commonly automatic in mechanism, firing repeatedly, rapidly, and independent of normal sinus function, which is inhibited. Impulse conduction is spread in a centripetal fashion across the atria, thence to the atrioventricular (AV) node and ventricles. Ablative therapy is aimed at obliteration or isolation of this localized discrete area ("hot spot"). (AV, atrioventricular; CS, coronary sinus; SA, sinoatrial; WPW, Wolff-Parkinson-White.) Reproduced with permission from Mavroudis *et al.* [41]. Arrhythmia surgery in patients with and without congenital heart disease. Ann Thorac Surg 86, 857–868. Copyright © 2008 Elsevier for Society of Thoracic Surgeons.

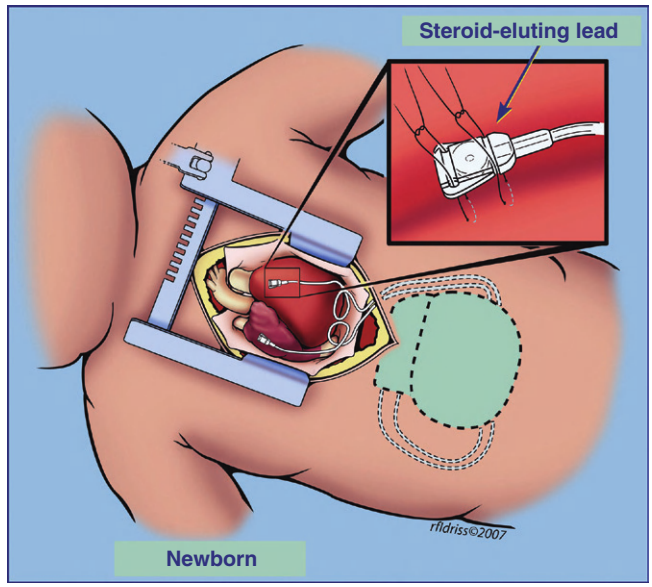

Plate 41.8 Dual-chamber pacing leads as placed through a full sternotomy in a neonate. The steroid-eluting leads are directly affixed to the epicardium with two 5-0 polypropylene sutures. Reproduced with permission from Kelle *et al.* [169]. Dual-chamber epicardial pacing in neonates with congenital heart block. J Thorac Cardiovasc Surg 134, 1188–1192.

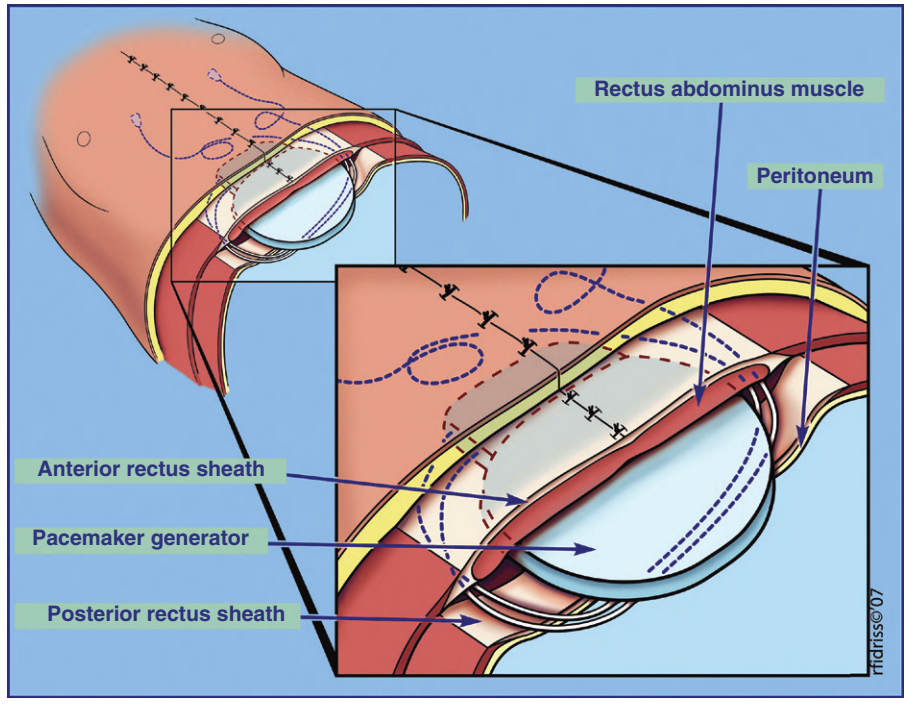

Plate 41.9 A pocket for the pacemaker is created beneath both rectus muscles. Through a midline incision extending nearly to the umbilicus, bilateral subcutaneous flaps are created, allowing mobilization of the anterior rectus sheath. The anterior rectus sheath is entered on either side of the linea alba. This opening is extended vertically to free up the anterior rectus sheath. Next, the rectus muscle is dissected off the posterior rectus sheath. The pacemaker is implanted just above the posterior rectus sheath. The peritoneum is not entered. The rectus muscles are reapproximated in the midline with interrupted polyglactin sutures (Vicryl; Ethicon, Inc., Johnson & Johnson, New Brunswick, NJ), providing a muscular padding for the pacemaker. The subcutaneous layer is approximated with running polyglactin and the skin with subcuticular polydioxanone or interrupted nylon. Reproduced with permission from Kelle *et al.* [169]. Dual-chamber epicardial pacing in neonates with congenital heart block. J Thorac Cardiovasc Surg 134, 1188–1192.
